Figure 5 18 days—Dog 5—gastric resection The line of apposition was demarcated by a zone of fibrous tissue in which the frayed ends of the muscle could be seen The mucous membrane was healed by a single layer of epithelium A silk suture surrounded by inflammatory cells lay near the healed mucous membrane The flange was barely present

Figure 6 21 days—Dog 11—gastroenterostomy The mucous membrane had healed completely with definite gland formation at the juncture A small flange was present

Figure 7 28 days—Dog 10—gastric resection The mucous membrane had healed completely with gland formation at the point of union An area of lymphoid hyperplasia was present in the muscularis of the stomach The flange was represented by an area of slight thickening

Figure 8 32 days—Dog 9—gastric resection The microscopic appearance was similar to the 28 day specimen

Figure 9 6 days—Dog 12—gastroenterostomy The gross and microscopic picture was about the same as the 5 day specimen A high power photomicrograph is shown to illustrate the manner in which the new single layer of epithelium grows on granulating bed beneath fibrinocellular membrane

HEALING PROCESS IN CLOSED ANASTOMOSES COMPARED WITH OPEN METHODS

The rate and manner of healing of gastrointestinal wounds made aseptically with the

actual cautery compare favorably with other methods The aseptic procedures used in these experiments apparently will result in mucosal healing in 14 to 17 days, while portions of the anastomosis may be epithelialized in eleven days There are ample opportunities to compare these results with the findings of others who have experimented with open anastomoses Gould, for example, found that the average time for mucosal healing in experimental gastrointestinal anastomoses was 14 days Flint came to the same conclusion after studying comparative rates of healing with the use of three different methods of suturing The more comprehensive study by Martzloff and Suckow (9) showed healing in 6 days in 2 anastomoses in which Halsted presection sutures were used When the same authors used the Connell suture they found epithelialization by a single layer in one 14 day specimen and incomplete coverage in another They also reported mucosal union in one of two 14 day specimens in which the commonly employed continuous hemostatic suture was utilized Healing with this method, however, was attended by intense inflammatory reaction, irregular mucosal defects, and frequent inclusion cysts

When healing at the line of apposition is used as a yardstick, the closed method compares to even better advantage The fact that all of the specimens showed the healing process to be a proliferative one attests to the advantage of preventing soiling by the use of an aseptic procedure

CONCLUSIONS

- 1 The healing in 17 aseptic anterior gastroenterostomies and 10 aseptic gastric resections, experimentally produced in dogs, was studied

- 2 Hemorrhage was most effectively prevented by leaving a seared 3 millimeter cuff of tissue protruding above the clamp after resection of the stomach or intestine had been carried out

- 3 The mucous membrane healed in 14 to 17 days

- 4 The usual microscopic picture of the healing at the line of apposition was a proliferative one

that a blue compound results from the combination of diphenylamine and a polysaccharide in the presence of hot concentrated hydrochloric acid. Colorimetric readings were made a single cell compensating photoelectric colorimeter of Evelyn, and No. 630 filter being used.

Phenol red determinations were made colorimetrically and the same type of photoelectric colorimeter with a No. 530 filter was used. A standard curve was first prepared the known concentrations of dye solutions being used and the unknown experimental concentration was read directly from the curve.

In the execution of phenol red clearance tests there are several essential points. The plasma concentration of the dye must be maintained at a level below 10 milligram per cent. When plasma dilutions are made the alkali must never be added to the plasma until after dilution otherwise precipitation will result with its concomitant false colorimetric values. The inherent chromogenic properties of the plasma must be compensated for in the colorimeter and each sample of plasma must be tested for hemolysis (Bling and Baker).

Interpretation of the experimental results
The tabulated results (Table I) demonstrate that continuous vesical drainage improves total renal function in prostatism. However no apparent relationship between the length of vesical drainage and the amount of renal functional improvement could be demonstrated. That is, improvement was dependent upon the amount of actual damage that occurred before the establishment of drainage and this no doubt must be dependent upon the duration of symptoms. Case 6 (Table I) with its limited functional improvement, though drainage was continuous over a 16 day period suggests this conclusion.

concentration in milligrams per cent. B = mean plasma inulin or phenol red concentration per cent. and V = urine volume in cubic centimeters per minute.

The method of measuring quantitatively the amount of inulin in plasma and urine was that described by Corcoran and Page. In principle this method makes use of the fact

Graph 1 Total renal function continues to a certain point and then ceases

The phenol red/inulin ratio was incorporated in the table since it more accurately represents renal function (Goldring, Clarke and Smith). The normal phenol red/inulin ratio is 3.3. That the ratio more nearly represents the true index of renal activity was demonstrated in Case 1 (the third hour of the clearance rate period on the tenth day of catheter drainage). Here it is seen that the clearance rate for inulin is 93 cubic centimeters per minute (normal 125 c.c.) and the phenol red clearance is 289 cubic centimeters per minute (normal 400 c.c.). These two figures would seem to indicate markedly impaired renal function though when the phenol red/inulin ratio is examined it is found to be 3.1 as compared to 3.3 which is normal. Hence, renal function is in this particular instance not impaired as seriously as one would be led to believe by examining the clearance rates separately.

Upon examination of Table II it is seen that phenol red clearances seem to have improved relatively more than the inulin clearance. From these figures the improvement of the tubule function, as compared with that of

the glomerulus, occurred in a ratio of approximately 2:1. Obviously to establish this as factual a larger series of cases will have to be investigated. It can be said then, in the final analysis of the experimental results obtained in this study, that renal function was improved following prolonged periods of vesical drainage in prostatism and that the increase was apparently more pronounced in the tubule than the glomerular elements of the kidney.

Graph 1 demonstrates that the improvement of total renal function continues to a certain point and then ceases, that is, apparently renal damage is reversible to a certain point and after that is irreversible. Just what determines the degree of irreversibility was not determined. However, this factor of reversibility of renal functional damage has long been appreciated by urologists and the stationary period (the plateaus on the graph) has been loosely termed "renal stability" and constitutes one of the principal criteria indicative of the optimum time for prostatectomy.

EVALUATION OF STUDY

The problem of renal dysfunction in prostatism has received little or no experimental investigation. In fact, careful search of the literature reveals no single reference dealing with this problem. Reference was made on occasion to the observed fact that renal function improved in prostatism with the institution of bladder drainage, but further than advocating this observation as significant as an operative index nothing could be found.

Strong studied the nephron by microdissection in experimental hydronephrosis and found that early in hydronephrosis the proximal convoluted tubule became markedly reduced in volume. Suzuki, using vital stains, found cells of the distal portion of the proximal convoluted tubules to be damaged before those in the initial portion of the tubule. Hinman, working with rabbits, found that the tubule suffered damage before the glomerulus. In these various experiments, the urinary back pressure, though created by different means was still in its early stages and from that point of view one might imagine at least, that the situation was somewhat comparable to the urinary obstruction of prostatism, and it is of

interest that the results of this work support these findings.

SUMMARY

1 Renal dysfunction was investigated by the use of simultaneous inulin and phenol red clearance tests.

2 Renal dysfunction in prostatism is primarily a tubule dysfunction.

3 The disturbed renal function in prostatism is definitely improved by continuous vesical drainage.

4 Renal damage due to prostatism is partially reversible. Re-establishment of renal function is not complete but reaches a peak

beyond which no further functional improvement occurs.

THE EFFECT OF HEPARIN ON THE BEHAVIOR OF INFARCTION OF THE INTESTINE

An Experimental Study

HAROLD LAUFMAN, M.D., Chicago, Illinois

IN his recent reports (3, 4) Murray advocates the use of heparin following resection for infarction of the intestine. These reports have stimulated our attempt to determine the effect of this anticoagulant upon various types of mesenteric vascular occlusions and strangulations. The high postoperative mortality in cases of mesenteric vascular occlusion has been ascribed to the propagation or extension of small thrombi into larger vessels after operation. The question arises as to the value of heparin in enhancing the viability of the intestine whose circulation has been compromised by mesenteric vascular occlusion. Our experiments were conducted to study this problem and to determine under what conditions it is safe to administer heparin.

METHOD

The circulation of the small intestine of the dog was impaired in 4 ways: (1) ligation of mesenteric vessels, (2) the injection of 2 per cent sodium ricinoleate¹ into the mesenteric vessels to produce slow thrombosis, (3) the injection of fibrinogen² into the mesenteric vessels to produce rapid coagulation and (4) strangulation of loops of intestine. Heparin³ was administered in some instances before the lesions were produced and shortly afterward in others. In each instance a control series of experiments was conducted, in which no heparin was administered.

Heparinization was maintained for varying periods of time up to 7 days. The multiple injection method was used, except in a few instances.

³ Heparin, 100 mg. ethylmercurate.

stances in which continuous venoclisis was administered overnight. The coagulation time was kept well above normal, but little effort was made to stabilize it at a constant level. It apparently made little difference in the results whether the coagulation time was slightly above normal or far above. A control coagulation time was taken before each experiment. Coagulation times after the administration of heparin varied from 10 to 45 minutes.

EXPERIMENTS CONCERNED WITH LARGE MESENTERIC VESSELS

In the first series of experiments the superior mesenteric vessels were ligated. The results of such ligations have been reported many times in the past. Scott and Wangenstein found that the average length of life following ligation of the superior mesenteric vein in dogs was 5½ hours, following ligation of the superior mesenteric artery, 20 hours, and following ligation of both artery and vein 19 hours. The results of control experiments were comparable to theirs.

The process of actual infarction is reversible up to 2 to 4 hours following ligation of the superior mesenteric vein and the animal usually survived if large quantities of blood were given by transfusion and the ligature released within this period of time. The blood volume ordinarily was reduced 50 to 60 per cent. Heparin, as might be expected, had no effect on the course of such animals. Because of the wide variation in survival times of control animals it was difficult to ascertain whether heparin actually hastened death by prolonging the coagulation time and allowing the animal to bleed more freely.

Ligation of the superior mesenteric artery in heparinized dogs produced the same end results as in the control series.

TABLE I—EXPERIMENTS CONCERNING SMALLER MESENTERIC VESSELS

Procedures	Hyperbated days	Result	Control days	Result
Devascularization of 70 to 80 cm small intestine by ligation		All survived, smooth adhesions		Death in 1 from gangrene and peritonitis in 48 and 70 hrs. One survived, others were adhesions
Devascularization of 10 to 20 cm small intestine by ligation		Death in 1 hrs, 4 days and 5 days respectively		Found dead after 24 and 48 hrs
1-2% sodium ricinoleate injected into mesenteric blood arteries, arches ligated on each side		One died after 48 hrs. survived		Death in 1 within 48 hrs.; (gangrene) Reaction of gangrene; worst case in 48 hrs. died from peritonitis
Cyanogen injected into mesenteric blood arteries, arches ligated on each side		Death within 12, 4, 24 and hrs. respectively (gangrene)		Death within 8, 12, and 24 hrs. respectively (gangrene)

Rapid thrombosis of the superior mesenteric vein was produced by placing a rubber guarded clamp on the vein near the junction with the portal vein. Five cubic centimeters of fibrinogen was then injected into the superior mesenteric vein distal to clamp and the clamp removed in 20 minutes. The mesenteric vessels became obstructed by a thick coagulum. The course of such animals was similar to that of those in which ligation was done. Heparin had no influence on the lesion.

Slow thrombosis of the superior mesenteric vein was produced by injecting 0.5 cubic centimeters of 2 per cent sodium ricinoleate solution distal to a rubber guarded clamp as described. When the clamp was removed after 20 minutes the cyanotic, relaxed appearance of the intestine due to clamping rapidly disappeared with the onset of hyperperistaltic contractions. A return of color gave one the impression that viability was assured. The abdominal wall was then closed. However a thrombus formed within the damaged vessel propagated postoperatively and caused death within 24 to 48 hours. Postmortem examination revealed massive hemorrhagic infarction of the intestine due to thrombosis of the superior mesenteric and portal veins.

In 3 of 5 such animals in which heparinization was maintained for 5 to 7 days, thrombosis was prevented, and they lived with no apparent ill-effects. The 2 other dogs died in 48 and 60 hours with hemorrhagic infarction of the intestine. In 2 other animals the administration of heparin was stopped after 24 hours, and these animals died several hours later from infarction due to mesenteric thrombosis. Apparently the heparin had not been

continued for a long enough period of time to prevent eventual thrombosis and death.

EXPERIMENTS CONCERNED WITH SMALLER MESENTERIC VESSELS

Welsh and Mall demonstrated that if more than 5 centimeters of intestine are deprived of blood supply gangrene results. Similarly Elsberg found that in the dog's intestine there is sufficient anastomosis of the intramural vessels in the longitudinal axis to supply at least 5 centimeters of uncontracted intestine if the vasa recta to such a segment are obstructed. In order to deprive a longer segment of its blood supply care must be taken to ligate all vessels from adjoining vascular arches, including those immediately adjacent to the serosa, as well as main vessel to that segment.

When the vessels supplying 10 to 12 centimeters of intestine were ligated, 2 of 3 control animals died from gangrene of the segment and peritonitis in 48 and 70 hours, respectively. The third showed no apparent ill effects. The 3 animals treated with heparin for 5 days all lived and remained well. Subsequent laparotomy on the surviving untreated animal showed more extensive adhesions than in the animals treated with heparin. The anticoagulant thus permitted the survival of a segment of bowel 10 to 12 centimeters in length after occlusion of its extramural blood supply. The death of the control animals confirms the fact that in the dog a segment of bowel 10 or 12 centimeters in length usually cannot survive when devascularized. It is possible that the anticoagulant by preventing thromb from forming in the intramural vessels, allows for more extensive collateral cir-

TABLE II—STRANGULATION EXPERIMENTS

Control series			Heparin series		
Time strangulated hrs	Length of intestine ft.	Result	Time strangulated hrs	Length of intestine ft.	Result
3	1	Recovery	3	1	Death Hemorrhage 24 hrs (found dead)
3	1	Death Peritonitis due to evisceration 72 hrs	3	1	Recovery
6	1	Recovery	6	1	Death Hemorrhage 24 hrs (found dead)
6	1	Recovery	6	1	Death Hemorrhage perforation and peritonitis 24 hrs (found dead)
3	2	Recovery	3	2	Death Hemorrhage 24 hrs (found dead)
3	2	Recovery	3	2	Death Hemorrhage 24 hrs (found dead)
6	2	Recovery	6	2	Death Hemorrhage 24 hrs (found dead)
6	2	Recovery	6	2	Death Hemorrhage 12 hrs
6	2	Recovery	6	2	Death Hemorrhage 12 hrs

culation from the normal bowel on either end. If increased bleeding occurs following heparin, apparently the blood loss from a short segment before recovery sets in is not sufficient to cause death.

When the vessels supplying 15 to 20 centimeters of small intestine were ligated, heparinization did not permit the survival of the segment, although these animals lived somewhat longer than did the control animals. All died within 5 days with gangrene of the deprived segment and peritonitis. None of the control animals lived longer than 48 hours, while the survival periods of the 3 heparinized dogs were 72 hours, 4 days, and 5 days, respectively. Blood loss was no doubt increased, but did not account for death in these animals. This experiment would indicate that a segment of bowel of 15 to 20 centimeters is apparently too long to allow collateral blood supply to nourish the entire segment from either end when the extramural blood supply is cut off.

Slow thrombosis of medium sized mesenteric vessels was produced by the injection of 0.5 cubic centimeter of 2 per cent sodium ricinoleate into such an artery distal to a clamp which included both artery and vein. This resulted in spasm of the involved segment of bowel, already cyanotic from the clamping. Removal of the clamp after 20 minutes was immediately followed by an apparent return to normal color. Palpation revealed pulsations in the vasa recta, and

hyperperistalsis was marked. It seemed that the bowel would survive. However, each of 4 such dogs showed infarction of the segment within 24 hours, and, unless the segment was resected, died within 48 hours.

The same experiment was carried out on 5 dogs which were heparinized at the time of injection and kept heparinized for 5 days. Four of the 5 animals survived. When the surviving dogs were reopened 1 or 2 weeks later, the omentum and neighboring intestinal loops were found closely adherent to the involved segment and its mesentery.

Rapid thrombosis of medium sized mesenteric vessels was produced by injecting 2 cubic centimeters of fibrinogen distal to a clamp, as described. Although a coagulum formed within the vessels within a few minutes, the survival times of 3 such animals varied from 8 to 24 hours. The 4 heparinized animals in which this procedure was done lived from 12 to 48 hours. Heparinization may have thus prolonged life to a certain extent, but did not prevent infarction and death in animals in which rapid thrombosis was produced.

STRANGULATION EXPERIMENTS

Scott and Wangenstein found that the length of bowel involved in strangulation is a factor in determining the survival period. Aird and others have emphasized other factors which play important rôles in the cause of death following low intestinal strangulation obstructions. It has been shown that in

short loop strangulations death is usually due to perforation and peritonitis. In strangulations of medium length death is apparently due to the absorption of certain toxins. In long-loop strangulations death is due to diminution in blood volume resulting from blood loss into the lumen and wall of the strangulated intestine and into the peritoneal cavity.

Our strangulation experiments were concerned with determining the effect on the recovery of medium lengths of gut strangulated for varying periods of time up to 6 hours. It was felt that release of the strangulation within this period would not allow the lethal factors associated with low intestinal strangulation obstruction to be effective.

Four groups of strangulations were carried out by means of binding tape (Table II). In each group a control series of dogs was compared with a heparinized series. Fasting dogs of about the same weight were used, and an attempt was made to produce the same amount of vascular obstruction in each instance. The tape was first tied around the mesenteric stump and then around the loop of ileum to be obstructed and was pulled as tightly as the tape would allow.

In most instances, when the tape was released after at least 3 hours, the bowel appeared questionably viable. In others, the infarction appeared irreversible. The bowel resembled that of the human during operations for strangulated hernia after incarceration for 12 hours or more. The segment was dark blue or black until released. It then became very red with purple or bluish areas in the wall and the lumen contained blood. The peritoneum contained a bloody transudate.

All but one of the control animals recovered after release of the strangulation and closure of the abdomen. The 1 death occurred after 72 hours and was due to peritonitis brought about by evisceration before strangulation was released. All but 1 of the heparinized dogs were found dead 24 hours after release of strangulations and closure of abdomen.

The cause of death in these animals was undoubtedly shock due to blood and fluid loss as evidenced by the large amount of bloody fluid in the peritoneal cavity and in the lumen

of the bowel. However, in one of the 6-hour 1-foot strangulations, death was due to perforation and peritonitis. The prolonged coagulation time following heparin apparently allowed free bleeding, thus increasing the amount of blood lost during the strangulation.

An observation was made during the strangulation experiments concerning the use of hot laparotomy pads in cases of questionable viability of the intestine. We wished to determine the safety of administering heparin after operation in such cases when resection was not done. Each of 4 dogs in which the bleeding points on a strangulated loop were controlled by means of hot laparotomy pads died from hemorrhage after heparin was administered. It was observed that the previously coagulated bleeding points began to bleed within 1 hour after injection of heparin.

RESECTION

We have performed several resections in the presence of heparinization. There was much more bleeding than is normally encountered, and much time was consumed for hemostasis. However, the procedure was satisfactorily completed in each case and the mortality following resection was no different than in control animals.

CONCLUSIONS

From our experiments it would seem that it is unsafe to administer heparin after operation in cases of impaired circulation of the intestine when resection is not performed. Although it appears that heparin enhances the chance of recovery of short devascularized segments, in cases of mesenteric vascular occlusion or strangulation it should be reserved only for those cases in which resection is performed.

EXTRATHYROIDAL METABOLISM OF IODINE

ASHER CHAPMAN, M D, Rochester, Minnesota

IODINE has been identified with the physiology of the thyroid gland since the findings of Chatin, Baumann, Marine, and others. These studies have tended to focus attention on the intimate rôle played by thyroid tissue in iodine metabolism. Reports of subsequent work on the function of iodine in the organism, for the most part, have assumed or implied the participation of thyroid tissue.

The recent experimental *in vitro* production of thyroxine or thyroxine-like substances by the iodization of protein has been accomplished. In view of the formation of these calorigenic substances in the absence of thyroid tissue, the effect of iodine on the completely thyroidectomized animal should be significant. The results of such observations form the basis of this report.

METHODS OF STUDY

For this investigation 42 male, albino rats aged 7 weeks and weighing approximately 165 grams were selected and divided into 2 groups. Twenty-four rats on which thyroidectomy was not performed formed 1 group and 18 thyroidectomized rats formed a second group. Thyroidectomy was complete in all animals but one in which a small amount of thyroid tissue was observed at necropsy.

All animals received the same goitrogenic, low iodine diet described by Remington, and all animals had free access to distilled water.

The groups of intact and thyroidectomized animals were each divided in half, 12 intact and 9 thyroidectomized animals each formed a group which received an iodine supplement. This was administered in the drinking water,

15 micrograms of iodine as potassium iodide per cubic centimeter of water, which supplied to these 2 groups, respectively, an average iodine intake of 34 and 27 micrograms per rat per day. Less than 5 per cent difference in the intake in the 2 groups existed, calculated on a basis of average body weight. Thus 4 groups of animals were arranged: 2 groups of intact animals, 1 receiving a supplement of iodine and the other on a low iodine intake, and similarly, 2 groups of thyroidectomized animals on supplemented and restricted iodine intake.

Body weights were recorded every third day and the consumption of food and water was measured and recorded daily. Respiratory metabolism was determined twice during the course of the experiment.

EXPERIMENTAL DATA

The data have been calculated and expressed in terms of unit weight and surface area of rat tissue because of the diverging weights of the different groups. Thus the food intake of a group of rats averaging 200 grams was compared properly with the food intake of a group averaging 150 grams.

Food and water intake and changes in body weight were observed from the fourth to the sixty-ninth postoperative day, thus constituting a 65 day experimental period.

The changes in surface area of these animals (Fig. 1) were based on the percentage change in weights from the onset of the experiment. Difference in the level of iodine intake made little change in the rate of growth of intact animals, but in thyroidectomized animals differences were observed. Those on restricted iodine intake lost weight and surface area more rapidly than the animals receiving the iodine supplement. The terminal rise of the growth curve (Fig. 1) in the thyroidectomized animals on low iodine intake is explained by the death of low weight members of this group, whereas the animals whose percentage loss of surface area was less survived.

A portion of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Doctor of Philosophy. This study combined with the essay "The Relation of the Thyroid and the Pituitary Glands to Iodine Metabolism," was awarded the Van Meter Prize by the Association for the Study of Goiter.

Work done at the Institute of Experimental Medicine under the direction of Dr. G. M. Higgins.

Presented in the Forum on Fundamental Surgical Problems, Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

Fig. 1. Growth curves expressed as percentage changes in surface area. — Group I, intact animal, adequate iodine intake; — Group II, intact animal, low iodine intake; — Group III, thyroidectomized animal, adequate iodine intake; — Group IV, thyroidectomized animal, low iodine intake.

The actual changes in weight and surface area of the 4 groups (Table I) included the changes occurring during the life of the rats which died during the course of the experiment. These figures represent the net performance of the groups more accurately than the graph of percentage changes but they do not show the progressive changes so well. Again there was noted very little difference in the changes in weight or surface area in the 2 groups of intact animals receiving low and

TABLE I.—CHANGES IN WEIGHT AND SURFACE AREA THAT OCCURRED DURING THE EXPERIMENTAL PERIOD

TABLE IV—CALORIC INTAKE AS FOOD, BASAL CALORIC OUTPUT (CALCULATED FROM OXYGEN CONSUMPTION) AND PERCENTAGE DEVIATION OF METABOLIC RATES FROM THOSE OF CONTROL GROUPS

Animals	Groups	Average caloric intake or output per sq m per 24 hrs		Basal metabolic rate, percentage deviation from normal caloric output	
		Intake	Output (basal metabolism)	Basis 1032	Basis 588
Intact	I Adequate iodine	1922.4	1032	0	
	II Low iodine	1947.6	1090	+6	
Thyroid ectomized	III Adequate iodine	1378.8	588	-43	0
	IV Low iodine	1177.0	482 (432)*	-53 (-58)*	-18 (-27)*

*One animal with regenerated thyroid tissue (rate -30) was excluded

iodine intake consumed almost as much food as the controls receiving iodine, yet they lost more than three times as much weight and surface area. That is, the thyroidectomized animals that received iodine utilized their food better than the thyroidectomized animals which did not receive an iodine supplement.

A study of water intake in relation to surface area, to change in surface area and to the intake of food showed (Table III) that the water consumption in intact animals on either low or adequate iodine intake was not altered significantly. The water intake in thyroidectomized animals on low iodine intake, however, was significantly greater than in the thyroidectomized animals receiving iodine. This was evident in relation to surface area as well as to the food intake. For every gram of food taken by the thyroidectomized animals receiving supplemental iodine, 1.7 cubic centimeters of water was consumed, while the thyroidectomized group on low iodine consumed 2.4 cubic centimeters of water for each gram of food. The expression of loss of surface area in relation to water consumed indicates that the loss was approximately proportional to the loss calculated on a basis of food intake, that is even though the water consumption was greater, the loss in weight and surface area

Fig 2 Relation of intake of food and water to change in surface area. The length of the brackets indicates the ratios of food to water intake in the groups

progressed. It is probable that the changes in weight and surface area were independent of the water intake and that the animal had diuresis and not retention of water. The relative differences in the amounts of food and water consumed and in the change in surface area of the 4 groups of animals are shown in Figure 2.

The metabolic rate of the animals was determined on the 49th and 64th days of the experimental period, a slight decrease in the oxygen consumption occurred in the second determination. The average of the two determinations was selected as a basis for comparison of the metabolic rates in the 4 groups (Table IV). A slight increase, 6 per cent, in the average basal metabolism of the intact (goitrous) animals receiving low amounts of iodine over that of the intact animals receiving adequate amounts of iodine may not be of sufficient magnitude to be significant. However, a real difference between the mean metabolic rate of the two thyroidectomized groups, with and without the iodine supplement, was observed. If the one animal in the thyroidectomized group which did not receive any iodine supplement and which showed regenerated thyroid tissue at necropsy was excluded then the basal metabolic rate for this group was depressed 27 per cent below that of the thyroidectomized control group receiving the iodine supplement.

Caloric value of the food intake of the groups was calculated (Table IV). However as this was not consumed under basal conditions the comparison with the caloric output is only relative.

EVALUATION OF STUDY

The presence of thyroid tissue in the intact animals permitted utilization of the small amount of iodine available in the low iodine diet. To accomplish this the thyroid hypertrophied, thereby maintaining the growth and well being of the organism, as shown in the growth curve of the two intact animal groups.

The thyroidectomized animals, on the other hand deprived of tissue especially adapted to the processing and utilizing of iodine, suffered a change in body growth and function. Unlike the intact animal groups, however the presence or absence of a plentiful supply of iodine made a distinct difference in the performance of the thyroidless animals. This was evident in the depressed growth curve the less efficient utilization of food, the greater intake of water and the distinctly lowered metabolic rate associated with the restricted iodine intake in the athyroid animal as compared with a similar group of animals receiving an iodine supplement. It is evident that iodine played some rôle in the body economy of the thyroidectomized animals.

The possibility that iodine may have an effect on vital processes in the absence of thyroid tissue was emphasized by the work of Swingle, Hoskins and Hoskins, Allen, and others who showed that iodine stimulated metamorphosis in thyroidectomized amphibians. Further evidence that iodine may affect growth processes in the absence of thyroid tissue was shown by Silberberg and Silberberg who reported stimulation of growth of bone in immature thyroidectomized guinea pigs by the administration of iodine. This resulted in a parallel to the growth of bone caused by the administration of thyroxine to thyroidectomized animals.

Abelin, Ludwig and von Mutzenbecher, Salter and Lerman, Block, and others have demonstrated the production of thyroxine

diiodotyrosine and calorigenic protein similar to thyroglobulin by the iodization of organic material *in vitro*.

It is possible that iodine in the thyroidless animal acted in a similar manner to that of iodine on organic matter *in vitro* possibly aided by enzyme action not necessarily confined to thyroid tissue. This effect of iodine in the thyroidless animal, then, may represent the action on the tissues of a certain concentration of iodine, thus elaborating a thyroxine-like substance.

If an extrathyroidal utilization of iodine exists, then its function in disease associated with iodine metabolism may be significant, especially in hypothyroid states. The untoward effects of iodine lack in the athyroid animal suggest that an absolute iodine deficiency would impose a more severe strain on the organism and that life itself may not be compatible with the complete absence of iodine.

SUMMARY AND CONCLUSIONS

A difference in iodine level in the diets of thyroidectomized rats significantly altered the changes in weight and surface area, the water intake, the food utilization, and the metabolic rate. These changes were not induced in the intact animals by deprivation or administration of iodine.

From the data presented it is concluded that iodine may play a rôle in body metabolism in the absence of thyroid tissue, possibly by the production of a thyroxine-like substance in the tissues.

THE DIAGNOSIS AND TREATMENT OF CANCER OF THE STOMACH

HOWARD K. GRAY, M.D., F.A.C.S., Rochester, Minnesota

BECAUSE cancer of the stomach has received so much attention in recent years, further comment at this time would seem to be superfluous. Several extremely discouraging facts stand out so vividly, however, that one is justified in reviewing the present status of the problem as it is obvious that even greater efforts will have to be expended if any appreciable improvement is to be achieved in the early diagnosis and treatment of cancer of the stomach.

The seriousness of cancer of the stomach may be emphasized by comparison of the 5 year survival rates of all patients who have a malignant lesion in the more common sites, whether treatment has been given or not. With the possible exception of primary carcinoma of the lung, the 5 year survival rate after the diagnosis of cancer of the stomach is appreciably lower than the 5 year survival rate in cases in which a diagnosis of cancer of the fundus of the uterus (55 per cent), thyroid gland (42 per cent), breast (32 per cent), uterine cervix (31 per cent), or large intestine (24 per cent) has been made.

Walters, Priestley, and I have reported elsewhere the results of the study of a large group of cases of malignant lesions of the stomach. From a study of these cases, it was noted that of all cases in which a diagnosis of a malignant lesion of the stomach had been made, operation was performed in only 57.7 per cent (surgical rate) and that resection of some type was possible in only 25.8 per cent. The immediate hospital mortality in the group of cases in which resection was performed was 16 per cent, which, when translated into terms referring to the total number of patients observed, reduces the number of patients who theoretically have any chance of survival to 21 persons for each 100. In 28.9 per cent of cases in which a malignant lesion of the

stomach was successfully treated by resection the patients were found to be alive at the end of 5 years, whereas only 6.2 per cent of the total number of patients observed with a malignant lesion of the stomach were alive at the end of the same period.

It is interesting to note the similarity in the operability rate and resectability rate in 127 cases of primary carcinoma of the lung reported by Overholt. In 41 per cent of the cases the lesions apparently were operable but in only 26 per cent of the cases exploratory operation disclosed the lesions were operable. At the time Overholt made the report, in 11 per cent of the cases in which the patients were living in which the malignant lesion had been removed, there was no evidence of metastatic involvement. It is impossible to determine at this date the 5 year survival rate as only 3 of 13 patients with no evidence of metastasis had been operated on more than 5 years before the report was made, and for this reason it is obvious that the 5 year "salvage" rate for the total number of patients observed will be appreciably less than 11 per cent and probably will be very close to that already mentioned for malignant lesions of the stomach.

The fact that early removal of a malignant lesion of the stomach is the only known method of cure has been emphasized repeatedly and is so widely accepted that repetition at this time seems trite and elementary. It may be assumed that because our study has been based on all cases of malignant lesions of the stomach observed in the years 1907 to 1938, inclusive, the surgical rate of 57.3 per cent and the resectability rate of 25.5 per cent will be low when compared to similar figures based on experience during the last 15 years. Unfortunately, such is not the case. The ratio of patients operated on to total patients who were found to have a malignant lesion of the stomach has varied

From the Division of Surgery, Mayo Clinic.
Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

little during the last 15 years from the surgical rate for the whole period and although the ratio of patients who underwent resection to the total number of patients is slightly higher than the rate of 25.5 per cent, the improvement is so insignificant as to be negligible.

The answer to this difficult and discouraging problem is not easy. One of the first responsibilities of the medical profession is to spread the knowledge that, with proper care, cancer of the stomach (in the broad sense) can be cured if it is attacked when the process is in its early stages and is localized in the stomach. That the symptoms of cancer of the stomach may be vague and ill defined is well known. Laymen must understand that there is no typical symptom complex that is characteristic of cancer of the stomach, and the physician and surgeon likewise must not wait for the development of characteristic symptoms before considering the possibility of the presence of a malignant lesion of the stomach and insisting upon a thorough examination in order to arrive at a correct diagnosis.

An attempt was made to classify the symptomatological picture presented by the patients who had cancer of the stomach in the group previously mentioned. This proved to be a difficult task because of the great variety of detailed symptomatological aspects inherent in such a large series of cases. The "unusual" type of symptomatological picture of a malignant lesion of the stomach occurred in three fifths of the cases and consisted of a symptom complex in which dyspepsia was the most prominent symptom and was associated with varying degrees of decline. Thirty per cent of the patients portrayed the symptomatological picture of "ulcer" which was characterized by epigastric pain occurring characteristically when the stomach was empty and which was relieved by the ingestion of food or alkali. Seven hundred ninety three patients who had a malignant lesion of the stomach had received some type of therapy for ulcers and 81 per cent of these patients had experienced definite subjective improvement. The observation would seem to discredit the value or the advisability of the use of the response to treatment as a criterion for distinguishing a malignant lesion from a be-

nign ulcer except under the most nearly accurate conditions of observation, which it is possible to obtain.

A reason for the discouragingly low surgical rate in cases of malignant lesion of the stomach has been suggested by the supposed frequency with which such lesions manifest themselves at such an advanced stage of development that the lesion is inoperable before the patient experiences symptoms which suggest its presence. That this occurs occasionally is well known. That this occurs frequently is not substantiated by the fact that only 18 per cent of this large group of patients had noted the first symptom referable to the stomach less than 3 months prior to their admission to the clinic whereas exactly half of the patients stated that they had experienced symptoms referable to the stomach for more than a year. It should be noted especially that the fact that a patient may have had symptoms referable to the stomach for a long time is no criterion upon which to exclude the presence of a malignant lesion of the stomach.

Among laymen, and particularly among physicians, there has been a lamentable lack of appreciation of the malignant potentiality of gastric ulcer. This statement does not suggest that all malignant lesions of the stomach start as benign ulcers. It is impossible from a pathological or clinical standpoint to determine how frequently this may occur perhaps not over 10 per cent, perhaps never. It is not really so important to quibble as to whether or not a particular malignant lesion was once a benign ulcer as to attempt to determine immediately whether or not the lesion under consideration is malignant. Through better experience it has been learned that there is no method by which an unequivocal clinical diagnosis may be made as to the malignancy or benignancy of any ulcerating lesion of the stomach. In spite of the fact that the most outstanding advances in the diagnosis of cancer of the stomach can be attributed to roentgenology and gastroscopy and that all other diagnostic methods in comparison become so insignificant that their importance can be disregarded, expert roentgenologists and gastroscopists admit that it is impossible in many instances to distinguish between a small ul-

cerating carcinoma, a malignant gastric ulcer, and a benign gastric ulcer. In our experience at the Mayo Clinic, approximately 9 per cent of carcinomatous ulcers had been diagnosed as benign by a roentgenologist, and what is even more significant, in 18 per cent of all cases of cancer of the stomach in which roentgenologic diagnosis was made, it was not possible to determine the exact nature of the lesion, and in 7 per cent of the cases a diagnosis of benign ulcer was made. It is particularly significant that some type of abnormal lesion of the stomach was noted in 99 per cent of cases in which a malignant lesion of the stomach was present. The fact that it is impossible to determine definitely by means of roentgenologic or gastroscopic examination the exact nature of certain lesions of the stomach is not surprising. This statement is not a criticism of either of these diagnostic methods. The two methods of examination of the stomach are supplementary and in many instances either one or the other may demonstrate an abnormal condition in the stomach while the remaining method may produce essentially negative results. A similar experience was recorded by Allen and Welch in a paper read before the American Surgical Association this year. This study dealt with 277 cases in which a surgical diagnosis of gastric ulcer was made. In 35, or 14 per cent, of the cases the lesion finally proved to be cancer. From this study, Allen and Welch have seen fit to recommend operation if (1) the gastric ulcer is of short duration and the patient is more than 50 years old, (2) the ulcer is more than 2.5 centimeters in diameter, (3) there is no free hydrochloric acid in the gastric contents, (4) the ulcer is situated on the greater curvature or in the prepyloric region, (5) the ulcer is chronic and is on the lesser curvature. They recommend hospital observation and treatment for 1 month if (1) the ulcer is acute and the patient is young, (2) the ulcer is less than 1 centimeter in diameter, (3) the ulcer is on the lesser curvature or on the anterior or posterior wall. If healing of the ulcer is complete in 1 month they said that repeated observation should be made 1 month after dismissal of the patient from the hospital. If healing is not complete in 1 month, as deter-

mined by roentgenologic and gastroscopic examination, then operation is advisable. My associates and I are in complete agreement with the principles of these conclusions. The fact cannot be emphasized too strongly however, that although the ulcer may give every evidence of having healed roentgenologically, gastroscopically, subjectively, and by the disappearance of occult blood from the stools, a malignant lesion may be demonstrated within a very few weeks after the fulfillment of these accepted criteria for a benign lesion.

TREATMENT

The purpose in treating cancer of the stomach is two-fold. The first is to effect a cure, if possible, and the second is to prolong life and reduce to a minimum the suffering which may be associated with the disease. It is obvious that the first purpose can be accomplished only by extirpation of the malignant mass together with accessible lymph nodes that are involved, including all of those in the greater omentum. In most instances, as shown by Carman, the question of operability, from the roentgenologic standpoint, depends on the situation, the extent, and the character of the cancer. He divided the stomach into 3 zones: the operable zone, corresponding to the pars pylorica, the borderline zone, corresponding to the pars media, and the inoperable zone, corresponding to the pars cardiaca. Tumors that are inoperable are usually situated in the cardiac end of the stomach, or have spread from a pyloric or fundic position to within the inoperable zone. Only rarely is a preoperative report of inoperability of a lesion in this situation not confirmed when exploratory operation is performed.

Roentgenologic evidence alone, however, should not be sufficient evidence in occasional cases to deny the patient what benefit may be derived from surgical exploration. This is particularly true of lesions situated primarily in the fundic portion of the stomach or near the cardiac orifice, as great strides have been made in the transpleural approach to these lesions. Although improvement in the "salvage" rate of patients with malignant lesions of the stomach may be expected with

the development and refinement of the more extensive surgical procedures a more promising field undoubtedly exists in widespread promulgation of the importance of early diagnosis and recognition of the malignant po-

tentiality of every ulcerating lesion of the stomach

USE OF FEMALE SEX HORMONES IN CLINICAL PRACTICE

E. C. HAMBLIN B.S., M.D. F.A.C.S. Durham North Carolina

ENDOCRINOLOGY during the past decade has been a veritable handmaiden of gynecology. Despite a widespread and often uncritical or ganotherapeutics, which has not failed to draw repeated criticism from conservative clinicians, securely established indications have now been delineated for the use of the newer hormones in everyday practice. Equally if not more important, contributions of endocrinology have ever have been manifest in the resultant evolution of a newer and more physiological approach to the handling of many of the ills of woman which emphasizes diagnosis of functional levels and has as its desideratum the utmost salvage of function and the preservation or restoration of the fertile state when it is possible. There is now less recourse to function-destroying surgery and roentgenotherapy unless it is founded upon securely established indications.

The ovary elaborates two kinds of female sex hormones *estrogenic substances (estrogens)* from the granulosa cells of maturing graafian follicles and also from the cells of the corpus luteum and *progestational substances (progesterin)* from the lutein cells of the corpus luteum. *Estrogens* are responsible for the manifold definitive changes in the sexual apparatus, and elsewhere which characterize the adolescent epoch of sexual maturation and for the maintenance during the reproductive years of a state of development in the sexual organs compatible with the functional re-

quirements placed upon them. These hormones are largely responsible therefore for the objective and subjective femininity of woman. *Progesterin* is concerned with the preparation of the uterus in particular and the woman in general for the monthly physiological anticipation of pregnancy and when gestation does occur with important roles in the nutrition and protective sheltering of the developing fetus. Opposing to some extent and perhaps, also acting as synergists or pacemakers to these female sex hormones, are the contrasexual *androgenic* hormones which are elaborated in woman solely by the adrenal cortex. Woman's hormonal moiety must be viewed then as being dual in sexual nature as Blair Bell has observed the older view that *propter ovarium solum mulier est quod est* is less a real statement of fact than *propter secretionem internam tota mulier est quod est*.

All of the ovarian and cortical adrenal hormones are steroids, or higher alcohols, which contain in common the cholane nucleus. Three different estrogenic hormones have been identified in woman's urine estrone, estradiol, and estradiol. Commercial preparations of all of these are available for therapeutic usage. These estrogenic hormones should be contrasted with certain nonhormonal drugs which possess estrogenic properties, but which have no chemical relationship to the natural steroids, for example diethylstilbestrol and its esters. During recent months diethylstilbestrol has been released into commerce by the Food and Drug Administration. Only one active progestational hormone, progesterin, has been recovered in small amounts from woman's ovaries and urine. Another progesta-

Presented before the Clinical Congress of the American College of Surgeons, Boston, Nov. 3-7, 63.

tional steroid, anhydro-oxyprogesterone, has been prepared synthetically from estradiol. Both of these progestational steroids are available commercially. While four 17-ketosteroids of adrenal origin have been recovered from woman's urine, androsterone, dehydroisoblanol3(a)-17-one, only two of these, androsterone and dehydroisoblanol3(a)-17-one, possess significant masculinizing or androgenic properties (2). Only the androgens, testosterone, which has been recovered from testes but not from urine, and its derivative, methyl testosterone, are used therapeutically.

USES OF ESTROGENS

Consideration of the known pharmacological properties of estrogens has justified as rational their trial under the following circumstances (9) (1) in certain established instances of estrogenic ovarian failure, occurring in adolescence or during sexual maturity, as substitutional or complementary therapy, (2) in certain subjective disturbances of the character as palliative but not full substitutional therapy, (3) in hypomastia for cosmetic effects alone, (4) in certain hyperfunctional states of other glands, i.e., the pituitary or adrenals, as antagonistic therapy, and (5) in certain cases for specific pharmacological effects upon the vaginal epithelium, the indication for therapy not being any endocrine disturbances.

In addition to these apparently rational indications, estrogens have been employed empirically and often contraphysiologically under various conditions.

Substitutional therapy in intrinsic ovarian failure. When severe grades of estrogenic failure of this character exist, the indication for therapy concerns the completion of sexual maturation in the adolescent and the prevention or correction of sexual regressions in the adult. Large doses of estrogens will produce dramatic endocrine responses under these circumstances, for the endocrine function of the ovaries can be substituted for just as effectively as that of the pancreas or the thyroid. Three important facts limit the practicality of prolonged substitution at the ovarian level (1) the expense involved the large dosages of

estrogens required day after day and year after year have imposed in the past an almost insurmountable financial burden, but the commercial availability of diethylstilbestrol has now circumvented this limitation, (2) the inability to overcome the sterility of the patient the germinal function of ovaries cannot be substituted for, and (3) the temporary nature of the results obtained regressions which erase, for the most part, all therapeutic results, occur when treatments are discontinued.

Fortunately, in view of these limitations, severe estrogenic deficiency rarely impairs health or somatic efficiency despite the cosmetic inelegancies it may impose upon the adolescent or the young woman. A limited trial of substitutional therapy is justified in the young woman with severe estrogenic deficiency upon the following grounds (1) to attempt to curb the abnormal somatic overgrowth of these young patients by effecting epiphyseal closures, a therapeutic hope not definitely established as a fact, (2) to bring about some degree of sexual attractiveness of the patient, for its salutary psychic effects, and (3) to alter beneficially the ovary-pituitary reciprocities of these patients by the resulting genital growth and development (9).

Complementary therapy in intrinsic ovarian failure. Intercurrent episodes of intrinsic ovarian failure occur, as for example, the occasional sterile (anovulatory) cycles which even normal, healthy women may have. A preponderance of these may produce sterility and eventual distressful menstrual irregularities. Frequently excessive or prolonged uterine bleeding of the young woman is due to these intercurrent episodes of lowered receptivity of the ovaries to gonadotropic influences from the pituitary. The employment of a system of cyclic steroid therapy embracing the use of estrogens and progesterone under these circumstances permits effective control of the uterine bleeding without any further damage to ovarian function, in fact, not infrequently, this therapy may permit tiding the patient over this ovarian crisis until such time when normal function returns (11). Without such supportive therapy, doubtless many of these

intercurrent episodes progress to graver degrees of ovarian failure.

These statements regarding the effectiveness of the hemorrhagenic hemostatic schedule permitted by cyclic steroid therapy should not be construed as representing the advocacy of endocrine therapy solely to regulate the menstrual cycle. Many menstrual irregularities are innocuous, if not actually fanciful and endocrine therapy under these circumstances is meddling and often contrapathological.

Palliative therapy in the physiological estrogenic failure of the climacteric. It is trite to state that estrogenic deficiency is physiological at the time of the climacteric, yet some of the massive doses of estrogens given at this time of life by some organotherapeutic enthusiasts would indicate apparent ignorance of the normal hormonology of this epoch. No need seems to exist for prolonged therapy with full substitutional or even larger dosages of estrogens at the time of the climacteric. Our knowledge of geriatrics has not reached such a state that we are justified in trying to postpone sexual aging.

All estrogenic therapy during the climacteric should fulfill this general therapeutic desideratum to lessen, but not to substitute for the physiological ovarian deficit of those women in whom severe subjective symptoms characterize this epoch, i.e. palliative not full replacement therapy. Therapy should be limited if possible in duration to several months dosages should be kept small and estrogens should be given orally if possible. If patients to be treated continue to have episodes of bleeding therapy should be adjusted cyclically so that it is withdrawn at the time of and during episodes of bleeding lest troublesome menstrual irregularities be added to the other symptoms of the patients.

Cosmetic therapy of hypomastia. A general statement regarding isolated hypoplasias of the genital system seems advisable at this time. When a woman who is apparently endocrinally adequate otherwise has unilateral or bilateral hypomastia or a hypoplastic uterus, the likely diagnosis is a faulty end-organ or end-organs rather than faulty ovarian function. Estrogenic therapy under these circumstances is usually of no benefit

At times a patient with typical adolescent hypo-ovarianism is concerned solely by her hypomastia. The use of estrogenic ointments by local massage applied to the breasts may give gratifying temporary results if rather large doses of estrogens are employed and some permanent benefits may result, probably due chiefly to massage. It has been reported that the concomitant use of progesterone by injection lessens the regressions which follow the discontinuation of estrogens.

Antagonistic therapy of hyperfunctional states of other glands. Theoretical considerations have suggested that large doses of estrogens given over prolonged periods may offer a means of depressing hyperfunctional states of the pituitary and of nullifying the virilizing effects of hyperactivity of the androgenic elements of the adrenal cortex. The results of estrogenic therapy in neither of these conditions have been satisfactory despite the fact that it seems well established that the moderate gonadotropic hyperactivity of the pituitary which characterizes the climacteric is reduced by adequate estrogenic therapy. Larger dosage and more prolonged usage of estrogens permitted by recently available diethylstilbestrol may have better results.

Therapy for local vaginal effects. The special trophic effects of estrogens upon the vaginal epithelium have permitted effective applications in the treatment of gonorrheal vaginitis of childhood and of nonspecific postmenopausal vaginitis. Since hypoestrogenism is physiological at these two periods of life estrogens do not fulfill the requirements of hormonal agents but rather of active substances having a desired local action: the production of vaginal cornification and increased vaginal acidity both of which effects augment the resistance of the host to the invading organisms. Since estrogens are active when applied directly to the vagina, and since large doses are not required undesired general effects of this therapy (precocious adolescent phenomena and uterine enlargement with return of uterine bleeding, respectively for the two classes of patients) may be avoided.

Good results have been reported by some gynecologists from the local use of estrogens before operation in postmenopausal women.

awaiting plastic vaginal procedures. The modus operandi of this therapy is similar to that in vaginitis. The improvement in vaginal proliferation has been said to facilitate operation and postoperative healing.

Empirical and contraphysiological therapy
Time does not permit even a listing of the various empirical and contraphysiological uses to which estrogens have been put. Most of these have been concerned with the treatment of subjective symptoms, by fact or theory, usually the latter, related to disordered ovarian function.

An explanation is due, perhaps, in regard to our meaning of contraphysiological therapy. When estrogens are used in large doses in women with apparently normal ovarian function with the hope that ovulation and corpus luteum function can be prevented, which has been stated to be the rationale of such therapy in dysmenorrhea and "menstrual migraine," this in our opinion constitutes contraphysiological therapy.

Recently another type of contraphysiological therapy has been reported. Dunn has given male criminals with abnormal sexual histories large doses of diethylstilbestrol for the purpose of depressing the endocrine function of their testes. He was apparently quite successful and, in addition, observed markedly degenerative changes in their seminal tubules.

USES OF PROGESTERONE

All of the therapeutic applications of progestin (progesterone) and anhydro-oxypregesterone have been concerned with the substitution for or the complementation of corpus luteum failure during the progestational phase of the menstrual cycle or during pregnancy. In the first category, the following conditions come up for discussion: dysmenorrhea, estrogenic bleeding, and ovarian sterility, in the second instance, repeated or threatened abortions.

Dysmenorrhea In line with the widely accepted theory that the corpus luteum exerts a quieting effect upon uterine motility, it seemed logical to employ progesterone, when it became available commercially, in the treatment of functional dysmenorrhea. Since results that followed were no better than those

obtained from diverse other therapeutic agents, it seemed logical to question the occurrence of any specific action. The reason for this therapeutic failure of progesterone seems obvious. Most women with functional dysmenorrhea have no evidence of corpus luteum deficiency, i.e., they bleed from progestational endometria and excrete essentially normal amounts of pregnandiol (a metabolic product of progestin) (6).

Estrogenic bleeding and ovarian sterility
Most of the functional disturbances of menstruation are characterized by estrogenic (anovulatory) bleeding and an associated sterility, i.e., lack of corpus luteum function. It seemed rational to use progesterone in the treatment of these conditions.

Misconceptions occurred at first in regard to the pharmacological effects to be expected from progesterone. It was believed that injections of progesterone would postpone bleeding (i.e., lengthen the interval) when given during nonbleeding phases and that, when given during episodes of excessive bleeding, progesterone would have a hemostatic action. In 1936, we (5) called attention to the fact that the exact contrary was true: progesterone has a hemorrhagenic effect when given during nonbleeding phases and increases the amount of bleeding when given during flowing.

Another error in therapeutic theorization was the assumption that a "medical curettage" in these cases, especially in patients with excessively proliferated endometria, could be produced by progesterone by transforming the endometrium to a full blown progestational one which in turn would be shed in the normal fashion. As early as 1936 (5) we cited the infrequent occurrence of progestational responses in these patients following progesterone therapy even when progesterone was synergized with ample estrogens. This phenomenon was related by us to some factor which brought about a lowered endometrial reactivity to progesterone (11).

In regard to the sterility associated with estrogenic bleeding, it seems unlikely that even effective substitution for the absence of progestin would induce ovulation any more readily than in the instances of adolescent ovarian failure wherein substitutional therapy

with estrogens is given. However when estrogens and progesterone are given cyclically, as in our regimen of cyclic steroid therapy until normal endometrial reactivity returns a good number of patients experience a return of the fertile state.

Repeated or threatened abortion. Deficient function of the corpus luteum has been predicated to be the etiological factor in the recurrent or threatening abortions of women in whom no obvious organic or metabolic causes for these abortions exist. Progesterone therapy under these circumstances is founded upon the assumption that these patients need more of the uterine quieting effect of that hormone. Many reports have appeared dealing with the good results obtained from repeated injections of relatively small amounts of progesterone in patients with histories of having had numerous previous abortions.

We have cast doubt recently (8-10) upon the correctness of the premise that corpus luteum deficiency is the cause of the abortions which are prevented presumably when progesterone is administered. Every patient of ours who had critically low pregnandiol (a metabolic product of progestin) excretions aborted despite intensive therapy with progesterone in amounts many times those commonly used. It is our belief that if progesterone has a specific action in preventing abortions, its *modus operandi* is something other than that of complementing corpus luteum deficits.

USE OF ANDROGENS

Androgens are not considered usually to be "female sex" hormones but a brief discussion of these in this paper seems advisable. It is justified upon two grounds: (1) the fact that these hormones form a part of the normal hormonal pattern of woman and (2) the fact that during recent years there has been a widespread use of androgens in gynecologic therapy.

No clear-cut rationale has been established for the therapeutic use of these steroids in woman (7). The only justification for their use has been apparently that they have pharmacological reactions which under certain circumstances appear to be expeditious, i.e. suppression of ovulation, hemostasis in menor-

rhagia, pituitary stabilization in the climacteric without endometrial stimulation, suppression of lactation, etc.

All of the described effects of androgens have been due to the "negation or overriding of the usual ovarian function" i.e., are contraphysiological effects (4-12). Few if any of the ultimate results obtained by androgens cannot be accomplished more satisfactorily from measures less likely to cause undesired side effects. The use of androgens in the female is beset with the dangers of grave symptoms of virilization, not all of which are reversed when therapy is discontinued. One theoretical indication for androgenic therapy is to antagonize hyperestrogenism. The only true and proved instance of this which we know clinically is that which is due to granulosa cell tumors of the ovaries, for which the recognized and satisfactory treatment is surgical ablation of the tumor.

SUMMARY

Estrogenic hormones have a limited, but well established role in the treatment of certain climacteric syndromes, gonorrheal vaginitis of childhood and senile vaginitis. Complementary therapy with estrogens and progesterone in certain instances of intercurrent ovarian failure may be followed by the return of normal ovarian function. Substitutional therapy in severe estrogenic failure of the adolescent or young woman yields only temporary results and does not circumvent the sterility of these patients. Untoward responses to estrogenic therapy are increasing since the availability of cheap orally active estrogens of the diethylstilbestrol type; these are due chiefly to overdosage. Diligence to avoid overtreatment should be observed.

Despite the expectations aroused by the commercial availability of progesterone no definitely established therapeutic role has been accorded it. As a part of cyclic steroid complementary therapy in estrogenic bleeding, it has given best account of itself. Its specific value in dysmenorrhea and repeated or threatened abortion is questioned.

Androgens have no place in rational gynecologic therapy. Their effects are solely of ovarian negating or depressing type. Viril-

ing effects from the use of androgens do not always disappear when the treatments are discontinued

VISUAL FIELD CHANGES AND SUBDURAL HEMATOMAS

GEORGE L. MALTBY M.D. Cincinnati, Ohio

IT is universally agreed that the clinical diagnosis of subdural hematoma is extremely difficult. Many authorities stress the importance of making exploratory burr holes when the diagnosis is in doubt. A negative burr hole is much less serious than a neglected subdural hematoma. In an effort to improve our diagnostic acumen in respect to this condition we have recently reviewed the series of verified subdural hematomas seen on the neurosurgical service of the Cincinnati General Hospital since October 1937. In the course of this review we were surprised to find that in slightly more than 10 per cent of the cases some mention of a visual field defect was recorded. Knowing the difficulty in examining visual fields, even roughly, in unco-operative patients this percentage seemed remarkable. It therefore seemed probable that a brief review of the type of visual defect, the diagnostic and prognostic value of such defects, and the underlying pathological changes behind the defects might be worthy of brief consideration.

In a series of 62 verified subdural hematomas there were 7 instances in which visual field defects were mentioned (Table 1). In 4 instances these were apparently a very definite finding borne out by careful confrontation tests. In 3 instances the defect was said to be probable. In 1 of the 4 definite examples it was possible to check the fields by actual careful perimetry. In all the cases the defect was homonymous in character. The homonymous defect was contralateral to the hematoma in 4 instances; in 1 case the clot was centrally placed that is interhemispherical, and the defect was a left homonymous abnormality; and in the seventh case the visual field change was ipsilateral. Five of the patients recovered and were discharged from the hospital. In 4 of these postoperative checks of the visual fields

revealed no definite abnormalities. In the fifth case that recovered the preoperative homonymous defect had been very definite. A postoperative check 2 weeks after surgery showed a residual almost complete left homonymous defect. This was checked again 1 month after the operative procedure and there was definite evidence of recovery. A third perimetric study was done approximately 2 months after the removal of the subdural hematoma, and at this time the fields continued to show improvement (Fig. 1).

Pathological studies were carried out on the brains of the 3 patients who died. In both cases there was definite evidence of herniation of the uncus portion of the hippocampal gyrus. In both, the greater herniation was in the right side. The clinical evidence in each instance had pointed to a left homonymous visual field defect. In the examination of both brains there was a suggestion that circulation in the posterior cerebral artery on the right had been interfered with by the uncus herniation. The first fatal case (No. 4) was the one in which the hematoma had been interhemispherical. There was gross evidence of moderate softening in the distribution of the right posterior cerebral artery. However in the second case (No. 7) there was very definite gross and microscopic evidence of bilateral posterior cerebral artery involvement with encephomalacia. This change was much more extensive on the right, the side on which the

TABLE 1.—SUMMARY OF CASES REPORTED WITH EMPHASIS ON VISUAL FIELD AND PUPILARY CHANGES

No.	Side of clot	Visual field change	Pupillary changes	Mortality
1	Left	Right homonymous	Right > Left	Recovered
2	Right	Left homonymous	Right > Left	Recovered
3	Left	Right homonymous	Left > Right	Recovered
4	Central	Left homonymous	Left = Right	Dead
5	Right	Left homonymous	Right > Left	Recovered
6	Left	Left homonymous	Right > Left	Recovered
7	Right	Left homonymous	Right > Left	Dead

From the Department of Surgery and the Laboratory of Neuropathology, Cincinnati General Hospital, University of Cincinnati.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 7, 1941.

Fig 1 Shows progressive improvement in left homonymous hemianopia 2 weeks 1, and 2 months after removal of a right subdural hematoma. Because of poor co-operation the fields are not entirely congruous.

hematoma had been found at operation. In neither case was there evidence of actual thrombosis or complete occlusion of the posterior cerebral arteries.

The mechanism of the tentorial pressure cone or uncus herniation is no new concept. The manner in which this change may produce various types of false localizing signs has been discussed by Jefferson, by Kernohan and Woltman, and by Moore and Stern. More recently Schwarz and Rosner as well as Allison and Morison have published complete reviews of the pathological mechanism of embarrasment of circulation in the posterior cerebral artery with tentorial herniation. Reid and Cone were able to produce experimentally certain parts of the tentorial pressure cone syndrome more particularly the pupillary changes. However, it is interesting to note in reviewing the cases reported by these various authors that none mentioned uncus herniation accompanying subdural hematomas. It also would appear that little has been

written about the reversibility of the changes that may occur. We believe that the visual field changes found in this series of subdural hematomas were most probably caused by embarrasment of the circulation in the posterior cerebral artery. Pressure from a herniated hippocampal uncus brought about slowing of the circulation and resulting anoxia in the occipital distribution of the posterior cerebral artery. It is fair to postulate that this change may be of any degree ranging from slight anoxia with transient functional impairment, through anoxia of such severe degree as to cause permanent functional impairment based on profound structural change, a mechanism discussed by Evans and McEachern. This supposition seems to fit the clinical and pathological facts found in this group of cases. It seems probable that in the patients that survived without residuals the factors causing the homonymous defect were mild and reversible. The patient who was followed for 2 months but still showed

slight visual field defects represented more severe tissue damage. Finally the cases which came to postmortem examination represented examples of gross irreversible cerebral softening.

SUMMARY AND CONCLUSIONS

In reviewing a series of 62 subdural hematomas, 7 cases, 11 per cent, were found to show evidence of visual field defect.

The visual field defect was always homonymous in character. In 5 instances it was contralateral to the clot, one was ipsilateral and in one the field defect was bilateral the subdural clot being centrally placed.

Four patients showed complete recovery without residual visual field defects. In one patient careful checks of the fields were carried out at intervals and gradual improvement was observed.

It is believed that too little stress has been put on the complications caused by uncal herniation in cases of subdural hematoma. Moreover it is felt that the visual field changes discussed in this report were caused by tentorial herniation and embarrassment of the circulation through the posterior cerebral artery.

There seems to be good evidence that these changes may frequently be reversible.

Efforts should always be made to determine the presence or absence of visual field defects in patients suspected of having subdural hematomas. In this small series the visual field changes were twice as reliable as pupillary changes in attempting to lateralize the subdural clot. Like other clinical signs that may indicate uncal herniation visual field changes should emphasize the importance of immediate surgical intervention in order to remove the cause of the herniation. The demonstration herewith of the apparent reversibility of the process emphasizes the importance of early effective removal of the source of the herniation.

THE PROTECTION OF THE OPERATIVE FIELD WITH AN IMPERMEABLE ADHESIVE SKIN COATING

A Preliminary Report

MICHAEL De BAKEY, M D, F A C S, E J GILES, M D, and EDITH HONOLD, M S,
New Orleans, Louisiana

ANTISEPSIS in surgery is usually considered to have had its origin with Lister's presentation of carbolic acid as a combatant against postoperative infections. In one of his earliest communications he stated "when it had been shown by the researches of Pasteur that the septic property of the atmosphere depended on minute organisms suspended in it it occurred to me that decomposition in the injured part might be avoided by applying as a dressing some material capable of destroying the life of the floating particles" (18). Using his antiseptic methods in his wards at Glasgow, during the 3 year period ending in 1870, Lister succeeded in reducing the mortality rate in amputations from 45.7 per cent to 15 per cent (19). Since Lister's epochal contribution, asepsis in surgery has become a constant and eagerly sought desideratum. It is now generally realized that infection at operations may arise from several possible sources of contamination: (1) upper respiratory tract, hands, hair, skin, and clothing of the operating personnel, and all individuals entering the operating room, (2) the air of the operating room, (3) the instruments and paraphernalia employed in the operation, and (4) the skin of the patient.

Various attempts have been made to control these sources of contamination, the efficacy of which is dependent to a great extent upon the degree of exactitude in application. In 1928, Sutton quoted the statistics of several authors in which the percentages of postoperative infections ranged from 28 per cent to 6 per cent. A review of more recent articles reveals a decrease in the percentages of infection after clean surgical operations, with an average of approximately 3 to 5 per cent (4, 7, 9, 10, 13-15, 26, 27). Beck, in 1936, stated that the incidence of serious infections in clean surgical wounds has been lowered to 1 per cent and of trivial infections to 5.4 per cent. Of the previously mentioned sources of infection which may be present at operation perhaps the most difficult to control with absolute assurance is the skin of the patient. Hirschfeld stated that the normal skin rarely harbors fewer than 10,000 organisms per square centimeter. The general opinion prevails that no antiseptic yet introduced nor technique yet devised completely sterilizes the skin. "Of the many sources of wound infection, all, with the single exception of the skin of the operative field, are under the control of the surgeon if he operates with competent help and in proper surroundings" (39). This is clearly demonstrated by the numerous attempts to develop a method which will produce relative sterilization of the skin of the operative field. Even a cursory perusal of the literature will reveal numerous compounds and solutions which have been offered as antiseptics (1, 2, 5, 6, 10, 13, 17, 21-42). A random selection of reported incidences of sterility following the use of four widely employed antiseptics are as follows: mercuriochrome, 95.4 per cent, tincture of iodine, 71.7 per cent, mercurochrome, 34 per cent, metaphen 91.1 per cent, and several others grouped together, 65 per cent (5, 16, 24, 28, 34, 36, 38, 41, 42). Each antiseptic has its advocates who make glowing claims for its value and its opponents who caution against its uncritical use or condemn it entirely. Allen and associates ob-

served that the morbidity rates are not widely divergent even though there are clinical differences between the various antiseptics. Hirschfeld stated that in spite of the different pre-operative preparations, the incidence of wound infection in different clinics varies slightly. Almost as numerous as the antiseptics themselves are the various *in vitro* and *in vivo* experimental tests which have been performed to evaluate the effectiveness of these substances (5 8 13, 21 22 24, 28-30 32 33 36 38 40 41). It is fairly well agreed that antiseptics showing excellent *in vitro* tests may not be at all satisfactory in actual clinical use. Likewise, *in vitro* laboratory ratings may not give an accurate index of the quality of the antiseptic, for as Bass points out, organisms added to the skin are more easily killed than the "basal flora."

Price (31) has shown that there are two types of bacterial flora on the skin: (1) the *transient* flora which is loosely attached and can be removed in a few minutes of scrubbing and (2) the *resident* flora which is tightly attached and is difficult to remove. In certain cases the resident flora may include virulent organisms as a result of prolonged exposure to their source. In addition, the bacteria of the deeper layer of the skin are brought to the surface by perspiration, especially during a lengthy operation and may contaminate the wound because the antiseptic applied at the beginning of operation is no longer effective. Therefore this source of contamination is a constant hazard whose threat increases commensurably with the length of the operation. Since the bacteria cannot be completely removed from the skin during the operation their introduction into the wound may be prevented by sealing the operative field with a sterile impermeable surface. Such a surface film has been produced by the use of mercuric bichloride but unfortunately due to perspiration multiplication of bacteria occurs at an increased rate beneath the film (32 33). Consequently any injury to the film allows the escape of the bacteria into the wound.

The current method of preparing the operative field consists of shaving, careful soap and water scrub, defatting application of an antiseptic agent, and draping of the area with

sterile towels. After the incision is made sterile towels are clamped to the edges to protect the wound from possible skin contamination. It is generally realized, however, that this careful preparation of the skin and the clamping of towels around the wound edges are measures of only relative efficiency and that they do not absolutely protect the wound from such contamination.

Obviously if there could be applied to the skin in the region in which the incision is to be made some impermeable substance which is sterile and which would adhere to the skin, the incision could be made through it and absolute protection from skin contamination would be afforded. Such a covering which would be most efficient should possess the following properties: (1) impermeability to bacteria (2) bactericidal action (3) non-irritancy (4) transparency (5) adhesiveness to skin (6) elasticity and (7) facile incisibility.

Because it fulfilled all these conditions except the first three, vinylite resin¹ was tested for the possibility of fulfilling the other requirements. This resin is a polymerized vinylite acetate which is soluble in practically all common solvents with the exception of water, gasoline and the higher alcohols. It is colorless, odorless, nontoxic, and it resists dilute salt, acid, and alkali solutions. It is widely used as an adhesive for a variety of materials and is an excellent adherent to practically all types of surfaces. It absorbs water and becomes leathery and pliable when large amounts are absorbed (43).

Several preliminary tests were tried in the laboratory before clinical application was begun. Solutions of the resin were made in different percentages to determine the formula which gave a satisfactory coating and which dried most rapidly. On the basis of these studies, the following formula was adopted:

- 5 grams vinylite resin, AYAF
- 50 cc acetone
- 3 grams nitrocellulose (to hasten drying)

This solution of vinylite resin was applied to the skin of volunteers and allowed to remain intact from 24 hours to over a week. Its

¹This material was supplied through the courtesy of Dr. A. C. Coe, of the Carbide and Carbon Chemical Corporation.

adhesiveness was definitely demonstrated and on peeling off the transparent resin, the skin beneath was dry and unaffected even at the end of a week. Skin irritation was never observed. Fifteen sterility tests were made. One-half cubic centimeter of resin was inoculated into tubes of meat digest broth and incubated aerobically and anaerobically for 4 days at 37 degrees C. At the end of this period, none of the tubes was sufficiently cloudy to justify the notation of positive growth. Therefore, all tubes were streaked on blood agar plates and incubated aerobically and anaerobically for 24 hours at 37 degrees C. Of the 30 plates, only one showed a growth of nonhemolytic *Staphylococcus albus*. An attempt was made to determine the bactericidal power of the solvent, acetone. Increasing dilutions of acetone were made with sterile broth, and these tubes were inoculated separately with *staphylococcus*, *streptococcus*, and *Bacillus coli*. At the end of 24 hours incubation at 37 degrees C, the tubes were replated and failed to show growth on the 1:1 dilution. Dilutions of 1:5 or higher had little or no bacteriostatic effect. Tubes of the prepared resin were inoculated separately with the same 3 organisms and transplants were made to tubes of meat digest broth and blood agar plates at the end of 8 minutes, 15 minutes, and 30 minutes. All tubes were negative and only one colony of *staphylococcus* grew on the plate made at the end of the 8 minute period. Since the real test of the compound is its usefulness clinically, the vinylite resin solution was tried on a series of cases. For this purpose, 1 per cent phenol was added to the formula to enhance its bactericidal powers. It was determined that this produced no changes in the chemical and physical properties of the resin as described above. This vinylite resin solution was used in 30 clean surgical cases. The usual ward preoperative preparation of shaving and soap and water scrub was performed. In the operating room, the area was scrubbed with ether, and painted with vinylite resin by means of a soft rubber applicator, and draped with sterile sheets to limit the operative field. When the sterile drapes were thus applied over the vinylite resin before drying had occurred the sheets would adhere closely to the skin at the borders of the operative field and towel clamps for the purpose of holding the sheets in place are obviated. This is particularly advantageous in areas having curved and irregular surfaces, such as in breast or thyroid operations. When the solution was applied in proper thickness, drying was complete within 5 minutes. The length of time and the type of each operation were noted. Most of the operations consisted of appendectomies, thyroidectomies, cholecystectomies, herniorrhaphies, and phrenectomies, and the duration of the procedures averaged 46 minutes. In each case, 6 groups of bacteriologic studies, depending upon the site of swab cultures, were made as follows: (1) solution of vinylite resin, (2) the skin of the operative field immediately after the patient's entrance into the operating room, (3) skin surface after ether scrub, (4) skin edge immediately before incision, (5) skin edge immediately before closure of incision, and (6) skin surface approximately 3 inches from the wound after the resin was stripped back and before the application of the dressings. The cultures were sent to the laboratory where each was streaked out on two blood agar plates and inoculated into two tubes of meat digest broth, one of each was incubated anaerobically and the other aerobically for 48 hours. At the end of this period, the plates were examined for growth, and the tubes were replated and incubated aerobically and anaerobically for a period of 24 hours.

The results of these bacteriological studies may be briefly summarized as follows:

Group 1. In 27 cases, the bacteriological studies on the solution of vinylite resin immediately before its application to the operative field showed no growth.

Group 2. In 30 cases the bacteriological studies made on the skin of the operative field before it was prepared except by shaving and washing with soap and water showed 100 per cent growth. *Staphylococcus* was recovered most frequently, which is comparable to other reports (11, 12, 14, 15, 26).

Group 3. In 30 cases, these studies on the skin of the operative field immediately after it was prepared by ether scrub showed the presence of growth in 11 (36.6 per cent) cases.

Graph Graphic representation of incidence of postoperative growth in bacteriological studies on the use of vinylite resin

Group 4. In 30 cases, the bacteriological studies of the skin edge immediately after the skin incision was made showed the presence of organisms in 5 cases or 16.6 per cent. Of these 5 cases 4 were positive in group 3 and showed organisms with similar bacteriological properties.

Group 5. In 30 cases, these studies made on the skin edge at the completion of the operation and before the skin edges were closed showed the presence of organisms in 8 cases or 26.6 per cent. Of these 8 cases only 1 was also positive in groups 3 and 4, and 3 were also positive in group 3 alone.

Group 6. In 28 cases, bacteriological studies made immediately after the completion of the operation on the skin surface in the operative field under the vinylite resin showed the presence of organisms in 3 cases or 10.7 per cent.

EVALUATION

Whereas it is recognized that the results of these bacteriological studies are based upon too few cases to be of conclusive significance they were considered of sufficient interest to be presented as a preliminary report. Moreover it should be realized that these bacteriological studies were done with the purpose of determining whether vinylite resin solution would fulfill the desiderata previously considered in the ideal preparation of the skin of the operative field. The clinical application of this method of skin preparation clearly demonstrated that it fulfilled the requirements of transparency, adhesiveness to the skin, elasticity, ready incisibility and non

irritancy. The significance of these requisites of such a skin preparation is clearly apparent. Transparency is desirable because it permits the surgeon to place the incision accurately according to the landmarks which may be clearly seen. The significance of adhesiveness to the skin lies in the fact that unless the impermeable film adheres closely and tenaciously to the skin there is the possibility that during the operative procedure perspiration containing organisms which have escaped from skin pores may readily seep beneath the film toward the edge of the incision. This is likely to be enhanced further by retraction and manipulation during the operative procedure. For this reason, the film must possess an elastic quality somewhat comparable to the skin to which it adheres. It was found that the vinylite resin film was readily elastic and simultaneously stretched with the skin and remained definitely adherent to it as the wound was retracted and manipulated. In fact it was observed that this adhesive and elastic quality remained present for several days after the operation. Moreover skin irritation was never observed in any of the cases even after the film had been allowed to remain in contact with the skin for as long as one week. In a few cases the vinylite resin solution was applied to the irritated skin surrounding an enterostomy opening and it was found to have a definitely protective and beneficial effect. Obviously this is another purpose for which it may be used to great advantage.

The results of the bacteriological studies clearly demonstrated its bactericidal activity. Bacterial growth was obtained in none of the 27 cases in which these studies were made on the solution itself (Graph 1). This is particularly significant in view of the fact that no special attempt was made to sterilize the solution. Moreover the solution was readily exposed to contamination since the rubber applicator was repeatedly dipped into the solution after it had been applied to the skin of consecutive patients.

The fact that bacteriological growth was obtained from the skin of the operative field in all of the cases after it had been prepared by shaving and washing with soap and water is to be expected and conforms with similar

previous studies (8, 22, 24, 31) It merely emphasizes further the importance of preparing the skin of the operative field Of particular interest is the fact that bacterial growth was obtained from the skin after ether scrub in 36.6 per cent This would seem to indicate that ether has a sterilizing ability of over 60 per cent, but this is not in accord with other studies (20, 32, 34, 36) Price (32) has expressed the opinion that ether is valueless as a sterilizing agent of the skin However, its detergent qualities are generally recognized and for this reason it is considered of definite value in the preparation of the operative field Perhaps the unusually low incidence of bacterial growth after ether scrub in this series may be explained by the fact that this was performed with especial vigor and thorough care, 8 or 9 separate scrubbings being used In our opinion this is significant and demonstrates the value of such careful mechanical cleansing

The results of the bacteriological studies of the skin incision edges immediately after the incision was made and following the completion of the operation immediately before the incision was closed are also of interest The fact that bacterial growth was obtained in only 16.6 per cent of the cases in the former instance and that this incidence had risen only 10 per cent in the latter would seem to indicate the effectiveness of this method of preparation Somewhat comparable studies were made by Maddock and Georg (22), who found an average incidence of contamination (with the use of mercuric iodine, merthiolate, and 2 per cent iodine-and-50 per cent propanol) of 37 per cent at the beginning of the operation and 60 per cent at the end of the operation and increase of 23 per cent Certainly if consideration is given other factors which may act as sources of contamination in increasing this incidence such as the air of the operating room and the manipulation of the wound with consequent squeezing out of bacteria at the skin edges the possibility that the skin of the operative field as a source of contamination in increasing this incidence would seem to have been reduced considerably This would indicate further that the vinylite resin film is

effective as regards impermeability This is also supported by the fact that all of the wounds healed by primary union and in none was there any evidence of even trivial infection

Perhaps one of the most significant findings in this connection is the fact that at the completion of the operation, bacterial growth was obtained from the skin of the operative field after peeling off the vinylite resin film in only 10.7 per cent of the cases It must be admitted that this was an unexpected observation Certainly if bacterial growth was obtained from this skin in 36.6 per cent of the cases before the film was applied, one would expect a higher incidence three-quarters of an hour later during which the factors of perspiration and manipulation of the skin with consequent escape of organisms may have been operative The explanation for this unexpected decrease in bacterial growth probably lies in the observation that the skin was absolutely dry when the vinylite resin film was peeled away This may be due to the operation of several factors, the significance of which can be only speculative Perhaps the vinylite resin produces a local inhibitive influence on perspiration or it may have an absorptive action Whatever the explanation may be, of practical importance is the fact that it has a desirable and bacteriostatic effect

SUMMARY

- 1 A brief discussion is presented of the importance of a sterile operative field Two types of bacterial flora are present on the skin (1) the transient which is easily removed by a few minutes scrubbing, and (2) the resident which is very difficult to remove
- 2 An ideal covering for the operative field should possess the following qualities (1) impermeability to bacteria, (2) bactericidal action, (3) nonirritancy, (4) transparency, (5) adhesiveness to skin, (6) elasticity, and (7) facile incisability
- 3 Vinylite resin fulfilled the requirements in laboratory tests, and was employed successfully in 30 clean surgical cases
- 4 Further studies are being carried out at the present time to substantiate its value for this purpose

PERITONEOSCOPY

New Applications and a New Supplementary Instrument

JOSEPH E HAMILTON, M D, F A C S, Louisville, Kentucky

THE peritoneoscope, devised for visualizing the abdominal cavity and its viscera, is similar to the foreoblique cystoscope except that it is larger and uses an air medium, whereas the cystoscope uses water. After preliminary pneumoperitoneum, the sheath and trocar tip are introduced into the abdominal cavity through a small stab wound. The trocar is then removed, the peritoneoscope inserted and an examination made. Biopsies can be taken with a special forceps which carries a small observation telescope. A detailed description of peritoneoscopic technique has been made by Ruddock (9, 10) who, in 1934, devised the instrument now most widely used. This author's last 750 cases without a single mortality testify to the safety of the procedure. Carried out as it is under local anesthesia, it is, furthermore, a minimal operation. As a rule, the patient may be up and around 8 hours after an examination, or the following day if a biopsy has been taken.

I wish to describe a new instrument for assisting peritoneoscopy and to present from my series of 125 cases several new or little exploited applications of peritoneoscopy.

THE NEW INSTRUMENT¹

The new instrument consists of a blunt tipped rod or "manipulator" and an insulated endothermy electrode, both of which fit into the sheath of a small paracentesis trocar through an airtight rubber nipple (Fig 1).

From the Department of Surgery University of Louisville School of Medicine and Louisville City Hospital.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941.

¹This instrument was presented both in an exhibit and in a moving picture at the meeting of the Southern Medical Association in Louisville, November 15-19 1940. The diathermy electrode was added 3 or 4 months later. Two other authors in recent publications have independently described instruments auxiliary to peritoneoscopy. Robinson and Fisk use an instrument similar in principle to our own and Lamb described a transparent bladder that can be inflated around the peritoneoscope, thus pushing viscera aside.

When needed, the trocar and sheath are introduced through a tiny separate stab wound. Under peritoneoscopic view, the trocar is removed and the manipulating rod or electrode is inserted. The electrode is capable of dividing adhesions, opening benign cysts, etc. With the rod, obstructions to peritoneoscopic vision are pushed aside or hidden structures lifted into view (Fig 2). The liver and gall bladder, usually accessible to the peritoneoscope, may either one or both become obscured by adhesions or loops of bowel. These obstructions can be gently pushed one way or another to allow adequate visualization. When overlapping, the edge of the liver can be lifted up to disclose the gall bladder, hidden between it and the colon. The spleen, not often seen by the unaided scope, unless greatly enlarged, can usually be manipulated into view. The appendix almost always hidden by loops of ileum or by the cecum, is easily lifted up for inspection by the rod. In the pelvis, tubes and ovaries are sometimes partly or completely hidden by their prolapsed position, but the tip of the instrument hooked under the round ligament will pull them up into plain view. Sigmoid, cecum, and colon can be pushed about to secure the best visualization.

We have so far used the auxiliary instrument 31 times. There have been no accidents and the results have been gratifying.

NEW APPLICATIONS OF PERITONEOSCOPY

Knowing the potentialities of the peritoneoscope and accessory instrument, the trained peritoneoscopist will come to adapt it to a widening variety of diagnostic and therapeutic problems outside its recognized routine. The following are examples.

Gunshot and stab wounds of the abdomen of doubtful penetration. Heretofore, surgical exploration has been the accepted means of ruling in or out perforation of the parietal

Fig. 1. The new instrument consisting of small trocar and sheath, manipulating rod, carrying the airtight rubber nipple and the insulated endothermy electrode and cord.

peritoneum. Peritoneoscopy will give the same information, for by probing the debrided entry wound with a hemostat the suspected area of peritoneum is tented inward for inspection through the peritoneoscope (4).

Prior to our use of the peritoneoscope in these cases, 12 per cent of all surgical explorations of abdominal bullet and knife wounds at the Louisville City Hospital revealed no penetration and hence were unnecessary. Furthermore, well over 90 per cent of these wounds were so located that their penetration or nonpenetration could be reliably determined by means of the peritoneoscope. So far peritoneoscopy was done in 16 patients with such injuries. In 7 of these penetration was found, thereby indicating immediate laparotomy. The other 9 patients were spared a laparotomy by visualizing an intact parietal peritoneum beneath the entry wound.

Differentiating between appendicitis and salpingitis and between appendicitis and cholecystitis. All are familiar with the occasional female patient who is suspected of having salpingitis but upon whom an exploratory operation is performed to rule out an acute appendicitis. In these cases it is our practice first to inspect the adnexae. If they cannot be visualized by the unaided peritoneoscope they are easily hooked up for inspection by the manipulator. If salpingitis is found for confirmation the appendix is lifted up on the rod and examined for abnormality. If the

Fig. 2. The manipulating rod in use.

tubes are normal and the appendix appears suspicious, laparotomy is performed.

So far we have used the peritoneoscope in this differential problem 5 times with complete success and with no untoward results. Three times a diagnosis of salpingitis was made and laparotomy avoided, and once the diagnosis of appendicitis was made and verified at operation. Once early appendiceal peritonitis was unexpectedly discovered. The patient was treated conservatively by the Ochsner regimen and made an uneventful recovery. Interval appendectomy 5 months later confirmed the previous diagnosis and revealed normal adnexae.

Rarely a differential problem arises between acute cholecystitis and acute appendicitis. This was exemplified recently on our wards by a 22 year old negro male. Symptoms and signs pointed chiefly to early acute cholecystitis, but an inflamed high lying appendix could not be ruled out. Peritoneoscopy was performed and by this means a distended, injected gall bladder was visualized. Pressure against it through the abdominal wall caused pain. The appendix was then lifted up by the manipulator and found to be normal. The patient's symptoms subsided satisfactorily on a conservative regimen.

Lysis of adhesions and rupture of ovarian cysts

Benedict and others have aspirated ovarian cysts under peritoneoscopic guidance. The only case we could find of peritoneoscopic lysis of intra-abdominal adhesions was reported by Jones in which he divided bands between liver and diaphragm to allow more complete pneumothorax. Since devising the insulated endotherm electrode a year ago, we have encountered only 1 patient suffering from genuine painful adhesions. This was a 44 year old negroess with persistent sticking pain beneath the right breast of almost incapacitating severity. Roentgen studies of the chest, gall bladder, and gastrointestinal tract were negative. Peritoneoscopy revealed a normal gall bladder, old pelvic inflammatory disease, and Curtis' "violin string" adhesions between the liver and the anterior abdominal wall and diaphragm. Tugging on these externally reproduced the sticking pain. The adhesions were divided with the cutting current under peritoneoscopic guidance and after 6 months the pain has practically gone and the patient has returned to work.

On 2 occasions we undertook to rupture follicular cysts of the ovary in young women with severe menorrhagia who had not responded to hormone therapy. The purpose was to remove, if possible, the stimulus for the excessive flow. In 1 patient examined before we had devised our manipulating rod, we were unable properly to visualize the ovaries. At laparotomy subsequently a cyst of the right ovary was found. In the second patient a follicular cyst of the left ovary was found and punctured with the escape of about 2 ounces of straw colored fluid. For 6 months the patient's excessive flow gave place to occasional scant bleeding or spotting and the endometrial biopsy changed from hyperplasia to anovulatory hypoplasia. The patient was so well pleased that when flooding recommenced, she requested another peritoneoscopy. However, the second examination revealed only small sclerosed ovaries and no sign of the previous cyst. The patient is now being given a trial of lactogenic hormone before surgery is resorted to.

Nonpenetrating abdominal trauma when internal injury is suspected Ruddock (10) and

Fry both recommend endoscopy. Nevertheless, we feel that the findings in cases of nonpenetrating abdominal trauma when internal injury is suspected must be interpreted with caution. Peritoneoscopy can safely rule in or out rupture of spleen or liver. However, although the discovery of laceration of bowel or stomach would constitute a clear-cut indication for surgery, the failure to find hollow visceral injury by the peritoneoscope would by no means rule it out.

Peritoneoscopy was performed in the case of 1 boy whose abdominal findings were only mildly suggestive of intraperitoneal hemorrhage following a bicycle accident. The discovery of moderate hemoperitoneum decided us upon surgery. At operation 2 lacerations in the right lobe of the liver were found and repaired. The boy made an uneventful recovery.

Differentiation between bleeding peptic ulcer and ruptured esophageal varix About 2 years ago we had the embarrassing experience, upon operating for massively bleeding peptic ulcer, of finding instead a typical hobnail cirrhotic liver and, indirectly, bleeding esophageal varices. A few months later we met with a somewhat similar case. This time, though ruptured varix seemed more likely, there were no ascites and bleeding ulcer could not be ruled out. A peritoneoscopic examination was gently performed, revealing a typically cirrhotic liver and thereby removing any question of surgery. It seems that this procedure is less likely to restart or to aggravate bleeding and is more certain in diagnosis than the alternative barium swallow proposed by Schatzki.

SUMMARY AND CONCLUSIONS

We have presented a new instrument to assist peritoneoscopy and have described a few new applications of the procedure to surgical problems with the same purpose in each case, that of avoiding laparotomy.

A number of authors (1, 8) warn against peritoneoscopy in cases of suspected penetrating abdominal injuries and the vast majority give as a contraindication any suspected acute inflammatory condition, such as acute appendicitis or salpingitis. However, in those cases in which exploratory laparotomy is the

only alternative method of deciding whether or not surgery is indicated and in which peritoneoscopy is equally capable of making that decision. I urge that peritoneoscopy be chosen on the grounds that it is much the lesser and safer procedure seldom incapacitating the patient for more than 24 hours.

Incidentally 3 of our 4 accidents (bile fistula from liver biopsy in a case of obstructive jaundice moderate hemorrhage following splenic biopsy in a case of monocytic leucemia, and perforation of ileum in a far advanced case of fibrocaceous tuberculous peritonitis) occurred in generally accepted and what we might term medical applications of peritoneoscopy. The only untoward result among

the surgical uses of the instrument was a mild pneumothorax caused in a patient with gunshot wound of the abdomen in which the bullet also penetrated the diaphragm.

positive tests for protein. Solutions containing 1 milligram per cubic centimeter are opalescent and milk like. The results of elementary analysis and fractionation given in a succeeding paragraph show the material to be nucleoprotein containing possibly a very small amount of fat.

HOMOGENEITY AND PHYSICAL STATE OF THE PROTEIN

The problem for first consideration has been the determination of the degree of the purity and homogeneity of the isolated protein in order to establish a basis for evaluating the results of analyses on constitution and behavior. Recent advances in the study of proteins have provided a number of physical tests suitable for application to this problem. Those used singly or in combination have been studies on (a) homogeneity with respect to rate of sedimentation in the analytical ultracentrifuge (b) homogeneity of electric charge density as measured by the reversible spread of the moving boundary in the Tiselius electrophoresis apparatus (c) the rate and manner of diffusion and (d) the viscosity of the purified protein solutions.

Sedimentation velocity studies in the analytical ultracentrifuge give information based chiefly on particle shape, size and mass. Such studies were made in parallel with development of the procedures of isolation. Examination of solutions of pellets obtained in the initial sedimentation in the quantity ultracentrifuge revealed the presence of an ultraviolet light absorbing material with a sedimentation constant of about $S_{20} = \text{ca. } 250 \times 10^{-13} \text{ cm. sec.}^{-1} \text{ dynes}^{-1}$ (1). In such a preparation the sedimenting boundary was not entirely sharp and there was seen also some of the usual tissue protein of molecular size so small that no sedimentation of it occurred in the ultracentrifugal field employed in the study. After 3 to 5 cycles of low and high speed spinning however there could be seen only the specific material all light tissue protein and very heavy insoluble colloidal material having been eliminated. With such a product the sedimenting boundary was very sharp and from studies of many samples, the sedimentation constant was $S_{20} = 278 \times 10^{-13} \text{ cm.}$

$\text{sec.}^{-1} \text{ dynes}^{-1}$ (8). The sharpness of boundary and freedom of products other than those associated with the specific boundary demonstrate a very high degree of homogeneity of the purified material with respect to this method of study. The examination of other substances by this method has shown that such a degree of homogeneity has been evident only with solutions of a single molecular species. These results, together with the high sedimentation constant, indicate the purified material to be a high molecular weight protein.

Further information of the physical nature and state can be obtained by examination in the Tiselius apparatus. For this purpose solutions containing 2.7 to 4.5 milligrams purified protein per cubic centimeter were studied (11). In the pH region from 3.78 to 7.7 the range in which the material is stable (2). In periods of 5½ to 23 hours, the protein particles migrated with a single very sharp boundary. The symmetry and singleness of boundary and its sharpness or lack of spread revealed a degree of electrophoretic homogeneity which has been seen only with solutions of a few highly purified proteins. These results indicate a remarkable similarity in electrical properties amongst the individual protein particles and thus provide a second and strong indication for the molecular state of the protein.

Evidence for the monodispersity of the protein has been seen in diffusion experiments. The rate of diffusion is a function of the size and shape of the protein particles. The shape of the diffusion curves is dependent on the degree of homogeneity. The experimental curves (8) observed here were of the shape of a gaussian normal error curve, revealing an ideal diffusion behavior and thus high uniformity in the size and shape of the particles. The observed low diffusion constant, $D_{20} = 6.65 \times 10^{-8}$ was again indicative of large molecular size.

The relative viscosity of a protein solution is a function of particle shape and practically independent of particle size. Studies on solutions of the purified protein showed that the relative viscosity was a linear function of protein concentration. This result is indicative only of normal flow and above is not an index of the state of dispersion. On the other hand,

the shape factor evaluated from viscosity data agreed with that calculated independently from the sedimentation and diffusion data. In the face of this agreement, the viscosity results can be considered additional evidence of homogeneity.

The results of sedimentation, electrophoresis, and diffusion experiments furnished evidence of a degree of monodispersity of the purified protein equal to that of the most homogeneous proteins studied. From a combination of diffusion with sedimentation and viscosity data, the shape of the molecule is seen to be that of an oblate ellipsoid with an axial ratio of 1:1 if hydration is neglected. The density of the material is 1.323, which together with sedimentation and diffusion data gives a value of 47,100,000 for the molecular weight.

RELATION OF THE PROTEIN TO THE PAPILLOMA VIRUS

These investigations have served, within the limits of the methods, to demonstrate the high state of purity of the isolated product and its existence in the molecular state. These tests are based on physical and chemical properties of the protein and serve to show that only one material is present. The problem now becomes that of determining the relation between this purified protein and the virus. The causative agent of the growth is recognizable only by its biological behavior, and a correlation of the properties of the protein with those of the virus can be accomplished solely through biological response in animal experiments. Because of the recognized variation in animal work, the results of biological tests cannot be employed as estimates of physical and chemical homogeneity but can be utilized for judgment of uniformity of behavior. Any correlation of the properties of the protein with those of the virus is dependent finally on the limits of the biological method employed.

The chief biological property of the virus is infectivity or the capacity to induce lesions in the form of warts. It has consistently been found that infectivity is associated with the protein. In numerous experiments, the yield of purified material has been roughly propor-

tional to the infectiousness of the wart extracts from which it was derived. This is strikingly emphasized in comparing results of ultracentrifuging cottontail rabbit warts with those of similar procedures on domestic rabbit growths. Naturally occurring warts from most cottontail rabbits are usually highly infectious. On the other hand, infectivity is rarely seen with extracts of domestic rabbit growths. Despite ultracentrifugation of many liters of extracts of domestic rabbit growths, no high molecular weight protein has been seen.

For studies on specific infectiousness associated with the purified protein, a special method has been developed (3) for its measurement with a relatively high degree of expected accuracy. Employing nitrogen content as an index of protein quantity, there has been found a linear relationship between the logarithm of protein amount and the incubation period in days of warts induced with it. With this procedure, many samples of the protein have been found highly uniform in their degree of infectivity. The infectious unit of protein, in terms of that quantity of it required to produce lesions at 50 per cent of the spots inoculated, is $10^{-8.305}$ grams (4). As a routine procedure, the volume of inocula has been 0.1 cubic centimeter of protein solution. From the molecular weight it has been calculated that this infectious unit is comprised of an average of 56,800,000 molecules in 0.1 cubic centimeter of inoculum. The uniformity of behavior is shown in the results seen with several different batches of material which have given infectious units of $10^{-8.355}$, $10^{-8.285}$, $10^{-8.3}$, and $10^{-8.308}$ grams. These findings, as determinations of virus infectivity, are in exceedingly close agreement. Another biological method used was complement fixation which gave results (6) of uniformity paralleling those with infectivity. Perhaps the most satisfying demonstration of uniformity is the quantitative nature of the serum-protein relations in the neutralization reaction (5). The constancy of the results is such that the reaction can be expressed mathematically with high accuracy.

Further evidence is available of close relationship between the protein and the papil-

loma virus. This is especially illustrated in parallel studies (2) on molecular stability of the protein and virus infectivity with respect to hydrogen ion concentration. Molecular stability is at a maximum between pH 2.9 and 10. This is likewise the region of maximum stability of virus infectivity. In solutions more acid than pH 2.9, the molecules disintegrate, as shown by analytical ultracentrifugation and here infectivity is lost immediately. In the alkaline range however infectivity is immediately lost at pH 10 where as molecular disintegration begins quickly only at pH 10.2 or above. The isoelectric point of the protein is at pH 5.0 where the protein is insoluble. Here the protein precipitates, and with it are carried the infectious qualities of the solution.

The foregoing results serve to establish with reasonable certainty the identity of the purified papilloma protein and the papilloma virus. The experimental findings thus can be interpreted as describing the properties of this infectious agent. Elementary analyses (1) have shown the virus protein to contain carbon, 49.6 hydrogen 7.2 phosphorus, 0.04 nitrogen 15.0 and sulfur 0.22 per cent. There is present 6.45 per cent carbohydrate. The possibility of fat as a conjugated constituent is still not entirely clear. Early fractionation with small amounts of material gave 3.2 per cent lipid. More recent investigation (18) has indicated a value of 1.49 per cent. Fractionation (18) has revealed the presence of nucleic acid to the extent of about 8.0 per cent. The nucleic acid is definitely of the thymus type there being no detectable trace of ribose or yeast nucleic acid.

EVALUATION OF STUDY

In the experiments described, a specific material exhibiting the biological characters of the rabbit papilloma virus has been isolated from infectious extracts of growths from cottontail rabbits. This component of the growths fulfills the criteria of a homogeneous macromolecular nucleoprotein which may or may not contain a small quantity of conjugated fat. The evidence thus far obtained indicates that this macromolecular material is the papilloma virus.

For present interpretations, the results of these investigations of the causative agent of the rabbit papilloma are best considered in comparison with the findings on other filterable viruses rather than other tumor agents. During the past few years, much attention has been given to studies on the isolation and properties of viruses, both those causing disease in plants and those pathogenic to animals. In 1935 Stanley (15) announced the isolation of a high molecular weight protein from plants diseased with tobacco mosaic virus. This material obtained by classical methods of chemical fractionation is crystalline, and its identity with the virus of tobacco mosaic disease has been well established. Subsequently with access to the newly developed air-driven ultracentrifuge numerous other plant virus proteins (16) have been isolated, and all thus far studied possess properties ascribable to entities existing in the molecular state rather than those to be expected of individuals classed as bacteria. Similar studies in the field of animal viruses have proceeded much more slowly. It has been possible to concentrate and to purify to a considerable degree a number of these agents. Only a few have been procured in amounts and in a state suitable for study namely the elementary bodies of vaccinia (7) the rabbit papilloma virus and the agent of equine encephalomyelitis (12). The criteria for judging the nature of these 3 viruses, however, are not applicable to the same extent for each of the three. Chemical analyses of vaccinia elementary bodies have given fairly uniform results. Microscopic examination has been employed for interpretation of homogeneity of purified preparations, but the findings can hardly be considered quantitative and further provide no indication of the nature of the bodies. Numerous studies have been made on the bodies in the analytical ultracentrifuge and those workers (14) having the widest experience have reported spread in the sedimenting boundaries indicating lack of uniformity in particle size. The elementary bodies are not of a nature suitable for electrophoresis studies by the moving boundary method (14) and other tests have not been applied. The results as reported cannot be employed to place the

elementary bodies definitely in either the category of molecular or that of bacterial entities. Considerably better evidence is at hand of the nature of the equine encephalomyelitis virus. Sedimentation diagrams (17) of the purified material show the sharp boundary of molecular substances. None of the data thus far obtained are incompatible with the view that this virus also is molecular.

In striking contrast to the findings with these other animal viruses are those with the papilloma virus protein. Here many of the rigid criteria of the physical state of proteins in general are applicable, and in all instances the results have consistently demonstrated the homogeneity and the molecular nature of the protein. The papilloma protein is thus at least one animal virus which can be grouped with assurance with the macromolecular plant virus nucleoproteins.

SUMMARY

The isolation and properties of a specific material from virus-induced cottontail rabbit papillomas have been described. This material, which behaves biologically as the virus responsible for the disease, is a nucleoprotein obtainable in solutions of high homogeneity. Its physical properties with respect to sedimentation, electrophoresis, diffusion, and viscosity are those of a molecular substance.

The values obtained in such studies indicate a molecular weight of 47,100,000. With respect to the physical state, this animal virus falls into the same category as occupied by the macromolecular plant virus nucleoproteins.

Only a few have been procured in amounts and in a state suitable for study namely the elementary bodies of vaccinia (7) the rabbit papilloma virus and the agent of equine encephalomyelitis (12). The criteria for judging the nature of these 3 viruses, however are not applicable to the same extent for each of the three. Chemical analyses of vaccinia elementary bodies have given fairly uniform results. Microscopic examination has been employed for interpretation of homogeneity of purified preparations, but the findings can hardly be considered quantitative and further provide no indication of the nature of the bodies. Numerous studies have been made on the bodies in the analytical ultracentrifuge and those workers (14) having the widest experience have reported spread in the sedimenting boundaries indicating lack of uniformity in particle size. The elementary bodies are not of a nature suitable for electrophoretic studies by the moving boundary method (14) and other tests have not been applied. The results as reported cannot be employed to place the

elementary bodies definitely in either the category of molecular or that of bacterial entities. Considerably better evidence is at hand of the nature of the equine encephalomyelitis virus. Sedimentation diagrams (17) of the purified material show the sharp boundary of molecular substances. None of the data thus far obtained are incompatible with the view that this virus also is molecular.

In striking contrast to the findings with these other animal viruses are those with the papilloma virus protein. Here many of the rigid criteria of the physical state of proteins in general are applicable, and in all instances the results have consistently demonstrated the homogeneity and the molecular nature of the protein. The papilloma protein is thus at least one animal virus which can be grouped with assurance with the macromolecular plant virus nucleoproteins.

SUMMARY

The isolation and properties of a specific material from virus-induced cottontail rabbit papillomas have been described. This material, which behaves biologically as the virus responsible for the disease, is a nucleoprotein obtainable in solutions of high homogeneity. Its physical properties with respect to sedimentation, electrophoresis, diffusion, and viscosity are those of a molecular substance.

The values obtained in such studies indicate a molecular weight of 47,100,000. With respect to the physical state, this animal virus falls into the same category as occupied by the macromolecular plant virus nucleoproteins.

THE GENERAL SURGEON'S APPROACH TO THE PROBLEMS PRESENTED BY FRACTURES AND OTHER TRAUMAS

WALTER ESTELL LEE, M.D. F.A.C.S., Philadelphia, Pennsylvania

PROBABLY many question the need for a discussion of a subject which seems to have been settled for some time by the orthopedists and the patients. In urban, most suburban and even in the rural districts, the patients themselves are consulting the orthopedists directly for the treatment of fractures, thus short circuiting the traditional route via the general practitioner the general surgeon while, for the correction of resulting permanent deformities, the orthopedist has a clear field.

This is a general statement, and the practice varies in different parts of the United States and Canada, but it would seem fair to say that it is only in the older parts of our land. In the regions where one finds the litter of antiques and traditions persisting the general surgeon still has the undisputed privilege of treating fractures. If this is the trend of the times is it right or wrong and if wrong what should or could be done about it by the general surgeon?

Is the specialization of surgery rational necessary, or in the best interests of the patient? I feel sure we are on common ground when claiming that irrespective of our personal interests it will be the welfare of the individual patient which will and should, govern the practice of medicine and surgery in the future.

Some years ago I discussed this subject with Dr. Meeker then dean of the Graduate School of Medicine of the University of Pennsylvania, and from what I have already said you will understand my side of the argument. I was not convincing him by any means, and finally a little heatedly I asked if he would define a specialist. He quickly and positively replied as he usually does, "a specialist is a surgeon or an internist who can and does one

thing well, and does it better than any one else." Again upon my request for his definition of a general surgeon his answer came just as promptly as before—a general surgeon is one who does not do any one thing particularly well.

The passing of time has softened to some extent my immediate resentment so much so that I am offering his definition as a text for our consideration.

You will note that Dr. Meeker said *does not do any one thing particularly well*. But he did not say "cannot." This seems to me to open the way for our discussion.

Is it true that the lay public (for Dr. Meeker is not a doctor of medicine but a doctor of philosophy in biochemistry) agree that general surgeons do not do any one thing particularly well and if so why? Is this attitude toward fractures much different from that which they have toward other specialties including obstetrics and gynecology genitourinary surgery neurosurgery facial maxillary surgery plastic thoracic and one of the latest diseases of the peripheral vascular systems?

In many of the medical schools at the present time all these fields of surgery are being taught by specialists, not by the general surgeons and is it any wonder that the graduate medical student when he becomes a practitioner refers his traumatic surgery, or at least his fractures, to the orthopedist? This being so and if the orthopedist does not give as good service to the patient as the general surgeon will this practice continue for long? I doubt it, for sooner or later the patient, or his family doctor will properly evaluate the services received.

By this indirect approach we come to the crux of the situation, as expressed by Dr. Meeker. Does the general surgeon give to the fracture patient as good or better service than the orthopedist? I shall deliberately avoid

giving my answer to that question for the time being

The next question then *can* he provide, as a result of his training and experience in general surgery, as good or better service than the orthopedist? I am positive that he can and should

My thesis, then, is that the general surgeon, because of his broad surgical training, should be able to compete successfully with the orthopedist in the care of trauma of the soft tissues, bones, and joints, but I have a feeling that he is not holding his own at the present time

Recently a new specialty has been developing, that of traumatic surgery, composed of general surgeons who are interested in fractures, and orthopedists who are interested in the general problems of trauma. This may be the answer to the dilemma, for in such a group we find surgeons who are particularly interested in the treatment of traumatic conditions, and orthopedists who are willing to admit that they need a much broader training in the care of trauma than is provided by a limited experience in the regional field of bones and joints. It may be that the surgeons of South America have already solved this quandary, for during a recent conversation with Dr Juan M. Allende, professor of clinical surgery in the University of Cordoba, Argentina, he told me that the surgery of trauma in South America is carried on exclusively by specialists, and the specialty is known as the surgery of traumatologia and orthopedia.

My effort tonight will be to call your attention to these changing conditions in the surgery of trauma in this changing world, and try to interpret them from the viewpoint of the general surgeon.

Interest in major trauma is being constantly stimulated in these days by military, industrial, and automobile catastrophes. During a similar crisis, under the pressure of the first World War, improved methods of fracture and wound treatment were instituted. Some of these methods, in the original or modified form, were promptly incorporated into the accepted lore of surgical treatment, while others have been discarded long since, for example, at the present time the elimination of Dakin's

solution from the United States Pharmacopeia is being discussed seriously.

¹ We are now faced with the probability of having to care for large numbers of war casualties, and it is apparent that in this war the surgical problems will be more complex than in the previous wars. The absence of well defined battle lines, and the use of air armadas and panzer units, which attack the civilian population over large areas of a country, spreads the casualties to the non-combatant population. In the present European struggle it is reported that civilian casualties have been ten times more numerous than have military, as a result of the bombing and shelling of cities. There are new types of injuries, and the wounds caused by the modern high explosive shells and bombs, whose fragments have terrific velocity, tend to be massive and more devastating than the wounds of former wars. The blast injuries resulting from bombs of this type require attention which was not even suspected in the last war (Fig. 1). They result from a high pressure wave, which is immediately followed by a low pressure one, and the injuries usually take the form of capillary hemorrhages of the lungs (Figs. 2 and 3), the liver, the spleen, intestines, adrenals, and kidneys.

² A second reason for particular interest in the problems of fractures and trauma at this time is the increasing pressure being exerted by the economic front of the workmen's compensation legislation. Methods of treatment which will insure the ultimate restoration of function in the minimum length of time are now demanded by the compensation boards and insurance companies. This has led to higher standards of reduction, fixation, and after-treatment of fractures. This trend is also directly responsible for more widespread employment of open reduction and internal fixation. Though internal fixation was strongly advocated many years ago by Arbuthnot Lane, the difficulties of the technique and the meticulous equipment in personnel and material incident to the proper attainment of this type of fixation discouraged its general use. Only recently have we realized the vital importance of the rigidity provided by internal fixation, which makes possible active motion

Fig. Wounds of the face resulting from high explosive bombs. (Courtesy of M. Broster)

of the affected extremity immediately after the operation. This ideal can now be obtained through the employment of the biplane fixation which was devised by Clay Rav Murray of New York.

As internal fixation became more generally practiced it was quite evident that improvement was necessary in the type of metals used. The plates and screws became eroded and would lie loosely on the bone fragments. It was Verne and Stuck who demonstrated that this erosion was due to the electrolytic action of tissue fluids upon the metals. They claim that when any two dissimilar metals are used as fixatives in the same wound an electrolytic process is set up between these metals in accordance with the laws of electromotive force. Vitallium was proposed by them as a metal entirely inert to the effects of body fluids when not associated with any other metallic substance. As a result of this research vanadium has been discarded as the standard metal for plates and screws and in its place vitallium or high-chrome low nickel steel, or tantalum are now in vogue.

3. Motor accidents provide the third need for increased interest in fractures and traumatic wounds. More stringent traffic regulations of all kinds are needed to stop this terrible waste. It is without question the responsibility of the medical profession and surgeons in particular to see that this evil is corrected. Legislation, publicity and the direct fostering of organizations such as the Red Cross, together with the guidance of state highway commissions in instructing laymen in the proper methods of administering intelligent first aid care to the victims of industrial and automobile accidents, are necessary to promote the interest of the laity in the subject.

A sign encountered this summer while motoring through New England indicates the responsibilities which motor accidents are bringing to the rural physician and surgeon, and the economic burden being thrust upon communities, many of which are unequipped and financially unable to bear them. A large billboard was found at the entrance to the town, which read "This town does not maintain a hospital, and motorists are warned that they should take every precaution to avoid accidents while driving through, for we are not equipped to take care of them. This may be the easiest way out, but I am sure it will not be the final answer even in that town. Nor should it be."

During September 1941 3,777 persons met death as a result of motor accidents in this country. This was an increase of 14 per cent over the same period last year and marks the fourteenth successive month to show an increase over 1939 and 1940. With 1941 three-quarters gone the total killings have been 27,860 which is a rise of 17 per cent over the fatality list for the same period of 9 months in 1940.

After this brief consideration of some of the many special fields of knowledge which must be mastered in order to cope with the changing problems in the treatment of traumatic wounds and fractures one might think that we had forgotten our original promise. On the contrary, it is exactly because of the complexity of these problems that we believe that a general surgeon, employing the basic knowledge of the principles of surgery, should be better

Fig 2 Low power view of lung of a woman killed in a steel shelter as the result of a "near miss" There was massive hemorrhage throughout the left lung $\times 58$ (H.L. 3) (Courtesy of Mr Broster)

fitted to arrive at a complete solution of them than are his more highly specialized colleagues

FIRST AID

I feel sure no one will disagree with the statement that the first essential in treating a patient suffering from a fracture or trauma is to try to evaluate the condition of the patient as a whole, and not to concentrate entirely on the local wound or deformity, immediate or final. Age, sex, physical development, nutrition, emotional status, all of these elements and many more must be grasped at the same time as one prepares to administer proper first aid care. I say proper first aid care because while the beneficial effects of such aid as immediate splinting of fractures or dressing of wounds is unquestioned—the methods of carrying out this first aid may be far from ideal.

May I offer here the slogan which we advocated and taught to the lay public during the last war, and to Red Cross groups during the interval between the two wars: namely, when in doubt as to what you are dealing with, do nothing, and when you are not sure about what should be done, even though you know the indications, do nothing. Those of us who do not see these patients until after the administration of well intentioned first aiders know too well that the patient too often would have been in better condition if he had

been left alone and had not received the treatment given to so many of them. Dr William Darrach has expressed this in a more scholarly way. "In our early examination and treatment we should be guided and restrained by our realization of the pathology, by the mental picture of what has actually occurred beneath the skin, and what may occur as a result of our first aid efforts."

Gentleness is unquestionably the keynote of first aid care and must be rated above all other considerations in the management of severe accident cases.

Hemostasis In dealing with traumatic wounds it is frequently necessary to control hemorrhage. This is accomplished most easily and with the greatest safety by applying a pressure dressing. The latter should be firm, but not excessively so. Tourniquets are sometimes required to control more severe hemorrhage, but only as a last resort, and one must not forget that periods of release are required if the band remains in place for more than 30 minutes. Gangrene is still too often the result of the application of tourniquets by conscientious first aiders.

Asepsis is secondary only to the control of hemorrhage in the primary treatment of open wounds. As a first aid measure the application of a sterile or mechanically clean dressing is the best safeguard against infection. Anti-

of the affected extremity immediately after the operation. This ideal can now be obtained through the employment of the biplane fixation which was devised by Clay Rav Murray of New York.

As internal fixation became more generally practiced it was quite evident that improvement was necessary in the type of metals used. The plates and screws became eroded and would lie loosely on the bone fragments. It was Venable and Stuck who demonstrated that this erosion was due to the electrolytic action of tissue fluids upon the metals. They claim that when any two dissimilar metals are used as fixatives in the same wound, an electrolytic process is set up between these metals in accordance with the laws of electromotive force. Vitallium was proposed by them as a metal entirely inert to the effects of body fluids when not associated with any other metallic substance. As a result of this research vanadium has been discarded as the standard metal for plates and screws and in its place vitallium, or high-chrome low-nickel steel or tantalum are now in vogue.

3. Motor accidents provide the third need for increased interest in fractures and traumatic wounds. More stringent traffic regulations of all kinds are needed to stop this terrible waste. It is without question the responsibility of the medical profession and surgeons in particular to see that this evil is corrected. Legislation, publicity and the direct fostering of organizations such as the Red Cross, together with the guidance of state highway commissions in instructing laymen in the proper methods of administering intelligent first aid care to the victims of industrial and automobile accidents, are necessary to promote the interest of the laity in the subject.

A sign encountered this summer while motoring through New England indicates the responsibilities which motor accidents are bringing to the rural physician and surgeon, and the economic burden being thrust upon communities, many of which are unequipped and financially unable to bear them. A large billboard, was found at the entrance to the town, which read "This town does not maintain a hospital and motorists are warned that they should take every precaution to avoid accidents while driving through for we are not equipped to take care of them." This may be the easiest way out, but I am sure it will not be the final answer even in that town. Nor should it be.

During September 1941 3 777 persons met death as a result of motor accidents in this country. This was an increase of 14 per cent over the same period last year and marks the fourteenth successive month to show an increase over 1939 and 1940. With 1941 three-quarters gone the total killings have been 27,860, which is a rise of 17 per cent over the fatality list for the same period of 9 months in 1940.

After this brief consideration of some of the many special fields of knowledge which must be mastered in order to cope with the changing problems in the treatment of traumatic wounds and fractures one might think that we had forgotten our original promise. On the contrary it is exactly because of the complexity of these problems that we believe that a general surgeon employing the basic knowledge of the principles of surgery should be better

more time must be allowed by the schools for the teaching of traumatic surgery, and fresh material of this sort should be made available to the students. As far as we know, Dr Galle of the University of Toronto was among the first to recognize this need and to make an effort to meet it.

The important elements of this subject cannot be learned in lectures and in dry clinics by viewing the bandaged wounds and splinted extremities. Students must see, and participate, if possible, in the whole procedure from the time the patient enters the hospital until his wound or fracture has been treated and he has been put to bed on the ward. In hospitals, internes and residents require special instruction in this field, and this can be made possible by spending a specified time on a traumatic service. The special value of a traumatic service has been proved to our satisfaction, and in such a plan the traumatic cases are segregated into special wards and cared for by a group of nurses and attendants specially trained in handling the equipment and problems incident to fractures and major injuries. Probably this ideal cannot be achieved generally because of the financial outlay which it entails. However, it is usually possible, at least, to practice a modified version of the idea by having traumatic cases under the care of the same surgeon or group of surgeons continuously for a period of 6 months, or preferably a year. In this way the plan of treatment undertaken is not as likely to be interrupted as when the direction of the service is changed at shorter intervals. Upon discharge from the hospital it is also advantageous to have the same team to carry on in the out-patient department. Both fractures and major traumatic wounds are treated intelligently only if they are followed carefully for prolonged periods after discharge from the hospital. The results of epiphyseal injuries, shortening or tilting of long bones, restoration of joint function, and contraction of scars, to mention only a few instances, cannot be evaluated fully until at least one year after the actual treatment has ceased. Such an organization may seem cumbersome and unwarranted to those who have not seen it in action. This may be true for a short time after its in-

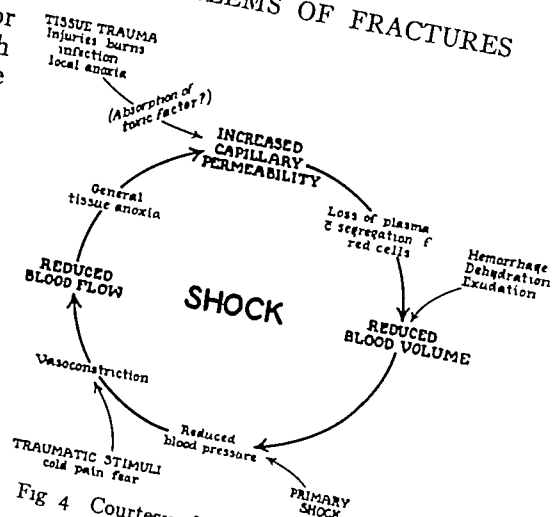

Fig 4 Courtesy of Dr Norman E Freeman

ception, but once established the results are so greatly improved that the satisfaction to both the patient and the surgeon is a sufficient stimulus and compensation to keep it running smoothly.

Undoubtedly one of the most perfect demonstrations, not only of the possibilities but also of the efficiency that can be obtained by the specialization of the surgery of trauma and fractures, is to be seen in the fracture service of Darrach and Murray at the Medical Center of Columbia University in New York. In referring to such an ambitious plan for the teaching of undergraduate, graduate, and postgraduate surgery of this type, one must pay homage to this contribution to the problems of traumatology.

Time will not permit of an exhaustive discussion of the many interesting phases of this subject. However, we have chosen three, namely, shock, burns, and compound fractures, for more detailed consideration.

SHOCK

In the discussion of shock the general surgeon must always define his understanding of the pathology of the process in order to justify the type of treatment used (Table I, Fig 4). We subscribe to the now generally accepted theory that shock is caused by one, or several, or all of a group of factors operative at the time of the injury. These factors are hemorrhage, dehydration, pain, cold, fear, asphyx-

TABLE 1 — SHOCK

sepsis probably do more harm than good when introduced into a potentially infected wound. Cleansing of the skin area around the wound should be left for the operating room inasmuch as proper solutions and the facilities for using them will probably not be available at the locus of the injury.

Simple methods There is a tendency among general surgeons who treat many traumatic wounds to utilize relatively simple and conservative methods. Soap and water cleansing of the skin surrounding a wound and irrigation of the wound proper with normal saline solution or sterile water should be used more often than complicated antiseptic skin preparations and antiseptic irrigants. Wounds of soft parts of the extremities should be splinted, not only to prevent pain and hemorrhage but also to discourage the spread of contaminating bacteria.

What appears now to be an epochal contribution in the control of infection in traumatic wounds is the experimental work of Trueta, which was undertaken with the object of explaining the localization of wound infection when the traumatized tissues were primarily immobilized in plaster. In two series of dogs, one being used for control and the other for experiment, the extremities in both groups were traumatized, the soft tissues lacerated and the bones fractured. The injured tissues were then inoculated with the *Bacillus welchii* perfringens and hemolytic streptococci. Following this the wounds were filled with sulfanilamide powder and packed open with vaseline gauze. In the control group the traumatized extremities were not immobilized while in the other group they were encased in plaster casts.

In the control group every animal died from a gas bacillus infection within 3 days while in the other group no deaths occurred. Tru-

eta explained this by the fact that the immobilization of the soft tissues resulted in stagnation of the lymphatic circulation. In the tissues of the animals examined after death he found, in the group with freely moving extremities the previously injected bacteria or their offspring had entered the blood stream within 24 hours after receipt of the injury. In the group in which the tissues had been immobilized the organisms remained within a short distance of the traumatized tissues but had not entered the lumen of the blood vessels.

FRACTURES

In the treatment of fractures the simplest technique which will afford adequate reduction and complete immobilization should be chosen. Open reduction with internal fixation is recognized as an ideal procedure for the treatment of simple fractures, but should be reserved for exceptional cases. Furthermore unless one has occasion to practice open reduction with internal fixation frequently we believe it is better not to attempt this procedure. It is usually not performed successfully by the occasional operator.

In summary we will repeat that our endeavor in treating traumatic wounds is to avoid intricate or cumbersome techniques and to adhere carefully to the fundamental principles of gentleness, hemostasis, asepsis, and immobilization.

It may be well to insert at this point a word about one phase of the treatment of fractures and traumatic wounds which has troubled the surgeons who form the Fracture Committee of the American College of Surgeons, namely the need for an educational program aimed at improvement in the care of trauma of all kinds.

Such a program must have its origin in the medical schools where more emphasis should be placed upon the recognition and management of various types of fractures and traumatic wounds. Furthermore medical students should be taught to recognize the types of cases which they will not be qualified to handle as general practitioners and which should be referred to one specially trained in surgery. In order to accomplish these aims

more time must be allowed by the schools for the teaching of traumatic surgery, and fresh material of this sort should be made available to the students. As far as we know, Dr Galle of the University of Toronto was among the first to recognize this need and to make an effort to meet it.

The important elements of this subject cannot be learned in lectures and in dry clinics by viewing the bandaged wounds and splinted extremities. Students must see, and participate, if possible, in the whole procedure from the time the patient enters the hospital until his wound or fracture has been treated and he has been put to bed on the ward. In hospitals, internes and residents require special instruction in this field, and this can be made possible by spending a specified time on a traumatic service. The special value of a traumatic service has been proved to our satisfaction, and in such a plan the traumatic cases are segregated into special wards and cared for by a group of nurses and attendants specially trained in handling the equipment and problems incident to fractures and major injuries. Probably this ideal cannot be achieved generally because of the financial outlay which it entails. However, it is usually possible, at least, to practice a modified version of the idea by having traumatic cases under the care of the same surgeon or group of surgeons continuously for a period of 6 months, or preferably a year. In this way the plan of treatment undertaken is not as likely to be interrupted as when the direction of the service is changed at shorter intervals. Upon discharge from the hospital it is also advantageous to have the same team to carry on in the out-patient department. Both fractures and major traumatic wounds are treated intelligently only if they are followed carefully for prolonged periods after discharge from the hospital. The results of epiphyseal injuries, shortening or tilting of long bones, restoration of joint function, and contraction of scars, to mention only a few instances, cannot be evaluated fully until at least one year after the actual treatment has ceased. Such an organization may seem cumbersome and unwarranted to those who have not seen it in action. This may be true for a short time after its in-

ception, but once established the results are so greatly improved that the satisfaction to both the patient and the surgeon is a sufficient stimulus and compensation to keep it running smoothly.

Undoubtedly one of the most perfect demonstrations, not only of the possibilities but also of the efficiency that can be obtained by the specialization of the surgery of trauma and fractures, is to be seen in the fracture service of Darrach and Murray at the fracture medical Center of Columbia University in New York. In referring to such an ambitious plan for the teaching of undergraduate, graduate, and postgraduate surgery of this type, one must pay homage to this contribution to the problems of traumatology.

Time will not permit of an exhaustive discussion of the many interesting phases of this subject. However, we have chosen three, namely, shock, burns, and compound fractures, for more detailed consideration.

SHOCK

In the discussion of shock the general surgeon must always define his understanding of the pathology of the process in order to justify the type of treatment used (Table I, Fig 4). We subscribe to the now generally accepted theory that shock is caused by one, or several, or all of a group of factors operative at the time of the injury. These factors are hemorrhage, dehydration, pain, cold, fear, asphyx-

Fig 5 Distribution of fluid between the capillary and tissue spaces.

la, and exhaustion as outlined by Freeman. The total effect of this phenomenon is to produce tissue anoxia which gives rise to abnormal capillary permeability. Consequently there follows a loss of blood plasma, a diminished blood volume, lowered blood flow, blood stasis in the capillaries, and finally a greater

degree of anoxia of the tissues. In this manner a vicious circle is established which can be broken only when the proper treatment is administered.

Treatment of this condition up to very recent times consisted of relieving the objective symptoms by means of well known methods.

About 10 years ago the intravenous infusion of saline and glucose was added to the armamentarium. This resulted in a temporary rise in the blood volume and blood pressure which was not sustained because the fluid left the leaking capillaries almost as fast as it was introduced and carried with it the vital serum protein so that the harm which was done was not only passive but was likewise active (Fig 5).

Following this routine use of saline and glucose, whole blood was infused into veins in order to raise and maintain for a length of time the flagging blood pressure. It is true there are definite indications for the use of whole blood in shock, particularly when it is associated with hemorrhage but the difficulty in performing transfusion into the collapsed veins of the shocked state have been experienced by every surgeon. In this connection we wish to call attention to the recent work of Tocantins in Philadelphia. During

Fig 6 Illustration of the distribution of the dye in the retrosternal veins, and the location of the needle during the injection. (Courtesy of Dr L. M. Tocantins)

Fig 7 A, B, C, D, infusion needles of various lengths E, component parts of a needle, from top to bottom needle guard, external needle gage 15, internal needle gage 18, solid stylet F, curved adapter (Needles made by the George Pilling Co., Phila delphia)

the stage when fluids are most urgently needed, the physician is left without ready access to the central portion of the circulation because of the collapse of the peripheral veins as a result of shock. It occurred to Tocantins that under such conditions such a stage offered the ideal site for the introduction of fluids until the patient reaches the stage that the peripheral circulation is restored and access to the veins is again possible. Since the marrow veins are surrounded by a rigid envelope, they are less likely to collapse, and probably can withstand forcible injection, without overdilatation and leakage, better than the poorly supported peripheral veins. Further, substances injected into the bone marrow cavity are taken up almost immediately into the venous circulation and apparently unchanged (Fig 6).

"We have experimentally demonstrated this by the injection of dye into the marrow of the sternum of a cadaver and found that it rapidly appeared in the right auricle. The comparatively short distance between the sternal marrow and the right side of the heart makes this possible. The rapid introduction of fluid into this side of the heart may, therefore, help to restore the cardiac output during the phase of acute peripheral failure, by increasing the

volume of the blood returning to the central portion of the circulation."

Tocantins needle (Fig 7) After the needle has been inserted through the cortex and the marrow has been obtained by aspiration, the syringe containing the material to be administered is connected with the needle and the material is injected as fast as the resistance offered to it will allow. In conscious patients, if the fluid is injected at a rate greater than 10 cubic centimeters a minute, there is usually a feeling of fullness in the sternum which, however, passes off immediately upon cessation of the injection. By using a two-way valve, one side connected by rubber tubing to the container of the fluid and the other leading from the valve into the sternal needle, it becomes unnecessary to remove the syringe from the sternal needle every time it has to be filled. In some instances, in which a more rapid rate of injection is desirable, two needles can be introduced into the sternum, one at either end, and since the marrow cavity of the manubrium and the marrow cavity of the sternum seldom communicate, it is possible to inject material through one orifice without it coming out of the other. This method can be used for the administration of any type of medication to patients with acute circulatory fail-

ure and it has been found to be much more efficient than when the material is injected by other routes.

In the 72 cases in which this method was used by Tocantins no untoward reactions of any kind were experienced.

But there are definite contraindications to the use of whole blood transfusion to combat shock which are readily understandable if one accepts the etiology of shock as outlined here. Whole blood infusions will provide an increase in blood volume but they also supply an element which is detrimental in shock—the red cells which when added to the circulation serve to increase the viscosity of the blood and thus cause greater capillary stasis. This in turn brings about a greater degree of anoxia and increases the capillary permeability. To put it briefly, whole blood transfusions are contraindicated in shock because they tend to exaggerate the existing hemoconcentration. Hemoconcentration however may be absent and not marked when shock is associated as the result of hemorrhage.

The search for a substitute for whole blood, which would raise the blood pressure by increasing the blood volume without increasing hemoconcentration, was terminated happily when the use of blood plasma was suggested. As early as 1917 Strumma first advocated the use of blood serum in shock treatment, but adverse reactions, since found to be due to the absence of the fibrin fraction, caused serum to fall into disrepute. Then in 1929 he found that plasma was equally effective in combating shock and did not give rise to reactions. Ten years were to pass before the plasma transfusion was widely accepted and employed in shock treatment, but now this therapy is well established. It has stood the test of the demands of war surgery and answers the physiological requirements of the damaged

PLASMA VOLUME

Fig. 9. Comparison of the duration of the shifting of the plasma into the perivascular tissues. Above: When local treatment only is used. Middle, new local treatment and blood transfusions are used. Below: local treatment, blood transfusions, and adrenal cortical extract are used.

tissue. Plasma dilutes the concentrated blood of the capillaries and tends to remain in the vascular bed better than any other material thus far used.

The history of the production of plasma for infusion in shock states is interesting but too lengthy for consideration here. The preparation of plasma from citrated blood is now accomplished both by centrifuging and by the simpler natural settling process. After preparation the plasma is probably best used in its liquid form, although dried and frozen types of plasma are available. One other interesting development has arisen from this plasma industry. Plasma, once an incidental dividend of the blood bank system, has now become the capital of that system. The demand which is made for plasma is now commonly stated as being four times that for whole blood.

When the use of plasma in the treatment of shock was generally established, it became necessary to discover some way of testing

Fig 10 Interference with the circulation of the hands and digits following the use of tannic acid in the local treatment of severe burns

clinically for the presence and degree of shock in order to determine the dosage. The laboratory tests devised for this purpose consist of the usual hemoglobin and hematocrit determination and red blood cell counts. From a consideration of these figures the state of hemoconcentration may be determined.

More recently these values have assumed added importance in that with them one can compute by means of a simple formula the amount of plasma lost. Thus replacement of plasma is removed from the realms of uncertainty and carried out on a definite volume basis. An example of such a formula is that of Black which is given as follows

$$\frac{HB}{100} \times \frac{5}{5X}$$

HB is the observed hemoglobin
X is the plasma lost in liters

This formula has been criticized from the point of view that it fails to take into account the fact that the hemoglobin may be very low in shock associated with hemorrhage in which there occurs a compensatory dilution of the blood. However, the formula has been of great value in emergencies and especially in war conditions when one cannot wait for or obtain more complicated tests. If the formula cannot be recalled it is a safe rule to give plasma to any patient in a shock state when the hemoglobin is found to be above 100 per cent.

When laboratory facilities are available for determining the hematocrit and plasma protein concentrations, we have found the following formula devised by Elkinton, Wolff,

and Lee to be more accurate than that of Black.

For calculating this quantity, the authors have proposed the following formula

$$\text{Plasma protein requirement in grams} = 3.5 W - \frac{W(100-Ho)HnPo}{2(100-Hn)Ho}$$

W = body weight in kilograms
Hn = normal hematocrit value, per cent cells
Ho = observed hematocrit
Po = observed plasma protein

If the plasma protein requirement in grams is multiplied by 14 the required volume in milliliters of plasma is obtained

Fig 11 Second and third degree severe burns of the forearms and hands, treated with tannic acid, on the right, and with triple dye, on the left

to apply successfully and, when applied as one of the various pedicle or flap grafts, the procedure is lengthy but the chances of success are improved. From a cosmetic standpoint the full thickness skin graft cannot be surpassed.

COMPOUND FRACTURES

Every compound fracture is potentially infected and therefore must be treated as though actually infected. This statement will not be questioned as regards grossly dirty wounds, but in cases of wounds with no external evidence of contamination there is disagreement from some quarters. Without being certain of the cleanliness and asepsis of the bared fragments it is too often assumed that the innocuous looking wound of the skin will heal satisfactorily and the lesion is treated as a simple fracture. The occasional wound of this type which becomes infected is responsible for the bad reputation of compound fractures. Tinker quoted by Kennedy stated the problem very aptly in 1909—"The most important consideration in the management of compound fractures is still the wound of the soft parts. If our wound is aseptic, tetanus and blood poisoning are impossible, bony union and a movable joint are favored, osteomyelitis will not develop and a useful, if not perfectly normal extremity will usually be saved."

As a diversion for a few minutes perhaps you will allow me to offer two illustrations which will help to date the period to which Tinker and Kennedy make reference in the previous statement.

I was asked by the late Dr. Astley P. C. Ashhurst, during the year of the bicentenary of the introduction of Listerism into surgical technique to determine if possible and to illustrate by means of graphs, the effect of asepsis and of antiseptics upon the surgical practice of the Pennsylvania Hospital in Philadelphia.

At the Pennsylvania Hospital we have continuous records of every patient from the time of its opening in 1751 to the present. This is not even possible in the Royal Infirmary at Glasgow where the work of Lister was first carried out. The records of his work in their wards have been destroyed.

With this type of record and fairly constant factors, before and after statistics obtained from such a source should be of peculiar value.

Figure 12 shows the influence of antiseptics and asepsis on the number of amputations performed at the Pennsylvania Hospital before and after the introduction of Listerism. Figure 13 shows the influence of these two surgical principles on the total number of operations in the hospital during these periods.

Could a better statistical experiment be provided to demonstrate that the prophylaxis of wound infection is the prime concern of the general surgeon in the treatment of compound fractures. The best method of prophylaxis is thorough débridement before contaminating organisms establish infection which means that débridement should be performed within 6 hours after the time of injury. In a few selected cases it may be possible to débride successfully as late as 10 hours after contamination occurs but every minute saved is added insurance against infection. We must impress upon our colleagues that minutes spent in the hospital preparing for operation are just as precious as those that were spent in transportation of the patient from the site of accident to the hospital. Therefore we should strive to organize the various hospital services so that the care of compound fractures will be given priority over that of all other operative cases.

The methods of débridement are well known but a few remarks to emphasize certain points of technique may not be amiss.

The use of antiseptics, regardless of their innocuousness should be confined to the skin surrounding the wound. Antiseptics should never be applied to the wound proper. Normal salt solution is the strongest solution which should be allowed to touch the exposed tissues.

Cultures of the wound both aerobic and anaerobic, should be taken routinely at the time of the débridement if laboratory facilities exist. In addition some surgeons advocate taking smears to be examined during the course of the débridement for the immediate detection of gas bacilli.

All compound wounds should be irrigated thoroughly with normal salt solution during

and after débridement After the final irrigation they should be dusted evenly with one of the sulfonamide powders Recently we have used sulfanilamide for this purpose and no ill effects in the local lesion have been noted although several patients have shown rather marked toxic effects of a systemic nature It is claimed that sulfadiazine can be administered in much larger doses than any others of the group without causing toxic manifestations It is excreted slowly and consequently we have unintentionally achieved higher concentrations in the blood than needed In one case in which the concentration reached 21 milligrams per cent there were slight toxic symptoms which ceased when the blood level fell to 10 milligrams per cent Whichever drug is used in the wound it should also be given by mouth as soon as the patient is able to take oral nourishment, in order to maintain the concentration in the blood at the optimum level

On the question of wound closure we stand firmly with the conservatives The soft tissue wounds of all compound fractures are packed wide open with vaseline gauze Primary sutures would doubtless succeed in many cases However, because of the horrible results—osteomyelitis, amputation, or death—which may occur in wounds which become infected after primary closure, it is our opinion that it is not fair to expose the patient to a risk such as this

Accurate reduction and complete immobilization are important The time for reduction of compound fractures is at the time of the débridement Most reductions can be accomplished under direct visualization and instrumental manipulation of the fragments while the soft part wound is open There is thus no excuse for inaccurate reduction

Fixation of compound fractures is possible by several methods

When a nonpadded plaster casing will hold the fragments adequately, this is probably the best and safest type of fixation It introduces no foreign material into the field of operation or into the proximal or distal portions of the affected extremity Because no special equipment or techniques are required this type of fixation is the one best suited to the occasional operator

A more positive scheme for maintaining rigid fixation is the two pin transfixion method advocated by H Winnett Orr A pin or wire is driven through the proximal fragment and another through the distal fragment By means of traction and countertraction on an orthopedic table, or on one of the special distraction apparatuses, the length and rotation of the affected bone are restored Then while the pins or wires maintain the reduced position a plaster casing is applied which incorporates the pins or wires by means of which a more rigid fixation than can be attained with simple plaster casing is effected

Perhaps the ideal method for maintaining reduction in compound fractures as well as in simple fractures is by means of biplane internal fixation performed simultaneously with débridement This type of fixation must be in two planes to be effective Frequently, the plates or screws must be removed before healing of the fracture has occurred because of infection However, in many cases it is possible to succeed in avoiding infection as a result of the rigidity afforded by internal fixation, and the fragments will unite just as rapidly as do simple fractures which are treated in a similar manner

We cannot leave this subject without mentioning the excellent work of Trueta in the recent Spanish War in his treatment of compound fractures by the Orr method His monograph we recommend to every surgeon practicing in the field of traumatology The theme which he emphasizes is that for war wounds the needs are débridement and complete rest of the tissues immediately following operation and during transportation, and infrequent dressings The best way to afford such conditions is by means of a plaster casing He treated 1,072 cases of open fractures of limbs by the typical Orr method There were 6 deaths and 976 good results This is the most convincing evidence which has as yet been offered for the excellence of this type of treatment

CONCLUSION

In conclusion, we feel sure that most general surgeons will claim that they are fully able to provide such service as we have out-

lined and the majority will feel that they do give such service. But do they carry this service as far as the orthopedists in their routine care of fractures? I refer to the painstaking personal follow up not only in the hospital but for months and years after the patient leaves. Is the general surgeon's aim—once a patient always a patient? In other words does he feel the responsibility for complete or as nearly complete rehabilitation as can be

provided through the routine use of multiple operations, gymnastics, the swimming pool, physical therapy and above all, occupational therapy? Is he as interested in the surgery of trauma as in that of the abdomen? If not, I am sure that patients in the future will not choose him in preference to the surgeon or an orthopedist who is. The question is not whether he *can* give the best service to such patients, but as Dr. Meeker queried *will he?*

A CRITICAL SURVEY OF TEN YEARS' EXPERIENCE WITH FRACTURES OF THE NECK OF THE FEMUR

MATHER CLEVELAND, M A, M D, F A C S, New York, New York

DURING the decade extending from 1930 to 1940 the fact that patients with fractures of the femoral neck may be rehabilitated in surprisingly large numbers gained wide acceptance. The enthusiasm which greeted this novel idea resulted in a vast array of techniques with relatively few careful analyses of the results attending the use of these various means of treatment.

This study of 110 fractures of the neck of the femur treated at St. Luke's Hospital during this period is an attempt to subject our experience to critical analysis and to dwell on our vicissitudes as well as our achievements. *Ad astra per aspera*, the motto of the state of Kansas, might serve as a text.

The first 50 of these patients treated during the first half of the decade have been previously reported, but they will be mentioned for contrast and to allow us to correct certain misconceptions which inexperience led us to postulate (1). These original 50 patients were treated by manipulation and application of plaster of Paris spica bandage or traction in a few instances.

In 1935 our first internal fixation of a fracture of the neck of the femur was performed. We adopted the three phlange nail devised by Smith-Petersen (4) and have never found any fixative agent to equal it. The metal used was originally stainless steel, but since 1938 we have used vitallium.

Smith-Petersen's open operative reduction and fixation of these fractures was followed in 14 patients, but the results were so disappointing that it was abandoned. It is to be hoped that other surgeons will in time publish their experiences with open reduction and internal fixation of these fractures. During this period of experimentation, we had 8 undis-

placed fractures of the neck of the femur, and since we had previously satisfied ourselves that these invariably did well if they were protected we merely kept them in bed 4 to 5 weeks and then allowed them up with a Thomas caliper splint with pelvic band and crutches. These patients have results that are in every way perfect.

Following our extremely unsatisfactory experience with open reduction, we turned in June, 1938, to closed reduction and internal fixation and since that date 38 patients have been treated in this manner with results which are greatly improved from every standpoint.

REDUCTION OF THE FRACTURE

In reporting the first 50 patients treated without surgery and in the light of a very meager experience with open reduction, the following conclusion was reached: "The chances of getting bony union with a useful hip may be greatly enhanced by open reduction derotation of the femoral head where rotation exists, and internal fixation." This expression of opinion, backed up with but little experience, is quoted to reaffirm what now seem the important factors, namely, *reduction* of the fracture and *internal fixation*. If the fracture is reduced, such rotation of the head fragment as existed has been overcome.

The reduction of these fractures is by no means as simple as it sounds. It would seem that open reduction should guarantee the end to end apposition of the fragments, but with the instability occasioned by the dissection of the ligaments of the joint almost 50 per cent of these fractures so treated displaced during the process of nailing.

With closed reduction (3) the situation was greatly improved at once. There were 38 patients treated with closed reduction and internal fixation, and of these, 26, or 68 per cent, were practically perfectly reduced, and 6, or 16 per cent, were reduced so that the bony

apposition was 75 per cent or better and 6 or 16 per cent, of these fractures were not reduced.

Of the 26 patients who had their fractures perfectly reduced, 22 survived and all of these had their fractures united, with excellent range of motion in the hip and few if any residual symptoms. Of those 6 patients who had 75 to 80 per cent apposition of the fractured surfaces, 5 survived and united, but 2 of these showed circulatory disturbance in the femoral head and all 5 had malunion with resulting deformity.

FAILURE TO REDUCE THE FRACTURE

It seems incredible but the fact remains that one half of the fractures treated by open reduction were not reduced when the nail was finally driven and the operation was completed. Since closed reduction has been prac-

ticed there have been 6 patients in 38 whose fractures have not been reduced. The reasons for these failures to secure reduction are worth recording in the 5 survivors.

1. A patient of 70 years of age whose reduction was attempted 10 weeks after injury and the fragments could not be mobilized. Non-union resulted.

2. A patient of 70 years of age whose fracture after repeated attempts, could not be reduced. Satisfactory roentgenograms were not obtained. Two weeks later a trochanteric osteotomy was performed and the patient has a useful hip.

3. Two patients had their fractures "reduced" with the aid of a fluoroscope and nailed. Check-up roentgenograms taken the next day revealed the situation that the fracture had not been reduced. This belongs in the department of locking the stable after the

The fluoroscope serves no useful function in
reduction of these fractures, and its use is not
recommended

4 In one patient, a fracture thought to be
reduced with end-to-end apposition in two
planes, was nailed, and a more careful study
of the roentgenograms the following day
showed the fragments nailed end-to-side In
this patient the fracture united, strange as it
may seem, but then developed extensive asep-
tic necrosis of the femoral head (Fig 1)

TECHNIQUE OF INTERNAL FIXATION

It is not the purpose of this presentation to
deal with technique, but it may be said that
the internal fixation of these fractures of the
neck of the femur may be readily accom-
plished without the aid of any gadgets what-
soever The proper insertion of the nail is not
altogether simple, and it is only with added
experience that confidence and familiarity
produce uniformly satisfactory results A nail
that is centered, or practically so, in the shaft,
neck, and head of the femur in both the an-

This nail was removed. Result is excellent.

teroposterior and lateral planes, as shown by roentgenograms, is the optimum position. During the earlier years when open reduction was performed a centered nail was placed in only 5 of the 14 patients so treated; an incidence of 35 per cent. Later in the 38 patients treated with closed reduction an increased experience enabled us to center 21 or 55 per cent, of the nails driven. Among the entire 52 patients treated by internal fixation there were 26 instances in which the nail was centered and 26 instances in which it was off

center. Union occurred in 16 instances in which the nail was centered and in 18 instances in which the nail was off center. However the incidence of nonunion was almost twice as frequent when the nail was off center as it was when the nail was centered.

Three phlange nail. The length of this nail varies from 3 to 4 1/4 inches. The average patient requires a 3 1/4 inch nail and about half of our patients had a nail this long.

The metal of which the nail was made was stainless steel but in 1938 we changed to

CLEVELAND FRACTURES OF THE NECK OF THE FEMUR

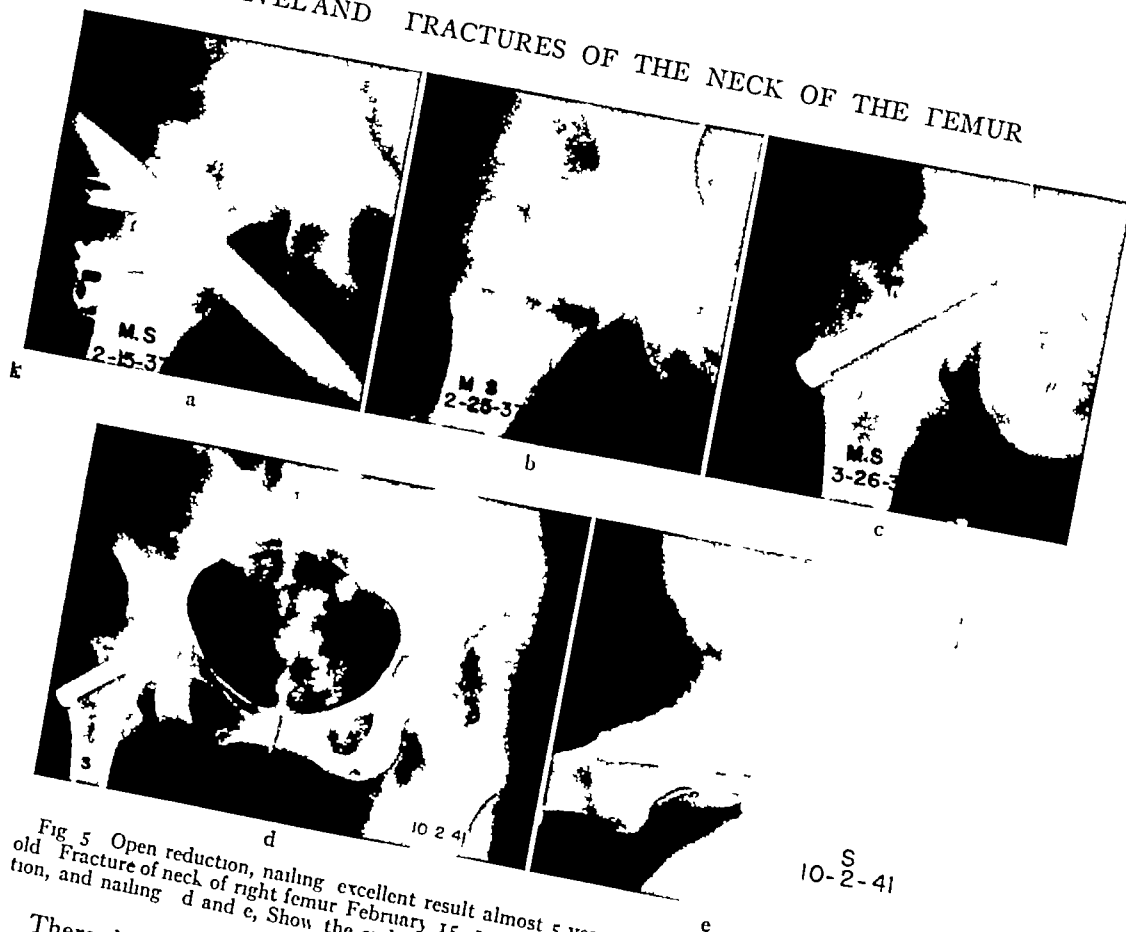

Fig 5 Open reduction, nailing excellent result almost 5 years later M S Female 68 years old Fracture of neck of right femur February 15, 1937 a, b, and c Show the fracture reduction, and nailing d and e, Show the end result 5 years later This is in all respects perfect

There has been no instance in which the nail broke. There has been comment about the so called migration of the nail used for internal fixation. This occurs chiefly in instances in which there is nonunion of the fracture. In this series, there were 8 survivors with nonunion, and in none of these did the nail remain in its original position in the shaft, neck, and head of the femur. Four of these nails extruded along the original path of insertion, 2 intruded across the joint line into the ilium, 1 simply disengaged from the head, remaining loosely in the shaft and neck, while the remaining one remained engaged in the shaft and neck, bridging across a gap to the head of the femur where it was reasonably firmly seated (Fig 2).

When the fracture is solidly united, there is seldom seen any migration of the nail. Among

the 34 united fractures which were nailed, there were 4 instances in which shortening of the neck as union progressed caused an extrusion of the nail along the path of insertion (Fig 3).

There were also 4 instances in which the nail was originally overdriven through the cartilage of the femoral head. This error is due to using a nail which is just about the same length as the shaft, neck and head pathway if driven flush and then blandly ignoring the fact that impaction of the fragments shortens the distance. When a nail of such exact length is driven fully after impaction, it is bound to penetrate the articular cartilage. There has been no further penetration of these nails (Fig 4).

Removal of the nail The nail has been removed only for cause. Among those patients with united fractures, 2 extruded nails, 4 over-

Fig. 6. An undisplaced fracture of the neck of the femur united, excellent result. E. M. 54, female 57 years old. a, b, Show fracture of neck of left femur without displacement. c, d, Show union of the fracture 9 months later.

driven nails and 5 nails in which the head of the femur showed evidence of circulatory disturbance have been withdrawn. In ununited fractures, the nail has been withdrawn in 4 of the 8 patients. In 3 of these 4 the removal preceded a trochanteric osteotomy.

Blaming the nail for failure to maintain reduction. It is our belief that instead of a certain tendency to blame the nail for failure to maintain reduction of the fracture the responsibility should be more properly charged to the surgeon's failure to obtain an original adequate reduction.

ROENTGENOGRAMS

The paramount importance of an exact and accurate roentgen ray technique cannot be overemphasized. The relationship of the shaft, neck, and head of the femur and the nail must be visualized during the reduction

and nailing by means of roentgenographic films taken in anteroposterior and lateral positions. With a portable roentgen ray apparatus and a developing room adjacent to the operating room the time of operation should be reduced to a minimum.

THE PATIENT WITH A FRACTURE OF THE HIP AS AN OPERATIVE RISK

There was but one operative death an incidence slightly under 2 per cent. This was an elderly hypertensive diabetic woman who was kept in the hospital under treatment for a week prior to her operation. She died 4½ hours after operation of shock and cardiac failure.

Wound healing has, in all instances, been prompt uncomplicated, and without infection.

These patients subjected to reduction and internal fixation have been kept in bed for 3

CLEVELAND FRACTURES OF THE NECK OF THE FEMUR

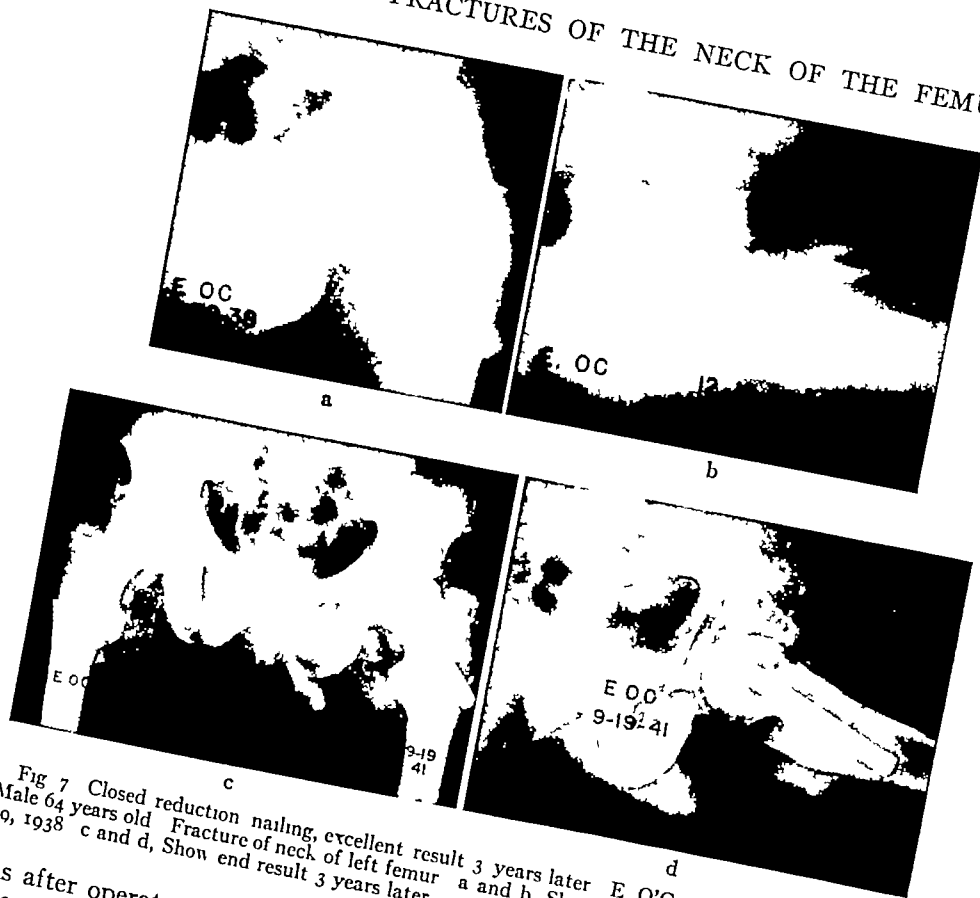

Fig 7 Closed reduction nailing, excellent result 3 years later E O C St Luke's No A 6937

to 4 weeks after operation Russell traction just sufficient to balance the pull of the muscles, that is, 4 to 6 pounds total, has usually been employed, and they are without pain after 2 or 3 days. Getting these elderly people with broken hips out of bed on the first, second, or third postoperative day is a stunt and serves no useful purpose. When they are allowed out of bed, a Thomas caliper splint with a pelvic band is applied and crutches are used. These supports are employed until the fracture is united or definite failure to unite is established. Union of the fracture occurs from 4 to 9 months after reduction and fixation on the average.

The average hospital stay of the 60 patients treated since 1936 has been 46 days after operation. This should be compared to an average of 122 days for the ward patients and 135 days for the private patients in our first series of 50 patients on whom no surgery was per-

formed. The saving in time and expense to both hospital and patient is at once apparent.

FOLLOW-UP STUDY

This is an elderly group of patients, 80 per cent women, whose average age was 66½ years at the time they sustained their fracture of the femoral neck. Under ordinary circumstances there would be a considerable mortality in a similar group over a 5 year period. In the first group of 50 patients we had a 96 per cent follow-up, and in the present series of 60 patients we have a 100 per cent follow-up for an average of 23 months after the fracture for the 51 survivors. We know the end-result in every patient except one in whom sufficient time has not yet elapsed for solid union. Known 5 year results are not common, but we have 6 of them.

Mortality During the first 5 years there were 11 deaths.

Fig. 6. A, An undisplaced fracture of the neck of the femur united, excellent result. L. M. St. Luke's. B, A 69-year-old female 57 years old. C and D, Show fracture of neck of left femur without displacement. E and F, Show union of the fracture 9 months later.

ing December 24, 1936. d and Show the end result 3 years later after removal of nail. Some pain and limp. Patient has worn Thomas caliber brace for almost 5 years.

treated in the main by plaster-of Paris spica bandage a gross mortality of 22 per cent. Four of these deaths were unrelated to the fracture which gave a mortality of 14 per cent attributable to the fracture. Among the second 60 patients there were 12 deaths a 20 per cent gross mortality with 3 deaths occurring 9 months to 3 years after the injury with the fracture solidly united in each instance. This leaves 9 deaths or 5 per cent, as the actual mortality due to the injury. It is interesting to note in comparing these 2 series of patients that operative surgery neither diminished nor increased the mortality in these patients with fractures of the neck of the femur. As might be expected, those patients who died were among the more advanced in years and 78 was their average age.

Union of the fracture. The known and widely accepted difficulty in securing union in these fractures until recently makes this subject one of absorbing interest. In the first series of 50 patients treated without surgery union with excellent function occurred almost entirely among those patients whose fractures showed no original displacement. Only 2 patients whose fractures were reduced by manipulation showed excellent anatomical functional, and cosmetic results.

The second series of 60 patients (53 treated surgically) whose results are herewith presented, shows a very different situation where the results may be interpreted toward the future in all respects.

only 2 of these, or 28 per cent, of those united were excellent results (Fig 5) The 8 undisplaced fractures treated without surgery were all excellent results from every standpoint (Fig 6) Among those patients treated by closed reduction and nailing there were 27 whose fractures united and 24 of these, or 88 per cent, of those united were excellent in every respect (Fig 7) while the 3 others had deformity due to malunion or varying degrees of circulatory disturbance in the femoral head sufficient to cause some symptoms

A comparison of the incidence of union in the two series of cases and of the various methods of treatment in the second series is shown in Table I

To make a long story very short indeed, union of fracture of the neck of the femur, in our hands, increased from 47 per cent of the survivors in the first half decade to 83 per cent of the survivors in the second half decade The credit for this must be ascribed to internal fixation and increasingly improved reduction of these fractures

Circulatory disturbance in the femoral head
The recently completed study by the Fracture Committee of the American Academy of Orthopaedic Surgeons (2) speaks of the incidence and degree of arthritic changes in the femoral head encountered in these fractures The term arthritic changes is misleading, and I believe circulatory disturbance or change is

Fig. Open reduction, malunion. It is bony overgrowths from the acetabular margin. J. McK. St. Luke's No. 4 3503. Female 67 years old. Fracture of neck of right femur December 7 1937 and b, Show fracture and incomplete reduction and d, Show malunion. It is bony overgrowths from the margin of acetabulum. 8 months after operation. This patient had healed and asymptomatic hip when last seen 7 years after operation.

preferable because arthritis of the hip is known and recognized in its various forms, while the alteration of the femoral head due to interference with its blood circulation is a different picture.

Actual arthritic change involving the hip joint following a fracture of the neck of the femur was found only once in this series of 60 patients.

These circulatory disturbances or changes in the femoral head may vary from a mild condensing osteitis to an advanced aseptic necrosis. In our experience they have in variably appeared within the first year after the fracture. We have had no instance in which the circulation failed after the first year had passed and union of the fracture was established.

The greatest predisposing cause of circulatory disturbance in the femoral head is non

union of the fracture. Six of the 8 patients with nonunion showed extensive aseptic necrosis of the femoral head.

Of the 7 patients subjected to open reduction of their fractures which united, 3 had extensive aseptic necrosis of the femoral head an incidence of 42.8 per cent (Fig. 8).

Among the 27 patients with union of their fractures treated by closed reduction and internal fixation 4 had a very slight condensing osteitis (Fig. 9) and 1 had an advanced aseptic necrosis. Three of these 5 patients had incompletely reduced fractures. Of the 8 patients with undisplaced fractures treated without surgery none showed the slightest evidence of circulatory disturbance but 1 patient with an undisplaced fracture which was nailed showed definite circulatory disturbance.

One is forced to the conclusion in this series of patients, that the most important

frequent in the younger age groups, it may be stated that the average age of the 8 patients who showed this phenomenon together with union of the fracture was 62 years, $4\frac{1}{2}$ years under the group average. Those 6 patients with ununited fractures who showed marked

circulatory disturbance in the femoral head were 70 years of age on the average. The circulatory changes encountered among those patients may be summarized as follows, in order of frequency of occurrence:

NONUNION OF THE FRACTURE

This is a problem which is definitely diminishing but will doubtless continue to exist. The situation of these patients can be greatly alleviated as far as pain and instability are concerned by a trochanteric osteotomy of the femur. This operation has been performed on 3 of our 8 patients with ununited fractures with great improvement in their situation (Fig 10).

SUMMARY

Open reduction and internal fixation. In our hands, open reduction and internal fixation of these fractures of the neck of the femur offered very little improvement in end-results over those obtained by nonoperative means. Of the 7 patients whose fractures united, only 2 were wholly satisfactory. There were 3 cases of extensive aseptic necrosis and 2 bad mal-unions with marked deformity. In certain cases of open reduction, there occurred bizarre overgrowths from the acetabular margin, perhaps due to stripping of the periosteum (Fig 11).

Undisplaced fractures. During this period of tribulation in dealing with open reductions, the undisplaced fracture of the neck of the femur, treated by 3 to 4 weeks' rest in bed and weight-bearing after the application of a Thomas caliper brace, gave invariably optimum results. Since our nailing technique has improved, a number of these undisplaced fractures have been nailed without reduction.

Closed reduction and internal fixation. The accurate reduction by manipulation and the careful insertion of a three phlange nail has yielded surprisingly good results, union of the fracture in 86 per cent of the survivors. We make every effort to center the nail in two planes but are not always successful. Overdriving the nail through the articular cartilage of the femur has been done in 4 instances. It is due to carelessness and can readily be avoided.

Circulatory disturbance in the femoral head The circulatory disturbance in the femoral head, based on our experience with these 60 patients, has always appeared within the first year after the fracture. Seventy five per cent of the patients with nonunion of their fractures had extensive circulatory disturbance in the femoral head. Of those subjected to open reduction with their fractures united, 42.8 per cent showed extensive aseptic necrosis of the femoral head. Of those 27 patients with united fractures who were treated by closed reduction and nailing 18.5 per cent showed some evidence of circulatory disturbance, for the most part very mild. The majority of all patients showing circulatory disturbance in the femoral head with fractures united had inadequate reduction of the fracture.

Adequate reduction of the fracture We have found in this series of 60 patients that accurate reduction of the fracture is the most important single factor in securing union and avoiding circulatory disturbance in the femoral head. The actual or so called migration of the

nail is usually due to failure to properly reduce the fracture and this migration occurs almost exclusively in ununited fractures.

Nonunion Patients with nonunion of their fractures may be greatly benefited by a trochanteric osteotomy of the femur.

CONCLUSION

An accurate end-to-end reduction of a fractured neck of the femur by manipulation and fixed by a properly placed three-phlange nail should result in a very high percentage of unions, 86 per cent of the survivors in this series, and a low incidence of circulatory disturbance in the femoral head. This procedure is therefore recommended.

FACTORS IN THE CHOICE OF MATERIAL FOR BONE PLATES AND SCREWS

CHARLES S. VENABLE, M.D., F.A.C.S., San Antonio, Texas

THE qualifications for determining and specifying the basic factors that are essential in internal fixation of fractures with metals should be defined. I see it there are three cardinal principles, three essential factors, which must be accepted and considered as a whole for the single purpose of securing and maintaining fixation without incurring changes that are detrimental to bone and that thus defeat the purpose of mechanical stability. These factors are (1) electrolysis (chemical), (2) physical properties, and (3) application.

ELECTROLYTIC (CHEMICAL) FACTOR

The entire change in our attitude and thought lies in the basic principle involved in the electrolytic factor. Without recognition of potential chemical changes resulting from the use of material affected by body fluids as the cause of deleterious effect upon bone, no matter how strong or how well applied the instrument used, a large percentage of delayed unions, nonunions, and marked bone necrosis as result of local decalcification and even osteomyelitis may be expected to occur.

I am aware that to delve at this time into all the whys and wherefores of electrolysis, the passing of electrons between metals of different potentials of electromotive force set in action by an electrolyte, and the series of changes that occur would not only bore you, but defeat the purpose of bringing about the broader understanding of the principle I desire to express, so I shall try not to be too technical.

Practically all of the so-called metals we use are a composite of different basic elements, each having a potential of different electromotive force and are known as alloys. They offer varying qualities of resistance to the given fluid to which they may be subjected. Some

are more resistant to acids, others to alkalis, but in the variance of the degree of resistance electrons pass from one element to the other. Thus the atoms of one constituent are combined with or separated from those of the other through the mobilization of ions which is electrolytic action. When any alloy, generally referred to as a metal, is spoken of as being passive in a given fluid it is meant that that metal is so resistant to that electrolyte (fluid) that the passage of electrons is reduced to such a minimum that corrosion is practically nonexistent.

When plain iron nails were used in fractures (which is within my memory) they caused little trouble, but when metallurgists began to make steel out of iron by adding elements to it, our trouble began. After our first announcement of the result of a series of experiments in determination of the part electrolytic action had to play, an unfortunate statement was made in error on a similar occasion that "all the changes in bone resulting from the use of metals in fractures ascribed to electrolysis were simple oxidation and were not the cause of loosened screws, or the discoloration of tissue or excess of serous fluid, about the plates and screws," and unfortunately it apparently created a great deal of confusion.

When electrons are removed from an ion atom, or molecule, the substance is oxidized, when electrons are added to a substance it is reduced. Thus every electrochemical change which takes place involves both oxidation and reduction.

If the difference is understood between one pure metal which is not subject to corrosion and a multiplicity of different metals combined into one (an alloy) which is subject to corrosion then it is clear why a single screw or plate—unless it be of a single element—is no longer a single metal and why it will corrode unless made resistant to the fluid to which it is to be exposed.

Presented at the Symposium on Fractures and Other Traumatic Injuries, held at the General Centres of the American College of Surgeons, Chicago, November 27, 1941.

I desire further to emphasize the point that different materials used in conjunction with each other such as the combination of passivated stainless steel screws in a vitallium plate etc. only serve to make stronger and more destructive batteries, though each may be inert if used separately. Only properly passivated steel should be used throughout or vitallium or tantalum should be used throughout. A combination of materials should never be used. An order to this effect has been issued to all Army hospitals by the Surgeon General of the Army.

It must be further understood that metals for use in surgery are passivated to be resistant only to blood serum or normal salt. For instance, 18-8 steel with molybdenum is resistant to solutions of sodium chloride but less resistant to bromine chloride and not at all to iodine chloride therefore the use of other chemicals in a wound, especially iodine in conjunction with metal fixation should be carefully avoided.

There are two recent articles in which use of Dakin's solution (hyperchlorite of soda) is advocated in the treatment of infected wounds in which compound fractures are plated to maintain fixation. Hyperchlorite of soda is a much stronger electrolyte than salt solution and may energize electrons not only in the substance of the plate but throughout the screws and so initiate destructive bone changes about the latter thereby causing an osteomyelitis otherwise avoidable.

Today there is increased interest and effort by metallurgists to create alloys that are as resistant to corrosion as possible for many industries as well as for bone surgery, but the criterion of that resistance which we must understand and demand must be all the more carefully assayed for our use.

The manufacture of alloys is one of the most intricate of technical specialties. It is not so simple as having a formula, just placing the materials in an oven, and creating steel. More over because of the complexity of manufacture each batch turned out must be carefully tested to meet specifications and required standards.

We now have as a guide the basic principle that material must be sufficiently inert in the

body through its chemical resistance to the electrolytic effect of body fluids to remain inert. Through clinical experience and observation over sufficient time we have come to expect and to realize the necessity for the inclusion of this factor in any attempt to standardize the material to meet our requirements.

The Subcommittee on Education of the Committee on Fractures and Other Trauma of the American College of Surgeons, consisting of Drs. Huber, Wagner, Clay, Murray and me is now actively engaged with metallurgists and the Bureau of Standards at Washington in the creation of such standards as are essential to meet our needs, based upon the practical absence of electrolytic changes and assured physical stability. The minimum requirements established are to be based upon results of tests of such materials as have been found to remain passive in experimental animals and in clinical cases for 2 or more years and upon tests of their physical fitness to withstand the stress and strain entailed. It is up to the metallurgists to create such material from available materials to meet these requirements.

PHYSICAL FACTOR

There is much more to the detail of the requirements of physical fitness than shape and size so that, though articles of different design may be added from time to time, all must conform to necessary specifications as to strength, ductility, malleability, fragility, torsion, and resistance to fatigue as well as resistance to corrosion which has been described.

The crucial failure of our previous effort to standardize plates and screws was to allow any manufacturer to produce them according to the formula sanctioned by the Bureau of Standards. The result was that vanadium steel plates appeared on the market with as many different characteristics and sold at as many different prices as women's hats.

The degree of heat applied in preparing the different metals to be combined, the difference in heat during the process, the manner and speed at which they are cooled, the way in which they are mixed as well as the selection of elements for use and the proportions, control the properties of the finished product.

Whether such metals are finished by machine or are cast, and whether or not the constituents are free from impurities, are factors which govern the price. Cheap, impure metal is the bargain stuff of the itinerant salesman. Is not success in attaining union of a fractured tibia worth more than the small difference in the cost of a plate?

The committee in its protocol of standards is not interested in low cost, or is it trying to meet prices. It is proceeding on the basic assumption that the surgeon desires only articles that will aid in the attainment of his goal and furthermore desires to be protected from unreliable gadgets.

The Pure Food and Drug Act protects us from impure chemical products. It is just as important, since we know what chemical and physical properties are essential for safety, that our patients and we be protected from metals that are unfit and may cause harm.

In addition to passivity, however, and to rigidity and strength it is most important that materials have varying properties, some must have machinability, others ductility and tensile strength so that the finest wires may be produced from them. In passing I will say that it is just as important for the abdominal surgeon to have passive material for wire sutures to bury in the tissue, though changes are not as obvious in abdominal surgery, as for the bone surgeon who uses the nail, even though the latter has the additional hazard of calcium changes due to electrolysis—splendidly termed by Masmonet 'electrolytic osteitis'.

APPLICATION

While chemical and physical properties of plates and screws can be made to conform to minimum standards their application in surgery cannot be controlled. Surgical judgment cannot be accurately measured nor technical skill standardized. Instead we can only point out principles for the application of plates and screws which will facilitate their use and will be most likely to ensure success.

Plates must be selected which are of sufficient strength and size to hold the involved bone. Small short narrow plates it goes without saying are inadequate for immobilizing a fractured femur in a large adult. Before the

electrolytic factor was recognized in its effect in the decalcification of bone plates, such as the Sherman type, were made in order to minimize the volume of material, for it was recognized that the deleterious effect of metals seemed to be in proportion to the extent of metallic contact. Now we know that plates may be as wide or as heavy as necessary to meet the requirements of stable fixation. I think that the length of the plate should be at least three times the diameter of the bone involved to provide proper lever support. Moreover, the plate should be shifted about or bent until it conforms closely to the surface of the bone so that a tight grip may be obtained. Whether the plate is thick, or thin, wide or narrow, straight or curved, is unimportant so long as it fits snugly and is sufficiently strong to support the bone ends involved. It should be malleable enough to be bent and still tough enough to meet the strain required.

A single screw on either end of a plate beyond the fracture should never be used as it creates a hinge at the fracture site. Also a plate applied with two screws on one side of a fracture and only one screw on the other side is bad mechanics.

The drill holes for the screws should be about the same diameter as the shank of the screws. A drill slightly larger than the shank makes a hole in which the threads are insecurely anchored and likely to strip out of the bone. A drill slightly smaller makes a hole in which the screws cannot be inserted without great force. As a result, screw drivers slip, screws break, tempers are lost, and the whole operation may be ruined.

An exception to this rule is that a drill must be smaller than the shank of the screw when it is to be inserted in atrophic or decalcified bone. Obviously, in soft bone in which it is difficult to secure any sort of hold with a screw the chances of success are greater when the screws compress the cancellous bone into a more firmly compact media. Conversely the drill should be larger in very hard or curved bone.

The choice of the type of screw to use is easily made if several important points are borne in mind. In the first place long screws obtain a more secure mechanical grip on the

Fig. Types of screws. a, dowel, b, wood plain, c, pull up. Note the obliquity and wider thread of the wood type screw.

bone than short screws and engagement of both cortices of the bone is more likely to prevent motion of the fracture than if only one cortex is secured. Holes drilled entirely through the bone permit the ends of the screws to penetrate the opposite cortex and hold the plate firmly without impeding the tightening of the screws.

Whether one uses a Sherman type of screw with its dowel end that is supposed to drill its way or a machine type of screw rather than a more deeply threaded wood type is immaterial so long as a tight grip is obtained. I personally prefer the last as it seems to obtain better engagement and is easier to apply. Any of these types are applicable to plates in which the detail of counter sinking or special screw heads are subjects of choice.

There is, however, another type of screw (Fig. 1) which is important. This is the wood or "pull up" type of screw which has a smooth shank of the diameter of the thread between it and the head of sufficient length to reach through the proximal cortex. The reason for this is that when the threads have pierced the opposite cortex the distal fragment is drawn tightly against the proximal fragment as the shank turns freely in the proximal cortex with the head against the bone as a fulcrum. A larger drill hole proximally serves the same purpose. On the other hand if threads are engaged in the proximal cortex the opposite fragment will be pushed away no matter how tightly the head may be against the bone. All carpenters know this when they wish to fasten boards tightly together.

After screws and plate are applied to the bone it is essential that adequate support and fixation of the extremity be provided as it is fallacious to assume that a plate alone, no matter how strong, will hold the fracture ends

tightly enough together to permit early exercise unless both peripheries are fixed. While the plate holds the upper periphery together during extension the margins of the opposite periphery are pulled apart. To illustrate if solid plates be substituted for hinges on a door it takes little force to show a crack on the opposite side. So in cases in which but one side is fixed with a plate alone a plaster cast controlling proximal and distal joints is necessary (Fig. 2).

This problem is encountered particularly in transverse or short oblique fractures of the femur and tibia due to the recumbent posture of the convalescent patient in whom it is so essential to maintain knee and ankle function, especially the former in which function is so easily lost. Because of the weight of the leg and the sag in the thigh or leg downward from the point of suspension by the plate on the upper periphery the margins of the lower periphery are separated in an inverted V throughout the width of the fracture ends. This is true no matter what manner of external fixation or support is used or how rigid the plate may be due to laxity of the posterior muscles which are beyond control of external fixation. Such a gap naturally predisposes to delayed union or to nonunion.

To meet this condition and secure an equally rigid fixation of both peripheries a long screw of the pull up or wood screw type placed obliquely to the axis of the plate through the upper surface of the proximal fragment, downward and backward across the fracture site through the cortex of the distal fragment will draw the fracture ends tightly together at the periphery opposite the plate and at the same time prevent any tendency to rotation of either fragment and also will materially lessen lateral movement (Fig. 3). This does not mean however that no external support is necessary that the limb is turned loose and the patient permitted to get up and walk. After suture of an abdominal wound, the patient is kept in bed a reasonable time for wound healing and so for bone healing there must be additional proper support and time allowance. However stable fixation allows almost immediate hip, knee and ankle function. In other words, encasement of the limb in plaster mass and board

Fig 2 "Sag separation" of the periphery distal to the plate resulting from fixation with a plate on but one side of the bone

Fig 3 Stable approximation of distal periphery by engagement with transfixion screw placed obliquely through both fragments

be avoided if possible, while a plaster gutter with suspension in a Thomas half ring splint with the knee joint usually is quite sufficient. Such a procedure may be expected to shorten the period of disability to some 6 to 10 weeks as compared with the 12 to 20 weeks usually allotted.

The long oblique fracture offers yet another problem which, however, is more easily met through control of the distal periphery by complete transfixion of both cortices transversely by the use of pull up or wood type screws to draw the fragments together tightly. Two or more such screws may be so spaced that the fractured surfaces are held so firmly that joint function is admissible directly. In such instances, the addition of a plate is rarely necessary unless there is a complicating transverse fracture in the same field.

In short, bone as other tissue must be closely approximated and held so that it may regenerate promptly in the process of new cell growth. This emphasizes the essential in plating that close approximation of the bone ends must be obtained in all instances whether additional transfixion screws are applied or not. We see far too many cases of delayed union or non-unions because of improper application of a plate in which a gap of a $\frac{1}{32}$ or $\frac{1}{16}$ inch or more has been left.

My theme, however, is in principle, so details of varied technical applications of plates and screws will not be discussed. As I see it, the most important principle evolved is the chemical factor through the understanding of which it now becomes possible to apply direct fixation to fractures under conditions heretofore impossible. Compound fractures occurring in the presence of most severe trauma and infection with the outlook of bone union during the period of healing of an infected and traumatized wound may be expected in a very

high percentage of cases. In many instances it is possible now to plate and close a compound fracture after proper débridement and to expect wound healing as well as bone union as though a simple fracture were present.

During the past war direct fixation was forbidden because metals we then had were highly electroactive and increased the damage through deleterious bone changes so that non-union and even amputation resulted. Today we can feel safe in using metals for we now have available material that is passive, this fact has been proved in the recent past in the most severely traumatized and infected compound fractures occurring in the toll of automobile and airplane accidents as well as in industrial surgery. The same expectancy of greatly diminished nonunions and even amputations may now be expected in compound fractures occurring in war wounds.

SUMMARY

The first two factors, chemical and physical fitness, in the material for use in the treatment of fractures are supplied us by metallurgists, the third factor, application, must be mastered by each of us individually by an understanding of the mechanical principles involved, skillful technique, and that judgment acquired only through training and experience.

The introduction into bone surgery of material that is so tolerated as to cause no disturbance, opens fields we have not before known, but we must warn that it becomes a dangerous tool in the hands of those not qualified to use it. The same hesitancy and respect should be felt in operating to reduce fractures as in performing gastrectomies or in operating upon the brain. I say this because I believe that though the first two factors which have been mentioned are essential, the last—application—is the *sine qua non* of success.

Fig. 1. Types of screw. a, dowel; b, wood-plain; c, wood-pull up. Note the obliquity and finer thread of the wood type screw.

bone than short screws, and engagement of both cortices of the bone is more likely to prevent motion of the fracture than if only one cortex is secured. Holes drilled entirely through the bone permit the ends of the screws to penetrate the opposite cortex and hold the plate firmly without impeding the tightening of the screws.

Whether one uses a Sherman type of screw with its dowel end that is supposed to drill its way or a machine type of screw rather than a more deeply threaded wood type is immaterial so long as a tight grip is obtained. I personally prefer the last as it seems to obtain better engagement and is easier to apply. Any of these types are applicable to plates in which the detail of counter sinking or special screw heads are subjects of choice.

There is however another type of screw (Fig. 1) which is important. This is the wood or "pull up" type of screw which has a smooth shank of the diameter of the thread between it and the head of sufficient length to reach through the proximal cortex. The reason for this is that when the threads have pierced the opposite cortex the distal fragment is drawn tightly against the proximal fragment as the shank turns freely in the proximal cortex with the head against the bone as a fulcrum. A larger drill hole proximally serves the same purpose. On the other hand if threads are engaged in the proximal cortex the opposite fragment will be pushed away no matter how tightly the head may be against the bone. All carpenters know this when they wish to fasten boards tightly together.

After screws and plate are applied to the bone it is essential that adequate support and fixation of the extremity be provided as it is fallacious to assume that a plate alone, no matter how strong, will hold the fracture ends

tightly enough together to permit early exercise unless both peripheries are fixed. While the plate holds the upper periphery together during extension the margins of the opposite periphery are pulled apart. To illustrate if solid plates be substituted for hinges on a door it takes little force to show a crack on the opposite side. So in cases in which but one side is fixed with a plate alone a plaster cast controlling proximal and distal joints is necessary (Fig. 2).

This problem is encountered particularly in transverse or short oblique fractures of the femur and tibia due to the recumbent posture of the convalescent patient in whom it is so essential to maintain knee and ankle function, especially the former in which function is so easily lost. Because of the weight of the leg and the sag in the thigh or leg downward from the point of suspension by the plate on the upper periphery the margins of the lower periphery are separated in an inverted V through out the width of the fracture ends. This is true no matter what manner of external fixation or support is used or how rigid the plate may be due to laxity of the posterior muscles which are beyond control of external fixation. Such a gap naturally predisposes to delayed union or to nonunion.

To meet this condition and secure an equally rigid fixation of both peripheries, a long screw of the pull up or wood screw type placed obliquely to the axis of the plate through the upper surface of the proximal fragment, downward and backward across the fracture site through the cortex of the distal fragment will draw the fracture ends tightly together at the periphery opposite the plate and at the same time prevent any tendency to rotation of either fragment and also will materially lessen lateral movement (Fig. 3). This does not mean however that no external support is necessary, that the limb is turned loose and the patient permitted to get up and walk. After suture of an abdominal wound, the patient is kept in bed a reasonable time for wound healing, and so for bone healing there must be additional proper support and time allowance. However stable fixation allows almost immediate hip, knee and ankle function. In other words, encasement of the limb in plaster may and should

Fig 2 "Sag separation" of the periphery distal to the plate resulting from fixation with a plate on but one side of the bone.

Fig 3 Stable approximation of distal periphery by engagement with transfixion screw placed obliquely through both fragments

be avoided if possible, while a plaster gutter with suspension in a Thomas half ring splint with the knee joint usually is quite sufficient. Such a procedure may be expected to shorten the period of disability to some 6 to 10 weeks as compared with the 12 to 20 weeks usually allotted.

The long oblique fracture offers yet another problem which, however, is more easily met through control of the distal periphery by complete transfixion of both cortices transversely by the use of pull up or wood type screws to draw the fragments together tightly. Two or more such screws may be so spaced that the fractured surfaces are held so firmly that joint function is admissible directly. In such instances, the addition of a plate is rarely necessary unless there is a complicating transverse fracture in the same field.

In short, bone as other tissue must be closely approximated and held so that it may regenerate promptly in the process of new cell growth. This emphasizes the essential in plating that close approximation of the bone ends must be obtained in all instances whether additional transfixion screws are applied or not. We see far too many cases of delayed union or non-unions because of improper application of a plate in which a gap of a $\frac{1}{32}$ or $\frac{1}{16}$ inch or more has been left.

My theme, however, is in principle, so details of varied technical applications of plates and screws will not be discussed. As I see it, the most important principle evolved is the chemical factor through the understanding of which it now becomes possible to apply direct fixation to fractures under conditions heretofore impossible. Compound fractures occurring in the presence of most severe trauma and infection with the outlook of bone union during the period of healing of an infected and traumatized wound may be expected in a very

high percentage of cases. In many instances it is possible now to plate and close a compound fracture after proper débridement and to expect wound healing as well as bone union as though a simple fracture were present.

During the past war direct fixation was forbidden because metals we then had were highly electroactive and increased the damage through deleterious bone changes so that non-union and even amputation resulted. Today we can feel safe in using metals for we now have available material that is passive, this fact has been proved in the recent past in the most severely traumatized and infected compound fractures occurring in the toll of automobile and airplane accidents as well as in industrial surgery. The same expectancy of greatly diminished nonunions and even amputations may now be expected in compound fractures occurring in war wounds.

SUMMARY

The first two factors, chemical and physical fitness, in the material for use in the treatment of fractures are supplied us by metallurgists, the third factor, application, must be mastered by each of us individually by an understanding of the mechanical principles involved, skillful technique, and that judgment acquired only through training and experience.

The introduction into bone surgery of material that is so tolerated as to cause no disturbance, opens fields we have not before known, but we must warn that it becomes a dangerous tool in the hands of those not qualified to use it. The same hesitancy and respect should be felt in operating to reduce fractures as in performing gastrectomies or in operating upon the brain. I say this because I believe that though the first two factors which have been mentioned are essential, the last—application—is the *sine qua non* of success.

RESULTS IN COMPOUND FRACTURES WITH OSTEOMYELITIS AS EXPERIENCED BY THE VETERANS ADMINISTRATION OVER THE PAST TWENTY YEARS

S. K. LIVINGSTON M.D. F.A.C.S. White River Junction Vermont

IN modern warfare low velocity missiles cause the majority of compound fractures with their associated lacerations and contusions contaminated by clothing and skin resulting in gross infection after about 12 hours.

The standard treatment during and subsequent to the last war for compound fractures and osteomyelitis, according to the Surgeon General's Report of the Army for 1927 was as follows: (a) proper splinting for transportation and first aid (b) debridement (c) skeletal traction and/or other immobilization (d) Carrell Dakin treatment or dichloramine T (e) surgery other than debridement as indicated (f) amputation and plastic repair (g) physical therapy.

During the fiscal year of 1926 a summary of fractures and amputations of the long bones was studied by the Veterans Administration. The greatest number of fractures, 4,736 occurred in the humerus the next greatest in the femur. The greatest number of deaths, 1,060, or 35.03 per cent, resulted from fractures of the femur.

The tables covered a study of 22,954 fractures of the long bones over a period of 6 years. This group formed 5 per cent of the World War Veterans disabled to a compensable degree. The rating schedule used throughout the period under study based the degree of disability upon the average impairment of earning capacity resulting from injuries in civil occupations. On that date, 15,597 or 54 per cent of the fractures had reached a stationary level, which was reasonably certain to continue throughout the claimant's life. Thirty nine per cent of the total showed improvement and 7 per cent had retrogressed.

Fractures of the femur comprise the group of most serious injuries in the length of time required to reach a stationary level and in the high degree of disability. Amputation of the

TABLE I.—SURGEON GENERAL'S REPORT

	1927	No. cases	Per cent	No. days
Fractures following gunshot wounds—6 % returned to U. S. for treatment		5,27		
80.3 % compound		6,006		
Fractures, nonbattle, due to injuries, simple		30,559		
Total		70,847		
Percentage of injuries caused by low velocity missiles			70.41	
Loss of one or more extremities		4,403		
Associated joint involvement (ankylosis, flail joints, contractures, etc.)		4,970		
Percentage of total discharges for disability due to fractures		740	45.6	
Days lost due to fractures				5,135,220
Per cent of all days lost due to all causes			39.3	
Average duration of treatment				5.39
Percentage of deaths as result of fractures in comparison to total			30	
No. deaths from fractures		757		
Total No. deaths		470

Radius and ulna	2 340	10	11 22 55	521	390	1 003	204	381	03

thigh contributed largely to the high rate of disability Table IV and the amputation report, by specific bone or bones, show the interval elapsing between the injury and the amputation Of the 4,179 amputations, 3,044 or 73 per cent were done within the first 15 days after injury The United States thus profited by the experience of the French and British by having mobile hospitals sufficiently equipped with surgeons and instruments to perform major surgery within the first 72 hours after injury

It should be noted that the average period of disablement is greatly in excess of the period recorded by observers for industrial fractures This is because the greater number of these fractures were compounded due to severe battle injuries Many of them later became septic with much destruction of tissue, including osteomyelitis, resulting in lasting deformity and much impairment of function Therefore, the character of these

fractures is of a far different type from those of civil life so the final results are not comparable

AMPUTATION REPORT

Phalangeometatarsal and transmetatarsal amputations These were infrequent but amputations in this area gave good function

Lisfranc's amputations at the transmetatarsal joint gave reasonably good function The dorsal flexors should be anchored to the ends of the bones to preserve dorsal flexion

Transarsal amputations Distal to Chopart's joint was preferable to Chopart's amputation, as proper balance of the dorsal and plantar flexors of the foot was better preserved

Chopart's amputations resulted in poor function Plastic repair did not usually improve the function and reamputation was often necessary Equinus deformity frequently developed and the stump was too short for proper prosthesis

Pirogoff's amputation Displacement of the remaining portion of the calcaneus was common The total end bearing stump, following the Syme's amputation, is quite as satisfactory

Syme's amputation The chief advantages in the Syme amputation were that it was total end bearing and the length of the limb was approximately preserved so the patient could get about without his prosthesis This amputation has been found highly satisfactory and must be considered as a site of election

Leg, lower third All cases observed as a reamputation because of poor vascularity and complications

Amputation of leg (calf) was considered in the Surgeon General's Report, 1927, as the ideal site for anatomical and prosthetic reasons Subsequent experience in the Veterans Administration has shown a high percentage of neuromas, ulcers, painful stumps, and painful weight bearing surfaces Reamputation (Gritti-Stokes or thigh) has been found the only answer to the problem in many of these cases

TABLE IV—STUDY OF END-RESULTS IN FRACTURES OF LONG BONES BY THE U S PUBLIC HEALTH SERVICE AND U S VETERANS ADMINISTRATION, 1919-1926

AMPUTATIONS

Interval elapsing between injury and amputation	Days 1-31	Months 2-48	Over 4 years	Death	Total
Thigh	1,374	354	14	76	1 818
Leg	860	250	25	40	1 190
Arm	641	44	3	39	727
Forearm	391	7	3	23	444
Total	3 66	681	45	187	4 170

Thigh. Knee joint and transcondylar amputations were found satisfactory. Gritti-Stokes amputation required a high percentage of reamputations (Surgeon General's Report, 97). Subsequent experience points with favor to this operation provided the patella has firmly adhered to the femur and is well placed. Amputations at various levels from high transcondylar to inches below the lesser trochanter have proved satisfactory. Amputation through the neck of the femur has been found preferable to disarticulation at the hip joint.

Hand. Cases in which only a débridement with heroic efforts to save all these possible pedicle transplants, and plastic repairs offered the most desirable results. Transcarpal amputation was found preferable to amputation at the wrist. Wrist joint amputation was preferable to any higher plane. The club-like stump eliminated much apparatus in the prosthetic hand.

Forearm. Amputation of the forearm should be done as low as possible. The importance of preserving supination and pronation warrants careful treatment of the periosteum to prevent bridging. A forearm stump should not be sacrificed to overcome painful scars, ulcers, etc., but plastic measures should be used on the soft structures.

Arm. Transarticular and transcondylar amputations have not proved satisfactory from the standpoint of prosthesis. Above this level all possible bone length should be saved. Short arm stumps may be improved so far as leverage is concerned by severing or raising the insertions of the pectoralis muscles, the latissimus dorsi, and teres major. The head of the humerus should always be saved if possible, to preserve the contour of the shoulder.

CONCLUSIONS

1. Eighty and thirty-one hundredths per cent of battle fractures were compound, nearly one-half of all discharges, nearly one-third of all days lost and one-fifth of all deaths were the result of fractures.

2. About one-half of all compound fractures required more than 5 years before becoming stationary.

3. The relatively large number of late amputations indicates early surgery is advisable and that mobile hospitals should be equipped for major surgery.

4. Seven years after World War I the majority of compound fracture cases were compensable from 10 per cent to 50 per cent, with a smaller but still large number from 50 per cent to 100 per cent.

5. In 1930 there were about 10,000 old and recent cases of osteomyelitis in the Veterans Administration due to all causes. From the treatment of these cases the following conclusions may be drawn:

a. In cases of compound fractures early anatomical alignment should be accomplished by open or closed manipulation with maintenance by external or internal fixation. Hardware, such as Parham bands, Lane or Sherman plates, screws, etc., may be applied at the time of the débridement, the presence of infection not being considered a contraindication.

b. A thorough but careful early débridement is advisable.

c. Antigas and antitetanus serum should be administered prophylactically in all cases. Only too often is antigas serum omitted. The prophylactic use of these serums is again advised before delayed surgery is attempted.

d. Lacerations should be sutured early with interrupted silk sutures which may be easily removed if necessary.

e. The early intravenous use of blood serum or plasma is a great aid in the treatment of shock.

f. The use of the sulfonamides by mouth and locally is strongly recommended.

g. Sequestrectomy in chronic osteomyelitis should be thorough and include areas of osteosclerosis. In a slowly but steadily progressing molecular necrosis wide excision to areas obtaining their blood supply from collateral circulation or amputation is indicated. Osteomyelitis of the lower third of the tibia, especially if involving the ankle joint, usually results in amputation and this is recommended early.

h. Syme's and Gritti-Stokes amputations are amputations of election. Amputation at the calf is usually to be condemned. A mid thigh or Gritti-Stokes amputation is preferable.

i. Maggot therapy although condemned by many is an effective treatment for osteomyelitis, as is the Orr method.

j. Local irrigating solutions, antiseptics, and pastes of various kinds have not proved effective in the treatment of osteomyelitis.

PRECANCEROUS LESIONS

C P RHOADS, M D , New York, New York

BY definition, a precancerous lesion is one in which, statistically, the tissue is more likely to become invasive and metastasizing than is tissue involved in other, non-precancerous types of change. Since I have been asked to discuss precancerous lesions, and the exact phase of the topic was not specified, I infer that considerable latitude has been left to my judgment. I have chosen, accordingly, to discuss a view in which I am particularly interested and toward which all the investigative energies of my group have been directed for a number of years. It would be redundant to present before this assembly the conventional statements regarding the changes which are considered to be precancerous. It is common knowledge that oral and vulval leucoplacia tend to become neoplastic, and that keratoses of the skin are very likely to do so. Less well known is the fact that only certain forms of mammary epithelial hyperplasia are prone to become malignant, and that the precancerous alterations of the gastric mucosa are not well understood. To obtain a better comprehension of the nature of the precancerous lesions, it is desirable to ascertain, from the study of those which have been proved, some common factor. Then, by the methods of modern scientific investigation, it should be possible to establish the means by which this common factor can be regularly induced in man and animals. Once such a mechanism were established, rational prophylaxis would follow logically, and only by the development of prophylactic methods are we likely to advance materially the cure of cancer, barring, of course, the occurrence of some major technical development.

What, then, is the common factor to be discerned in those changes which are known to tend to become neoplastic? In the skin, in the oral cavity, as well as in the hematopoietic apparatus, this common factor appears to be a chronic irritative one, but actually is probably an atrophy due to some mechanism which prevents the normal life and reproduction of the affected cells. Similarly, atrophy may well play a rôle, although as yet unproved, in the precancerous lesions of the genital organs, notably the breast, the uterus,

and the prostate. At least one is safe in stating that cancer of these organs occurs at a time when their epithelium becomes functionally inactive, and when the metabolism of the specific chemicals, the sex hormones, which control their activity, becomes gravely altered. It is fair to assume, then, from the evidence, that the overgrowth which, when uncontrolled, is neoplastic, is in some instances a pathological response to the cause of the primary atrophic lesion. Obviously, then, it is desirable to establish clearly the cause of tissue atrophy in general.

In Table I are presented recognized examples of cancer which is known to follow the appearance of an atrophic process. Among these certain ones stand out as disorders without any known etiology. In at least three types, however, one can advance rather strongly suggestive evidence concerning causation. These types affect the skin, the liver, and the hematopoietic apparatus.

The evidence concerning the atrophic and precancerous lesions of the skin is clear, and needs little further discussion, since methods of measuring the function of its cells are not well established. As concerns the blood-forming organ, somewhat more information is available. From the observations of Hunter and Mallory, to which we have been able to add confirmatory evidence (3), it is clear that exposure to compounds of a known chemical structure, notably benzene, will cause, first, an atrophy and later the malignant overgrowth which we call leucemia. These changes are illustrated in Figs 1 and 2.

Liver cancer, however, provides a particularly useful experimental tool, since in the animal it can be produced regularly under certain circumstances by a compound of known chemical constitution. Furthermore, in the animal sufficient

Fig. 2.

quantities of liver tissue for analysis can be made available easily. It is desirable, then, to examine the facts in order to ascertain to what extent liver cancer represents a primary atrophy followed by a malignant overgrowth, and how far experimental liver cancer is analogous to liver cancer in man. Kinosita has proved that the feeding of dimethylaminocarbenzene (butter yellow) to rats taking a diet of rice will produce regularly hepatic cirrhosis followed by hepatic cancer. Cirrhosis is clearly an atrophic process, and in this instance is precancerous.

How far can the analogy be drawn between this type of experimental neoplasms and liver cancer in man? Some points of similarity certainly exist. Human liver cancer tends to occur on a basis of cirrhosis, a point clearly proved by a recent communication from South Africa. In a very large series of patients with hepatic malignant neoplasms cirrhosis was always present.

What, then, is the nature of cirrhosis? Clearly it is a process which involves damage or death of normal liver cells and their replacement by regenerative tissue. How then, can this basic process of atrophy be induced, and why should the regenerative effort of the liver give rise to cancer? The experiment of the Japanese workers previously described provided a method for the analysis of these problems. Obviously it was desirable to ascertain how the combination of a rice diet and the administration of butter yellow operated to produce the primary cellular damage marked by

atrophy. Kensler and Segura, in my laboratory immediately attacked the problem. First they proved that the experiments described by the Japanese could be repeated regularly. Next the diets were analyzed to see what factor in them was lacking and was supplied by yeast. Third, the effect of butter yellow feeding on liver cells was examined and fourth, the compounds into which butter yellow is broken down in the animal were isolated and identified. We proved that at least two factors were lacking in the diet which rendered the animals susceptible to liver cancer following the ingestion of butter yellow. The effect of the feeding of this carcinogen was found to be a poisoning of the activity in the liver cells of certain enzyme systems required for the respiration and metabolic function of normal cells. Here then, was an explanation of the atrophic or precancerous process. Next the particular breakdown product of the chemical carcinogen which interfered with the respiration of normal cells was identified. Finally certain evidence was obtained as to how this injurious effect was exerted. The fact became clear that the cancer-producing chemical induced atrophy of liver cells by competing successfully for the protein component of the cells without which their enzyme systems could not operate. If the efforts of the cancer-producing chemical to steal the enzyme protein could be directed into innocuous channels it would be possible to prevent the cancer-producing effect.

Why, then, does malignant overgrowth take place? All the details of this mechanism are, of course, not as yet worked out. One fact does appear clear, however. The cancer recurs and grows in the face of a milieu which is incompatible with the life and growth of normal cells. One would infer, therefore, that the cancer cell is malignant because it has developed some new way of life which renders it insusceptible to damage by the chemical compound employed in the experiment and concurrently immune to normal growth restraint. Were this the case, the compound involved in our experiments should stop the respiration of normal liver cells and not that of liver cancer cells. This is the case. Furthermore, this observation should be confirmable by another technique in another laboratory. Robert Chambers, at New York University, has confirmed the observation in tissue culture. Here, again, a concentration of a toxic breakdown product of butter yellow which will kill normal rat liver cells has no effect upon the growth and multiplication of liver cancer cells.

It may be argued that this type of fundamental work has no bearing on the problem of cancer in man. This may be the case, but if, as we assume from the results of the experiments described, the cancer cell is different in its respiratory mechanism from normal cells, it is not impossible that the future will provide us with effective chemotherapeutic agents.

THE RÔLE OF THE RADIOLOGIST IN THE CANCER CLINIC

GEORGE W. HOLMES, M.D., Boston, Massachusetts

DURING the past 25 years there has been a considerable advance in our knowledge of and our interest in, the diagnosis and control of cancer. Early in this development it was recognized that some methods of attacking the problems should be devised which would bring together those physicians and scientists interested in the problem and which would permit the grouping of patients suffering from this disease for study and follow-up. In an attempt to solve this problem two plans have been developed which have received general acceptance throughout the world, namely, the cancer hospital, and the tumor clinic—both of these methods have advantages and disadvantages.

The cancer hospital is a considerably older development in point of time than the tumor clinic and in general it may be said that this method of approach has been more successful in fundamental research and in adding to our knowledge of the whole problem than has the tumor clinic. On the other hand, the tumor clinic has been outstanding in the therapeutic field and seems to be a better method of bringing a knowledge of the disease to physicians in general.

The cure of cancer is still largely a surgical problem. Irradiation being reserved for those patients who have passed the stage in which surgery can reasonably be expected to effect a cure or in whom for some reason surgery is contraindicated. If this general statement is accepted, the treatment of curable cancer then becomes largely a question of surgical skill. No surgeon is equally skillful in operating upon all parts of the human body; surgeons have recognized this fact, and specialization takes place along anatomical lines rather than by disease. The surgeon working in a cancer hospital must of necessity confine himself almost wholly to the treatment of cancer in some particular anatomical location and it is questionable whether or not a surgeon would receive sufficient material for his proper development in a cancer hospital except in a few very large centers of population. As a matter of fact most cancer hospitals do not attempt to

treat cancer in all of its anatomical manifestations, as for example tumors of the brain, lungs, and gastrointestinal tract. In most of the cancer hospitals today surgery plays a minor rôle, the major effort being devoted to research and radiation therapy.

The tumor clinic, on the other hand, offers an excellent opportunity for the development of surgical treatment in all fields of cancer. The operating surgeon in these clinics occupies an important position on the surgical staff of a large general hospital and the material which he has for study is ample. Another advantage of the tumor clinic is that its work is brought directly to the staff of the general hospital and to the practicing physicians of the community. In this way these physicians obtain first hand knowledge of the problem, rather than obtaining such information from occasional visits to large cancer centers or through the literature.

In so far as I am able to determine the first tumor clinic, as it is known today, was established at the Massachusetts General Hospital in 1925 and grew out of a consultation service developed by the department of radiology dating back to 1919 when the first consultant was appointed to this clinic. At the Clinical Congress of the American College of Surgeons held in Philadelphia in 1930 Dr. Robert B. Greenough read a paper in which he described the work of the tumor clinic and told of its developments. The advantages of the clinic as stated by him at that time were as follows:

The work in cancer cases is placed in the hands of those members of the staff who are most interested in that subject.

Opportunity is given by consultation with representatives of the clinical, pathological, and radiotherapeutic departments for mutual instruction and increase of knowledge of the disease and its treatment.

3. A definite rational plan of treatment can be determined for each individual case, after consultation and the results can be checked and discussed, by the group, in the subsequent follow-up.

4. Concentration of the hospital material permits greater experience and more productive work.

5. The standards of the hospital for efficient diagnosis and treatment of cancer are inevitably raised, and the educational effect extends beyond the hospital to medical students and to physicians in general practice in the immediate vicinity.

From the Massachusetts General Hospital.
Presented at the Cancer Symposium before the Clinical Congress of the American College of Surgeons, Boston, November 2-

6 The additional expense to the hospital involved in the maintenance of the tumor clinic amounts only to about \$3000 00 a year

This report received the favorable attention of the College and the development of similar clinics in other centers has been largely due to their effort

The personnel of a tumor clinic should consist of a surgeon, or better, a group of surgeons trained and interested in the treatment of cancer, a radiologist, or group of radiologists, similarly trained and interested in the problem, an internist, a pathologist, a social service worker, and one or more clerks and nurses. It is of the greatest importance that the physicians composing the staff be on a somewhat equal footing. The clinic should not be dominated by either the surgeon, the radiologist, the pathologist, or the clinician. The executive head of the clinic should be chosen for his personal qualifications and for his interests in the problem as a whole, rather than because of his position in any one field of medicine.

At the present time, at the Massachusetts General Hospital, the direction of the tumor clinic is in the hands of a committee which represents surgery, medicine, radiology, and pathology—the chairman of the committee being the chief surgeon. All appointments to the staff are approved by this committee on the recommendation of the chief of the service involved.

The tumor clinic acts primarily as a consulting and follow-up service. The treatment, whether it be surgical, medical, or radiological, is under the control of the chief of the general medical, surgical, or radiological service. Much of this treatment is handled by special assignment by members of the tumor clinic regarding treatment receives serious consideration. It has been found advantageous to carry on a certain amount of minor surgery in the tumor clinic itself, such as the taking of specimens for biopsy or the removal of small superficial lesions. It has also been found desirable to hold the clinic in close contact with the x-ray therapeutic department, this encourages the follow-up of patients and makes available to the department of radiology immediate surgical or medical consultations. Patients referred to the clinic for consultation are first seen by the resident surgeon or radiologist assigned to the department and are referred to the specialty in which the location of their disease places them. Whether or not other specialists are asked to see the patient will depend largely upon the possibility of surgical, medical, or radiation therapy. The opinions given to the service referring the patients is that of the clinic as a whole, rather

than of a single individual in most cases and in all controversial cases. Since the treatment of cancer in most cases at the present time is either surgical or radiological the selection of cases for these procedures is of great importance. In arriving at a decision many factors should be considered, most important of which are the stage of the disease, histology of the tumor, the age and condition of the patient, the location of the tumor, and the chance of cure or relief by the various methods of treatment. It is not sufficient for the surgeon to state in a given case that he believes the disease is curable by surgery. He must also state the amount of permanent damage resulting from the operation and the risk, the same is true regarding the opinion of the radiologist. If, in the opinion of the surgeon, the tumor cannot be removed completely, or if the operative risk is too great, irradiation should be considered. An attempt to cure by irradiation usually results in considerable discomfort for the patient and in permanent damage to tissue in the radiated field. It should not be undertaken unless there is a reasonable chance of cure. Palliative treatment, on the other hand, will often control the disease for a considerable period of time and relieve suffering. It is important that this distinction be recognized and that the treatment be not too prolonged or severe with an incurable patient.

The selection of the kind of irradiation in a given case will depend largely upon the location and character of the tumor. The use of radium in our clinic has decreased rapidly during recent years and is now largely confined to treatment within accessible body cavities, an excellent example of which is the uterine cervix. It may be used to destroy a residual tumor after irradiation with x-ray, but this field of its use is definitely limited, needles or seeds should not be inserted where there is danger of infection. Since the use of radium at the present time requires, in most cases, a surgical operation we have found it more satisfactory to allow the surgeon to carry out the entire procedure rather than to call in a radiation therapist to apply the radium. The application of radium as used today is relatively simple and the surgeon can master the radiation technique with much greater ease than the radiologist can the surgical technique. The use of irradiation with x-ray, either preceding or following a surgical procedure, also has, in our opinion, a limited field of usage, although it has in the past been used extensively.

Postoperative irradiation, rarely if ever, cures a patient who was incurable by surgery in the beginning, although it may prolong the period in

which the patient is free of recurrence. Nor will preoperative irradiation make an inoperable case operable. The feeling prevalent among some surgeons that, if the operation fails, irradiation may be used to effect a cure should be discouraged. An operation should not be attempted unless there is reasonable chance of cure. These patients are better handled by irradiation alone. Post operative irradiation should be used in those cases in which after operation, it is found necessary to change the original diagnosis. In those cases in which the surgeon realizes at the time of operation that he is unable to remove the tumor completely or in which histological examination of the tumor following operation shows the disease to be of high degree of malignancy. In this latter group, particularly if the tumor is known to be radiosensitive, preoperative irradiation in rather small doses may be found to be of value.

It has been our experience that the best results are obtained when the therapeutic procedure is planned after consultation between the surgeon and the radiologist. The procedure then is carried out as a joint undertaking in which either of the consultants may proceed independently calling the other in for consultation when his method has failed.

The tumor clinic affords an excellent opportunity for free discussion of the therapeutic procedure to be adopted in individual cases, and the end-results made available by the follow-up system allows comparison of results.

Perhaps it may seem to you that I have wandered considerably from the subject which I was asked to discuss, namely "The Role of the Radiologist in the Cancer Clinic," but to me it seemed necessary to state the fundamental principles involved in the management of a cancer clinic before attempting to answer the question—which, after all, can be stated in a few words.

The position of the radiologist in the tumor or cancer clinic is that of any other members of the professional staff—that of a consultant.

The physician in charge of the patient will make the final decision after he has received the advice of the various specialists connected with the clinic and the treatment accepted will be carried out by the physician or service to which the patient is referred. The physician should accept full responsibility once the patient is placed in his hands. In other words, if after consultation and discussion surgical treatment is believed to be the method of choice, the responsibility should be in the hands of the surgeon in charge.

If on the other hand, irradiation is considered the method of choice, the radiologist is responsible for its administration and for the care of the patient during the time in which it is being administered.

Any attempt to direct the surgical procedure by the radiologist or the radiological procedure by the surgeon can result only in confusion.

Finally the position of any specialist in the clinic depends to a large extent upon his ability and his willingness to serve.

RADICAL SURGICAL TREATMENT FOR CARCINOMA OF THE CARDIAC END OF THE STOMACH

JOHN H. GARIOCK, M.D., F.A.C.S., New York, New York

IN a recent communication I called attention to the fact that the renewed interest in the surgical treatment of cancer of the thoracic esophagus has centered attention on a problem in abdominal surgery which has received little recognition in the past. I refer to carcinoma of the cardiac end of the stomach. In spite of rapid advances in the diagnostic methods of roentgenography, esophagoscopy and gastroscopy, and improvement in surgical technique, surprisingly few attempts have been made to extirpate cancer of the cardiac end of the stomach. The paucity of reports in surgical literature of this subject is noteworthy. Sustained interest in a subject such as the surgical treatment of cancer must be maintained by repeated and continued reports of encouraging progress in the fight against this disease. With this in mind, I would like to summarize my experience with the surgical treatment of carcinoma of the cardia to date, enlarging somewhat on a few of the details reported in the paper already referred to.

The cardia of the stomach may present considerable variation in size, shape, and position. In most individuals, the terminal one half to three-quarters of an inch of esophagus lined by squamous epithelium, occupies an intra-abdominal position just below the diaphragm. It is known as the cardiac antrum. Operative experience has shown that the junction between esophagus and stomach is usually sharply defined and is indicated by an indentation on the greater curvature side, the incisura cardiaca. At the point of union with the esophagus, the musculature and mucous membrane of the stomach are thickened to form what I believe to be a cardiac sphincteric mechanism. Although the anatomy textbooks do not stress this point, I am convinced from clinical experience that the muscular thickening at the cardiac orifice acts as a sphincter to prevent regurgitation of gastric contents into the lower esophagus. The pars cardiaca is that portion of the stomach at, and just distal to, the point of union with the esophagus. It extends to the greater

curvature side to include the upper part of the fundus. The cardiac orifice is usually situated at the level of the eleventh thoracic vertebra behind, and the seventh left chondrosternal junction in front. At the esophagocardiac junction, there is a sharp change in the histological characteristics of the mucous membrane. Above, the mucosa is of the squamous cell variety, while below, it assumes columnar characteristics. It is important to remember therefore that carcinomas originating in the cardia assume the histological features of an adenocarcinoma in contradistinction to the squamous cell tumors arising in the esophagus. An adenocarcinoma of the cardia may grow upward along the lower esophagus for a considerable distance. The biopsy specimen obtained by esophagoscopy will always indicate the origin of the tumor. It is important to stress this point because on numerous occasions I have heard the statement made that the finding of an adenocarcinoma in the lower esophagus often indicated malignant degeneration in misplaced gastric mucosa. This I believe to be completely inaccurate because a large operative experience has proved that every instance of adenocarcinoma of the esophagus has originated in the cardia or upper stomach.

It is important to stress what direction the lymph node spread may take from cancers of the upper end of the stomach. In general, the initial spread is toward the nodes in the gastrohepatic omentum and those located along the greater curvature near the incisura. Involvement of the peripancreatic nodes may occur late in the disease. In general, it may be said that adenocarcinomas arising at the cardia spread peripherally below the diaphragm toward the gastrohepatic or gastric lymph nodes, depending in part, upon the location of the tumor with respect to the lesser or greater curvatures. Extension above the diaphragm to the nodes in the posterior mediastinum occurs not infrequently. Early metastatic involvement of the liver is a frequent finding. This is unpredictable and is dependent upon chance invasion of the gastric veins by tumor tissue with extension to the portal system. As with carcinoma elsewhere, the prognosis is materially altered when gross node involvement is demonstrated.

TABLE I.—ESSENTIAL DETAILS OF THE CASES REPORTED IN THIS PAPER

Patient's Sex Age	Approximate duration of symptoms	Location of tumor	Biopsy	Operation	Postoperative complications	Follow up	Remarks
R. Z. M. 62	5 mos.	40	Adenocarcinoma	10-12-30 Abdominal exploration, inoperable	None	Died of disease months later	
L. S. M. 56	mos.	30	Adenocarcinoma	10-29-30 Thoracic exploration, inoperable, gastrostomy performed	Fulminating peritonitis at autopsy	Died on third day	At present time, would explore abdomen first to determine operability
M. M. M. 60	1 1/2	40	Adenocarcinoma	10-6-30 Transverse resection, inoperable. Gastrostomy performed	None	Died 2 mos later	At present time, would explore abdomen first to determine operability
S. R. F. 58	1 1/2	33	Adenocarcinoma	2-11-30 Abdominal exploration, transverse resection with gastrostomy	None	Well 18 months post-operative	One lymph node showed involvement
A. M. M. 60	About 2 mos.	40	Adenocarcinoma	6-6-30 Abdominal exploration. Transverse resection with gastrostomy	None	Well 18 months post-operative	No involved nodes found
C. L. M. 60	mos.	30	Adenocarcinoma	2-7-30 Abdominal exploration, inoperable. Jejunostomy performed	None	Died of disease 2 mos later	
H. S. M. 67	mos.	40	Adenocarcinoma	6-21-30 Abdominal exploration, inoperable	None	Died 2 mos later of disease	
S. L. M. 63	10 wks.	35	Adenocarcinoma	2-25-30 Abdominal exploration, inoperable	None	Died 2 mos later of disease	
G. K. 3	mos.	33	Adenocarcinoma	10-27-30 Abdominal exploration, inoperable. Jejunostomy performed	None	Died 2 mos later of disease	
I. G. F.	8 wks.	30	Adenocarcinoma	6-26-30 Abdominal exploration, inoperable. Jejunostomy performed	None	Died 2 mos later of disease	
J. G. M. 46	6 mos.	40	Adenocarcinoma	2-10-31 Abdominal exploration. Transverse resection and gastrostomy	None	Well 2 mos post-operative	Swollen lymph nodes removed with tumor showed involvement
H. C. M. 66		40	Adenocarcinoma	2-11-31 Abdominal exploration. Transverse resection and gastrostomy	Gastrostomy occluded on 4th day. Autopsy	Died suddenly on 4th day	Length of history and operability noteworthy
I. M. M. 51	1 wk.	40	Adenocarcinoma	2-2-31 Abdominal exploration, inoperable	None	Still alive	
J. A. M. 49	mos.	30	Adenocarcinoma	10-20 Transverse resection and gastrostomy	Cephalic emulsion. Autopsy	Died on 3rd day	Lymph nodes showed involvement
M. R. F. 70	mos.	30	Adenocarcinoma	2-29-31 Abdominal exploration. Inoperable. Jejunostomy performed	None	Died of disease 2 mos later	
J. B. M. 62	mos.	40	Adenocarcinoma	10-2-30 Abdominal exploration, inoperable. Jejunostomy performed	None	Died of disease 2 mos later	
W. C. M.	mos.	30	Adenocarcinoma	10-17-30 Abdominal exploration, chest exploration, inoperable	None	Died of disease 2 mos later	Extensive mediastinal node involvement
C. D. M. 56	mos.	40	Adenocarcinoma	2-1-31 Jejunostomy performed. 2-10-31 Chest exploration, inoperable	Postoperative peritonitis	Died 2 mos later	
L. R. F.	10 wks.	30	Adenocarcinoma	8-2-30 Transverse resection and gastrostomy	Became comatose on 3rd day	Died on 4th day	Autopsy essentially negative
B. H. M. 49	1 1/2	30	Adenocarcinoma	6-20-30 Transverse resection and gastrostomy. 7-5-30 Right thoracotomy for pyopneumothorax	Developed ruptured lung abscess of right lung	Lived for 16 mos. Died of extensive metastasized carcinoma	Resected thoracic showed extensive node involvement

ble at operation. However, this should not deter the surgeon from carrying out radical extirpation of the growth and all the associated lymph nodes. Follow-up studies have demonstrated that a not inconsiderable proportion of such cases have survived the 5 year period. Metastatic involvement of the liver immediately classifies the case as inoperable. I do not believe that any patient with a resectable growth associated with hepatic involvement should be subjected to so extensive a procedure as a palliative measure.

The symptoms produced by a neoplasm at the cardia of the stomach will, in large part, depend upon the exact site of origin of the tumor and the direction of this growth. Cancers arising at the cardiac orifice quickly interfere with the act of deglutition and produce symptoms of lower sub-sternal pain, especially on swallowing. These tumors usually extend upward to involve the lower esophagus. On the other hand, a tumor originating on the greater curvature side of the cardia, in the so called silent area of the stomach, may produce no symptoms whatever until the growth has extended into the orifice itself. By the time dysphagia is noted by the patient, the carcinoma may very well have reached the inoperable stage. This type of case has been a factor in lending discouragement to active surgical treatment for cancers of the upper end of the stomach. However, it is important to emphasize that many of these patients may have persistent indigestion which resists medical treatment or that there may be an unexplained loss of weight. In such circumstances, it is imperative that the physician avail himself of every diagnostic method to demonstrate the presence of a tumor in this region. In

general, the symptoms will depend upon the proximity of the tumor to the stream of swallowed food and the size of the growth with respect to diminution of the caliber of the cardiac orifice or lower esophagus.

In a number of instances, operative exploration has demonstrated extension of the growth beyond the wall of the stomach to the posterior parietes or to the body of the pancreas. These patients have complained of back pain usually located to the left of the midline at the level of the eleventh or twelfth thoracic vertebra. This symptom has generally occurred late in the disease. A careful evaluation of the symptom of persistent back pain is of considerable importance in estimating probable operability.

An analysis of the cases reported in this paper indicates that loss of weight does not reach the extremes frequently seen in operable squamous cell carcinomas of the esophagus and that when great weight loss has occurred, the tumor, in all probability, will be found to be inoperable by reason of extensive node involvement or extension to the liver. The question of weight loss, therefore, is of considerable importance to the surgeon in helping him to estimate operability.

Malignant degeneration of a pre-existing benign ulcer at the cardia brings up the ever recurring debatable problem. There were 3 instances in this series of a long-standing ulcer history with relief of symptoms by the usual medical therapy, and, in one instance, the x-ray films, fortunately preserved, taken 10 years ago, showed a small penetrating ulcer at the lesser curvature side of the cardia. In the latter case, symptoms became more persistent in the last few months and did not re-

ble at operation. However, this should not deter the surgeon from carrying out radical extirpation of the growth and all the associated lymph nodes. Follow-up studies have demonstrated that a not inconsiderable proportion of such cases have survived the 5 year period. Metastatic involvement of the liver immediately classifies the case as inoperable. I do not believe that any patient with a resectable growth associated with hepatic involvement should be subjected to so extensive a procedure as a palliative measure.

The symptoms produced by a neoplasm at the cardia of the stomach will, in large part, depend upon the exact site of origin of the tumor and the direction of this growth. Cancers arising at the cardiac orifice quickly interfere with the act of deglutition and produce symptoms of lower sub-sternal pain, especially on swallowing. These tumors usually extend upward to involve the lower esophagus. On the other hand, a tumor originating on the greater curvature side of the cardia, in the so called silent area of the stomach, may produce no symptoms whatever until the growth has extended into the orifice itself. By the time dysphagia is noted by the patient, the carcinoma may very well have reached the inoperable stage. This type of case has been a factor in lending discouragement to active surgical treatment for cancers of the upper end of the stomach. However, it is important to emphasize that many of these patients may have persistent indigestion which resists medical treatment or that there may be an unexplained loss of weight. In such circumstances, it is imperative that the physician avail himself of every diagnostic method to demonstrate the presence of a tumor in this region. In

general, the symptoms will depend upon the proximity of the tumor to the stream of swallowed food and the size of the growth with respect to diminution of the caliber of the cardiac orifice or lower esophagus.

In a number of instances, operative exploration has demonstrated extension of the growth beyond the wall of the stomach to the posterior parietes or to the body of the pancreas. These patients have complained of back pain usually located to the left of the midline at the level of the eleventh or twelfth thoracic vertebra. This symptom has generally occurred late in the disease. A careful evaluation of the symptom of persistent back pain is of considerable importance in estimating probable operability.

An analysis of the cases reported in this paper indicates that loss of weight does not reach the extremes frequently seen in operable squamous cell carcinomas of the esophagus and that when great weight loss has occurred, the tumor, in all probability, will be found to be inoperable by reason of extensive node involvement or extension to the liver. The question of weight loss, therefore, is of considerable importance to the surgeon in helping him to estimate operability.

Malignant degeneration of a pre-existing benign ulcer at the cardia brings up the ever recurring debatable problem. There were 3 instances in this series of a long-standing ulcer history with relief of symptoms by the usual medical therapy, and, in one instance, the x-ray films, fortunately preserved, taken 10 years ago, showed a small penetrating ulcer at the lesser curvature side of the cardia. In the latter case, symptoms became more persistent in the last few months and did not re-

spond to medical treatment. While the clinical and pathological evidence of malignant degeneration of a pre-existing ulcer in these cases is more speculative than real, the course of events is certainly most suggestive.

The general examination of a patient suspected of harboring a cancer of the cardia rarely yields positive findings. Occasionally one may demonstrate an enlarged lymph node in the left supraclavicular fossa, the Virchow node. Unusual hardness of this node or fixation to surrounding tissues is an indication for biopsy to demonstrate metastatic involvement. Rarely can one palpate the tumor on abdominal examination. Metastatic liver involvement may or may not be demonstrated by palpation. It is important not to omit rectal examination to exclude metastases to the rectal shelf.

Every patient presenting the symptoms enumerated should be referred to a competent radiologist for roentgenographic visualization of the esophagus and stomach. In most instances, the presence of a tumor will be clearly demonstrated by the usual methods. The most common roentgenographic findings are obstruction of the lower esophagus, irregular filling defects at the cardia, rigidity of the lesser curvature on fluoroscopic observation and loss of the normal mucosal pattern. It may be extremely difficult to demonstrate any abnormality when the tumor is located on the posterior wall toward the incisure. Persistency on the part of the examiner with the aid of a heavier mixture of barium and the taking of multiple films in the lateral, oblique, recumbent, and standing positions will usually demonstrate the growth.

Every patient presenting the symptom of dysphagia, associated with positive findings in the x-ray films, should, in my opinion, be subjected to esophagoscopic examination. This is an important part of the complete work-up. The esophagoscopist accurately locates the upper level of the tumor with respect to the distance of the upper incisor teeth and thereby guides the surgeon in his operative approach. Histological examination of the biopsy specimen will indicate whether the tumor has originated from the stomach mucosa, or from esophagus. I have preferred esophagoscopy to gastroscopy because with the former more accurate visualization of the tumor may be obtained, and at the same time, a biopsy specimen may be secured. In the hands of a competent operator there is little difference in the risk of the two procedures.

Once the decision to attempt radical extirpation of carcinoma of the cardia is made a period of preparation for the ordeal is in order. In previous

publications I have elaborated on the details of this pre-operative preparation and will not discuss them at this time. Suffice it to say that this should include careful attention to oral hygiene, high caloric liquid diet, parenteral administration of vitamins, the administration of fluids by venoclysis, recently the use of intravenous amino acid both before and after operation, and a preoperative transfusion of whole blood. On the basis of our favorable experience with the preoperative administration of galliumamide in colonic surgery as reported by Garlock and Seley I have routinely administered this drug to patients with cancer of the cardia for 72 hours prior to operation. It is my impression that this drug has been a considerable factor in minimizing infection. The recent report by Seley and Colp concerning the bacteriological studies in cancer of the stomach is confirmatory evidence of this opinion.

The demonstration of adenocarcinoma in the biopsy specimen will immediately indicate to the surgeon the plan of surgical attack to be adopted. There seems to be general agreement at the present time that the operation of choice for cancer of the lower esophagus and cardiac end of the stomach is a left transthoracic, transdiaphragmatic resection with intrathoracic esophagogastronomy. Any other operative procedure which is limited to an abdominal approach falls far short of the ideal sought for in the radical surgical treatment of cancer anywhere, namely, free exposure and complete visualization of the field of operation. However, because the lymphatic spread of cancers of the cardia is most often in a peripheral direction *below the diaphragm*, it is important to determine operability without exposing the patient unnecessarily to the risks of transthoracic exploration. For this reason, I suggested some time ago that exploration be carried out through a small upper left rectus incision. Palpation will quickly indicate whether the tumor is resectable. Metastases to the liver or to the pancreatic lymph nodes and fixation of the growth to neighboring vital structures are contraindications to further surgery. Rarely abdominal exploration will indicate operability yet, when the chest is opened extensive mediastinal node involvement will be demonstrated. This, in my experience is so infrequent that it may be considered only as a remote possibility.

If the tumor seems resectable, the wound may be closed quickly with buried figure of eight steel wire sutures and skin clips. The patient is now turned on his right side and, following change in the operative setup the left thoracic cavity is entered through the eighth interspace. There

interested in the details of the operative procedure are referred to previous publications on the subject. Briefly, the operation, considerably modified from the original Fischer and Sauerbruch procedures, includes division of the eighth, seventh, and sixth ribs close to the spine, mobilization of the distal esophagus, radial incision of the left leaf of the diaphragm, mobilization of the upper two-thirds of the stomach by dividing the left gastric artery and the left gastroepiploic vessels, resection of the tumor-bearing portion with a wide margin of normal tissue, block dissection of the associated lymph nodes with the primary tumor, the performance of a two layer silk suture anastomosis between the end of the esophagus and the anterior wall of the stomach, and the telescoping of the esophagus into the stomach in order to obviate tension on the suture line. Under water drainage of the pleural cavity by a tube inserted through a stab wound in the subjacent intercostal space completes the operation. I believe it is important that every patient receive a transfusion during the course of the operation. In every case, I have employed positive pressure ethylene or cyclopropane anesthesia after a basal dose of avertin. Intratracheal anesthesia may also be used, provided that the trauma of intubation is minimal.

Reference should be made to the advisability of staging the operation so as to diminish the likelihood of operative shock. Marshall, in his case report in 1938, divided the operation into two stages. At the first operation, through an abdominal approach, the blood supply of the upper part of the stomach was ablated and the mobilized portion was pushed up into the posterior mediastinum through the surgically enlarged esophageal hiatus. Approximately 2 weeks later, the second stage was performed and consisted of a left transthoracic resection with anastomosis. My objection to staging the operation in this manner is threefold. In the first place, during the first stage, it is impossible to demonstrate mediastinal node involvement, second, it is technically easier to free the upper end of the stomach by the transthoracic, transdiaphragmatic approach than from the abdominal side, and in addition, the entire field of operation is more clearly visualized, and third, operative shock has not been a factor in the causes of postoperative mortality. If bleeding is carefully controlled, if tissue trauma is reduced to a minimum and if the patient is transfused during the course of the operation, surprisingly little shock will be noted. The operating time for the one stage procedure has varied between 2 hours and 2 hours and 30 minutes. For the reasons stated, I prefer the one stage operation.

Experience has proved that the operation of resection of the upper stomach with intrathoracic esophagogastrostomy is physiologically sound and that solid healing takes place at the site of suture. Including a group of squamous cell cancers of the distal esophagus, I have carried out this operation in 16 cases and in not one instance has there been any evidence of dehiscence of the suture line or leakage. I, therefore, see no reason for employing any of the complicated procedures to protect the suture line such as were recently reported and which were based only upon observations made in the experimental laboratory.

Before the operation is undertaken, it is important to explain to the patient that he must not swallow for a period of 4 or 5 days. The processes of repair at the suture line will be hastened by the full co-operation of the patient in this respect. Fluids are administered by a continuous intravenous drip of 5 per cent glucose in normal saline.

The character of the material draining through the intercostal tube will indicate the progress of the intrathoracic situation. During the first 48 hours, the fluid is sanguineous. After this, it gradually assumes a lighter color and decreases in amount until the seventh or eighth day when the tube may be removed.

Small sips of water may be given on the fourth or fifth day. Increasing amounts of liquid are given until the twelfth or thirteenth day when custards, gelatins, cereals, etc., are permitted. The diet is rapidly increased thereafter. Solid food should not be given until the third week.

As with adenocarcinoma of the rest of the gastrointestinal tract, the results of radiation therapy have been extremely disappointing. Even the direct exposure of the tumor by the use of a special intragastric tube, as reported by Pack and others has failed to show results sufficiently encouraging to warrant substituting this method of treatment for direct surgical attack. Unless obvious contraindications exist, I believe every patient with a cancer of the upper end of the stomach should be explored to determine operability. If this plan is followed, it is obvious that many more successful resections will be carried out.

RESULTS

During the past 4 years, I have explored 25 patients with adenocarcinoma of the cardiac end of the stomach. Nine were found operable, an operability percentage of 36. There was no operative mortality in the inoperable group. Nine patients were subjected to the radical operation. There were 4 postoperative deaths, an operative mortality of 44.4 per cent. Of the 5 survivors, 1 patient

died of retroperitoneal metastases 13½ years after operation. The 4 remaining patients are alive and well (no evidence of recurrence) 18 months, 17 months, 8 months, and 7 months, respectively. The essential details of the entire series are tabulated in Table I.

SUMMARY AND CONCLUSIONS

Until recently cancer of the upper end of the stomach was generally considered beyond the scope of radical surgery and patients afflicted with the disease were placed in the hopeless group. With the development of the more accurate diagnostic procedures of roentgenography, esophagocopy and gastroscopy an increasing number of patients in the early and perhaps curable stages of the disease is being referred for treatment. Whether such treatment should be by radiation methods or radical surgical extirpation, should, in my opinion, be a matter of little discussion. The results of radiation therapy of the most modern type have been universally disappointing and no cured case has, thus far, been recorded. On the other hand, with the modern improvements in surgical technique and recent advances in the field of anesthesia, surgery has much more to offer the patient harboring this disease. On the basis of the experience cited in this paper and in others already published, the patient with a resectable cancer of the upper end of the stomach has 60 per cent chance of surviving the operation and an 80 per cent probability of living more than 2 years. It remains for the medical profession to be alive to the possibility of the existence of a cancer

of the cardia in every patient who complains of persistent indigestion and difficulty in swallowing and to accept the operation of transthoracic resection with esophagogastronomy as a standard procedure, one which offers the patient the best chance of being cured of his disease.

TRENDS IN CANCER RESEARCH

CARL VOEGTLIN, Ph D, Bethesda, Maryland

ON behalf of the National Cancer Institute, I wish to acknowledge our indebtedness to the American College of Surgeons, first, for improving the standards of tumor clinics, which has been of great value to us in the effective distribution of radium loans and in the provision of free training for physicians in diagnosis and treatment¹, and second, for having kept alive the constructive interest of the medical profession and laity in the cancer problem

Trends in any field of research change with time as new facts are discovered. Up to the end of the last century cancer research was confined to descriptive observations on cancer in man. Isolated reports of cancer in other mammals were ignored. Speculation was rampant as to causation. A remarkable exception was the keen observation of Percival Pott who, in 1775, recognized the possible relationship of coal soot and cancer of the scrotum in chimney sweeps. A century later, Virchow's hypothesis focused attention on the tissue cells, which were supposed to undergo malignant transformation as a result of "chronic irritation." Subsequent modifications of the cell theory attributed cancer to embryonic cell rests or to abnormal conditions during regeneration of injured tissues. With the recognition of the parasitic origin of certain diseases, the search for a specific infectious agent for cancer was let loose and to some extent has continued to this day. In retrospect it is clear that each one of these attempts to explain the causation of cancer had the weakness of oversimplifying the problem. At last, at the end of the nineteenth century, Claude Bernard's plea for controlled experimentation was applied to the cancer problem. As a result a large number of new facts have been discovered. The following discussion is restricted to mammalian neoplasms.

The first important conclusion reached from experimental work is the high specificity of malignant cells. Each one of the many types breeds true *in vivo* and *in vitro*. For instance, a mam-

mary carcinoma of the mouse transplanted into other susceptible mice reproduces itself in an unlimited series of generations. Furthermore, many types of malignant cells have been maintained in tissue culture for years without losing the ability to produce the specific tumors after being inoculated into the same strain of animals from which they were derived. The maintenance of such cultures over a long time requires an aseptic technique which is more strict than that used in surgery. The slightest infection as a rule causes the loss of cultures. It is difficult to bring these and other facts into harmony with the view that mammalian cancers are due to a specific infectious agent, especially since it has not been possible to isolate such agents from any tumors. Moreover, numerous attempts to produce curative serums without exception have failed. On the other hand it is established, both clinically and experimentally, that certain parasitic infections can predispose tissues to the development of cancer, but it should again be emphasized that these parasites do not play a specific rôle and are not detectable in the resulting neoplasms.

Basing their investigation on Pott's observation, Yamagiwa and Ichikawa in 1915 announced the production of skin cancer in rabbits by the long continued topical application of coal tar. This important discovery shifted the trend of cancer research into the field of chemistry. Through painstaking work a highly potent carcinogenic chemical, 3, 4-benzpyrene, was isolated from coal tar. At present the carcinogenic properties of about 250 synthetic chemicals have been recognized. Some of these, as 20-methylcholanthrene, have been extremely valuable for the experimental production in animals of almost every type of malignant tumor seen in man. Fractions of a milligram of this compound can produce malignant tumors at the site of injection or in distant organs.

The ease of chemical carcinogenesis has thrown much light on tumor histogenesis under controlled conditions (3, 6, 7). Morphologically recognizable tissue injury may occur but does not necessarily precede tumor formation. As exceptions, I mention induced as well as spontaneous pulmonary and mammary tumors. In fact, the term "chronic irritation," while still of value for cancer-control education, has outlived much of its scientific use-

fulness in cancer research. The conversion of normal into malignant cells is apparently due to changes which are far too subtle to be analyzed exhaustively by the available histologic methods. Even the most refined cytologic technique at present fails to differentiate malignant cells from the cells of origin. After all, what we see through the microscope is only an infinitesimal part of what is present and going on in living cells. For this reason I have maintained for some years that carcinogenesis, as well as other fundamental cancer problems, should be attacked from the view point of cell physiology and biochemistry for we are dealing with a fundamental biological problem.

Work with chemical carcinogens has firmly established the fact that tumors appear only after a relatively long latent period, which depends on the type, dose, and method of administration of the chemical, the animal species and strain, and the sex (2). The great value of animals with a relatively short life span of 2 to 3 years, such as mice and rats, may well be due in part to the rapidity of aging which may be assumed also to speed up the cancer process. The physiological time factor is certainly important in human and animal carcinogenesis. Therefore, a better understanding of carcinogenesis will go hand in hand with a better understanding of the process of aging of which we know relatively little.

Another remarkable fact is the ease with which such a powerful chemical as methylcholanthrene can produce malignancies in a great variety of tissues, as the brain, skin, striated muscle, subcutaneous tissue, lung, etc. This lack of specificity with regard to the cell type involved deserves further study. It is, indeed, exceedingly important to explain the intricate mechanism of action of methylcholanthrene on any normal cell type which is known to be convertible into the malignant state. Work on this subject has been in progress for some time at the National Cancer Institute and elsewhere. We have found for instance, that prolonged exposure of cultures of normal subcutaneous mouse fibroblasts to high dilutions of methylcholanthrene causes apparently permanent changes in cell physiology comparable with those observed in cultures of sarcomas induced by methylcholanthrene in the subcutaneous tissue of mice of the same strain (4). Efforts are being continued to prove that carcinogenesis can take place *in vitro*. Positive results would be of great theoretical interest, since this would indicate that carcinogenesis does not depend on favorable systemic conditions, but can be explained by a direct interaction between carcinogen and cell.

Recently some progress has been made in the study of the dietary factor in the production of induced tumors. These cells are highly organized biochemical units. Their normal function depends partly on a continuous supply of energy yielding chemicals and of other chemicals which are needed for the construction of cell proteins, lipids, and carbohydrates, or for the regulation of cell activity as enzymes and vitamins. Hence it is logical to consider the composition of the diet as a possible modifying factor in carcinogenesis. Some years ago, we (10, 20) showed that the growth rate of spontaneous mammary carcinoma in mice could be strikingly inhibited by diets deficient in certain essential amino acids. This inhibition of tumor growth was not accompanied by any evidence of general malnutrition. Recently other workers found that the development of hepatomas in rats induced by the azo dye butter yellow can be considerably delayed by certain diets (16). Work at our Institute (23) has also shown that the response of mice to skin painting with methylcholanthrene is strikingly influenced by the composition of the diet. If the diet contains an adequate amount of the amino acid, cystine, the mice develop acute leukemia with great regularity. On a low cystine diet however the development of leukemia is greatly retarded, and instead the mice exhibit extensive sclerotic lesions of the larger arteries.

Butter yellow and methylcholanthrene are toxic for young rats maintained on a diet low in cystine. The growth rate is strikingly inhibited and is accelerated as soon as cystine is added to the diet (8, 24). Dietary cystine may be regarded as a detoxicating agent for the two chemical carcinogens in question. Hepatoma formation by butter yellow is accompanied by severe liver injury and liver cirrhosis, which may or may not be a requisite for hepatoma formation (5). It is not easy therefore to differentiate the specific carcinogenic action from the nonspecific toxicity. Similar work on spontaneous tumors has also yielded results indicating dietary influence.

It has been suggested that abnormal diets may play a part in the causation of gastrointestinal tumors, an idea which at least has the merit of stimulating research. Rodio reported that rats which are maintained for a long time on a diet containing boiled fats develop gastric adenocarcinoma. Careful work at our Institute so far has

(10) J. H. and Anderson, of this Institute, recently made the following observations: Upon 100 mice when diets of two different compositions were given. One group was fed laboratory low protein diet (1) the diet and the other relatively low protein-high cystine diet (2). At the end of 10 months all mice on the high cystine diet had developed spontaneous mammary tumors, whereas 40 mice in most of the mice on the low cystine diet had mammary tumors.

not confirmed this claim. On the other hand, we have succeeded in producing for the first time gastrointestinal carcinoma in mice by means of methylcholanthrene (15). The forestomach of the mouse is lined by squamous epithelium and the rest of the organ by glandular mucosa. Spontaneous gastrointestinal tumors have never been observed in the mice used. At first the carcinogen was given continuously to the mice as a dilute emulsion in the drinking water. After many months there occurred squamous cell carcinomas in the forestomach, whereas the glandular portion was normal. Some of the animals also developed typical carcinoma of the small intestine (13). This curious susceptibility to malignant change of gastric squamous epithelium and the apparent lack of susceptibility of the gastric glandular mucosa must be explained. Can it be due to the inability of the carcinogen to penetrate into the dispersion of methylcholanthrene was injected into the glandular mucosa of mice of the same strains. Up to the present five typical adenocarcinomas have thus been produced at the site of injection. One of these tumors has been successfully transplanted subcutaneously into other mice. The transplants grow rapidly, and the tumors have retained their histological structure in two generations. To me the most interesting point is the probability that the layer of gastric mucus functions as a protective barrier when the carcinogen is given orally. If this be true, it follows that the production of gastric adenocarcinoma by carcinogenic dietary components, if such exist, may be conditioned by a break in the mucus barrier under pathological conditions.

The discovery of the artificial chemical carcinogens is a milestone in cancer research as it has made possible the experimental production of tumors under controlled conditions. Nevertheless, the great unsolved problem still is the causation of so called spontaneous neoplasms. The tumors strengthen the belief that the naturally occurring tumors are caused by chemicals formed within the body. In fact, it is firmly established that very large doses of female sex hormones acting over a long time can induce malignant tumors of the breast and uterus in mice and rats. Furthermore, experiments with different inbred strains of mice have revealed a unique influence of the mother's milk on the development of mammary cancer in the offspring (1). Foster nursing of newly born female mice from a strain with a normally high tumor incidence by a mother of a low tumor strain strikingly decreases the tumor incidence in the foster nursed animals.

On the other hand, foster nursing of young females from a strain with a normally low tumor incidence by a mother of a high tumor strain greatly increases the tumor incidence in the fostered mice. Work on the nature of the agents responsible for these effects is in progress at our Institute, as is also the question as to whether or not the findings apply to human mammary carcinoma.

Mention may now be made of recent claims of the carcinogenic action of cell free extracts of tissues and of urine from cancer patients. This work is based on the assumption that as a consequence of abnormal metabolism endogenic substances exert a carcinogenic action. The first report in this field was made by the Russian scientist Shabad (12). He extracted grossly normal livers of individuals dead from cancer of the stomach, lung, and other organs, with benzene, since benzene is a good solvent for many carcinogenic hydrocarbons, sterols, and bile acids. After evaporation of the benzene extract the residue was injected subcutaneously into mice. This caused local tissue destruction and killed some of the animals. Malignant tumors were observed after 8 months or longer, both at the injection site and in distant organs. Few tumors also occurred in nontreated control mice. Similar results have been reported by British and American investigators. Taken as a whole, these findings should be accepted with considerable caution. While there is no doubt that malignant tumors were observed, it is premature to accept this evidence as conclusive proof for the existence of endogenic carcinogenic chemicals in cancer patients. Most of the tumors appeared after a very long latent period and in a relatively low percentage of injected animals. Sesame oil was used by some as a solvent, an oil which is known to cause subcutaneous sarcomas occasionally. Other workers used a rather drastic chemical method for the preparation of the test material, which leaves some doubt as to whether the carcinogenic material was preformed. Final proof must wait, therefore, until the agents are isolated in chemically pure form and until it is shown that the sufficient active compounds occur in the body in great enough concentration and can act over a sufficient time to induce tumors. This line of investigation serves as an illustration of the great effort and time required to establish fundamental facts in cancer research.

Brief mention should now be made of work designed to explain the difference in behavior of malignant and normal cells. Here again the biochemical approach seems to be advantageous.

since it is reasonable to suppose that the difference in behavior may be due to differences in biochemical organization. One of the chief difficulties is the availability of a suitable control tissue for a given tumor (17). We have recently used with some success the normal and regenerating liver of the rat for comparison with a rat hepatoma. The regenerating liver serves as a comparison of a proliferating normal tissue with the proliferating liver tumor. The results so far obtained indicate that the tumor is characterized by a high anaerobic and aerobic lactic acid production and a respiratory quotient below unity¹ by a very low content in riboflavin (18) and coenzyme (19) by a great reduction in glycogen (6) with an apparently unchanged amylase activity and, most striking, by a reduction in the catalase activity to one one thousandth of that of the normal control tissues (9). The activity of some other enzymes seems to be unchanged. In short it appears that some of the important enzymatic activities of the tumor show marked decreases, which may perhaps account for the specific tumor biology. It is evident that whatever differences have been found are of a quantitative not a qualitative nature.

Another line of inquiry which in the past has been ignored deals with the systemic influence of cancerous growth as evidenced by cancer cachexia. Here again biochemistry may be helpful. I have just referred to the great diminution of catalase in the rat hepatoma. Work at the Institute has shown that the catalase activity of the morphologically normal liver of rats carrying large subcutaneous hepatoma transplant is reduced to less than one-tenth of that of the liver catalase of a normal rat. This effect is easily reversible, because after extirpation of the tumor the liver catalase returns to normal within 48 hours (8). Since catalase functions in the chain of oxidative reactions in tissue metabolism, it is rather interesting to find very great reduction in catalase activity in the hepatic tumor and lesser decrease in the apparently normal liver of the tumor-bearing animal. Unpublished data indicate that this decrease in liver catalase occurs also with other rapidly growing malignant tumors. Further studies may lead to information of use for correcting the pathological cancer metabolism.

As to research on diagnosis and treatment, I must refer to my Barnard lecture of a year ago (16).

CONCLUSION

In conclusion I have tried to formulate some phases of cancer research and to report in a general way on the progress which is being made. Emphasis has been placed on the study of carcinogenesis, since hope of preventing cancer not only the so called occupational but also the spontaneous neoplasms, must be based on such studies. I have also stressed the importance of work aimed at a better understanding of the behavior of cancer cells in comparison with the normal cells of origin. Great difficulties are met in the study of these problems in human beings. The limitations of purely morphologic studies were mentioned and the value of physiologic and biochemical approach was pointed out. The outlook is good for further progress from combined laboratory and clinical research. Under present world conditions, the main responsibility for such studies for years will rest on American investigators.

¹Work carried out in the Department of Biochemistry, Cornell Medical School.

²The first indication of systematic biochemical action of the growth of two malignant tumors was reported some years ago (17). It was found that the neoplastic (schylar) compounds in certain tissues of the tumor-bearing animals showed progressive decrease with increasing tumor growth.

THE IMPORTANCE OF A COMPLETE DIAGNOSIS TO A SUCCESSFUL TREATMENT OF STRABISMUS

JAMIS WATSON WHITE, M.D., New York, New York

AS in all branches of medicine, a complete diagnosis must be made before an intelligent course of treatment can be instituted with any hope of a successful termination. The day is past when convergent strabismus can be considered always due to hypermetropia and a divergent strabismus due to myopia or to a so called anomalous position of rest.

A divergent strabismus is not uncommon in a high hyperope, nor is a convergent strabismus uncommon in a myope of even a low degree.

A vertical strabismus may be seen occasionally without an elevator or depressor being involved—in other words, due to an anomaly of sursumvergence—but in my experience this is most unusual.

The usual observation is that a large percentage of cases of lateral strabismus have a vertical element, which is a varying factor in the development of the lateral squint.

A certain number of cases of convergent strabismus of the convergence excess type are corrected completely by a full correction of the hypermetropia, augmented if necessary by orthoptic training, but many cases of low or high degree of hypermetropia are but little, if any, affected by a correction of the ametropia. Many patients are seen with a hypermetropia of low degree and a strabismus of 60 to 80 prism diopters, or again, with a hypermetropia from 2 diopters up, in which a full correction of the ametropia has really no appreciable effect on the strabismus. Discussion of the various theories has continued many years but our patients come and go while we are trying to find one solution to the whole problem as to diagnosis and treatment, be it operative or nonoperative.

I must quote again from McReynolds, of Dallas, who said in my hearing, "Every ophthalmologist who has ever had insomnia has devised a new operation or modification of a former procedure for the surgical correction of convergent strabismus, and, furthermore, every ophthalmologist at some time had insomnia."

I believe that the unsatisfactory results from operations and the unsuccessful search for one procedure that will be generally adopted for the cor-

rection of squints are due to the failure of the operator properly to determine and evaluate the several factors that may enter into the production of any given squint, and that nonsurgical or surgical treatment will vary as the exact type of strabismus varies. This statement includes convergent, divergent, and vertical squints and any combination of these.

Stated briefly, the various factors entering in the production of squints are:

1. An anomaly of one or more of the individual muscles. This may be from a faulty structure of the muscles, from a faulty insertion of the muscle, or from a faulty innervation. Each of these may have an added anomaly due to secondary contraction, secondary deviation, or to a primarily overacting muscle, as is occasionally seen in the large hypertrophic muscles.

Hence any squint should be studied first as to the possibility of an anomaly of any of the extraocular muscles.

2. The disjunctive acts of convergence, divergence, and sursumvergence.

Given a case of convergent strabismus in which individual muscle involvement has been eliminated, is the deviation greater for distance than for near? If greater for distance, it proves quite conclusively a primary divergence insufficiency, but if it is greater for near, it is primarily a convergence excess. If it is determined to be a convergence excess, is it due to hypermetropia, myopia, to a vertical imbalance, or may it be due to some systemic cause, as chorea, or even a lesser nervous irritation?

If a divergent strabismus is present and again the individual lateral muscles are normal, is the deviation greater for distance than for near? If greater for distance, it is a primary divergence excess, but if greater for near, it is primarily a convergence insufficiency. In either case, is the condition caused or modified by the kind or amount of ametropia or may an associated vertical imbalance be a main or contributing factor? In a conversation with F. W. Marlow, I stated that I believed that over 70 per cent of cases of divergence excess had a vertical anomaly. He had statistics to prove that nearer 85 per cent were so complicated. My experience is that most cases of

Presented in the symposium Surgery of Heterophoria and Heterotropia, before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941

anomalies of sursumvergence are primarily due to a vertical anomaly of another variety

TESTS

Examination should include tests to determine deviation for distance and for near. At some time in the examination, these tests should be made with and without any ametropia being corrected. The effect of complete cycloplegia should be noted also the correction of any vertical anomaly. The deviation should be measured in the 6 cardinal fields and, if a strabismus, the fixing eye in each field should be determined. The power of convergence should be studied and it should be determined whether this is affected by correction of an ametropia or vertical imbalance. The presence and degree of binocular fixation or suppression should be determined. The history of heredity, illness, birth, or other injuries should be investigated. Not the least of the contributing factors is the nervous mechanism of the patient.

Squints may be caused by chorea, hysteria, and other neurological conditions. If it is possible for these to be the sole cause, how probable it is that they may be a contributing factor when hypermetropia, myopia, astigmatism, or any of the afore mentioned causes are present. Very frequently the convergent strabismus is worse when the patient is ill, overtired, or excited or a divergent strabismus is noticed only when a child is "day dreaming."

When one has clearly in mind the things to be observed the method of testing may be quite optional. It is unnecessary to state that my preference is for the cover test with the amounts of deviation measured by prisms. It is purely an objective test, can be used in any patient who has vision enough or is old enough to fix any chosen object, and it depends solely on the examiner's understanding of muscle anomalies and upon his powers of observation.

TREATMENT

After consideration of a patient with these different factors in mind and with some estimation

of their relative importance in producing the given squint treatment can be intelligently begun.

If for example, glasses definitely lessen the strabismus almost at once one is encouraged to expect a continued improvement, but if they have little or no effect within a month, then another factor is present which has not been given its due importance. This may be any one or more of the causes stated previously. Orthoptic training is in some cases a most helpful adjunct, but when orthoptic training is prescribed to a majority of patients with heterotropia, it is done through ignorance or dishonesty and may do much harm. Orthoptic training has a larger field in heterophoria, but even here the field of usefulness is definitely limited.

As soon as the ophthalmologist has determined that the results from different forms of nonoperative treatment are not giving the desired results or knows from experience that any form of nonoperative treatment will be a disappointment and expense then surgery should be considered and the sooner the better.

SUMMARY

1. An examination should be made as soon as a muscle anomaly is observed or suspected.
2. If it is impossible to make an exact differential diagnosis at once, the patient should be re-examined at intervals until such diagnosis is made.
3. The effect of various methods of treatment should be observed, by using those that will most probably prove the points in question.
4. These methods include consideration of the effects of cycloplegia, correction of an existing ametropia, correction of a vertical imbalance, and the results of the fusional tests and orthoptic training.
5. A complex either of inferiority or of defense commonly develops in cases of strabismus and often at a very early age.
6. When a patient so studied fails to respond satisfactorily to any probable nonoperative treatment, surgery should be considered and before school age unless there is a definite contraindication.

SURGICAL MANAGEMENT OF HETEROPHORIA

DERRICK VAIL, M D, F A C S, Cincinnati, Ohio

HETEROPHORIA may be defined as a break in the amplitude of fusion, or the decompensation of muscle balance is maintained by fusion and the neuromuscular mechanism. Having diagnosed the nature and type of a phoria, the question of treatment presents itself. The diagnosis and the medical treatment with glasses, prisms, and orthoptic exercises, is not the function of this assignment. These most important points have been or will be discussed in the symposium. But it is necessary to emphasize that the decision to operate rests squarely on them. The analysis of the individual case is the prime requisite of the judgment. Success or failure in ocular muscle surgery particularly, depends entirely on the accuracy of our presurgical study and conclusions.

Lancaster said "the two things for which we strive in operating are, first, a position of orthophoria since, other things being equal, the nearer the eyes to a position of orthophoria, the less the task of the neuromuscular mechanism in maintaining binocular vision, second, an effective range of fusion, this being, if possible, even more important than the former. A neuromuscular mechanism, for example, may be made to produce an orthophoria by so shifting the position of the eyes in the orbits that approximately the same working angle of the controls will now result in orthophoria because the eyes start from a position nearer the ideal one. The idea that the purpose of operating on the ocular muscle is to weaken or to strengthen some muscle which is too strong or too weak is unsound physiologically."

Having concluded that operation is necessary, a conclusion often arrived at only after repeated interval observations, two questions arise (1) when to operate, (2) what to do and how much. The first question can be simply answered. I think that one should operate when a phoria produces symptoms that can be relieved in no other way, provided that there is some degree of fusion power available and capable of being increased in its amplitude. This is particularly applicable to hyperphoria when it may happen that the patient has not suppression of the false image but it does not cause trouble because it is so far

from the true image. The more closely the false image is approached to the true one without fusion the more annoying it becomes. Such patients are not grateful.

The age of the patient, I believe, makes little difference although it seems wise to overcorrect an exophoria and undercorrect an esophoria in the very young (under 8 years). It has been my experience that adduction decreases and abduction increases with age. Phorias, particularly of high degree, may easily develop into tropias without the child complaining. It is easier to learn suppression when very young and when the fusion impulse is not as strong as it is later. Older children and particularly adults, complain of diplopia, occasionally for a long time, when fusion decompensation occurs. Such decompensation may occur as the result of age, illness, or fatigue. The learning of suppression takes much longer in these cases and for that reason the adult himself seeks relief from the annoying diplopia.

The second problem, what to do surgically, and how much, is more difficult of solution. I shall leave to our distinguished South American confrère, Dr. Alvaro, the task of describing the modern surgical techniques employed in squint, since these maneuvers are the same for the phorias as for the tropias, with few exceptions. The choice of the type of operation is that with which the surgeon is thoroughly experienced and skilled. Since the object of surgery in the phorias is to facilitate fusion, it is not necessary to do as much, I think, as in the tropias. In other words, it seems better to do too little than too much. Although with modern materials and techniques the chances of sutures slipping and making matters worse are not nearly as great as hitherto, such cases do occur and must be guarded against. For this reason it would seem better to restrict the operations to recession or at least controlled or partial tenotomy for lengthening, and tucking or the O'Connor cinch operations for shortening.

The choice of an anesthetic is that of individual opinion. Many prefer local anesthesia, injecting the anesthetic well back into the belly of the muscle in the orbit in order to obviate, if possible, the annoying edema of the muscle at its attachment. A general anesthetic, particularly when given through an intratracheal tube thereby freeing the field of cumbersome masks, appears to be

Presented in the symposium, Surgery of Heterophoria and Heterotropia before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941

ideal for all ages, provided of course that there are no contraindications.

Whatever operation is done must be done meticulously. The various steps of the operation from the conjunctival incision to its final closure must be methodical, painstaking and surgically precise. Tenon's capsule must be preserved as far as possible; the muscle and tendon bruised as little as is necessary and the wound closed completely if one wishes to avoid postoperative trouble.

Since we are dealing with living tissue and not mathematic figures the problem of just how much to do is indeed a thorny one. Many times it appears to be solved only by intuition based on many years of bitter experience. The causes of failure are many and discouraging but if a proper analysis of the case has been made, particularly the investigation of hyperphoria, the percentage of failures will necessarily decrease. Too often is the presence of hyperphoria missed. It is much more common than thought, as can be seen by the analysis of 1,955 cases of ocular motor anomalies by White and Brown, who found that 36.6 per cent had an accompanying vertical anomaly. They concluded

"In uncomplicated convergence excess with either lower or higher degree of hypermetropia, double recession will give most satisfactory result. However, when vertical imbalance is present, the same amount of recession for an equal amount of lateral squint may result occasionally in undercorrection but more frequently in overcorrection, about as much as the original squint. This result may be delayed or it may develop immediately after operation.

In uncomplicated divergence excess with normal convergence near-point, conservative recession of one or both external rectus muscles gives good result. In the presence of vertical imbalance, there may be an undercorrection, but such more probably marked overcorrection.

In convergence insufficiency with secondary divergence excess, or when the divergence excess is primary one can judge the operative results accurately when there is no vertical imbalance. But in the presence of complicating hypermetropia, the same amount of recession or resection may result in undercorrection, but much more probably there will be an undercorrection of the lateral deviation.

"These failures will become less frequent if the vertical imbalance can be corrected before the lateral imbalance.

Certain general rules have been laid down by the experience of others in an effort to determine what to do in average cases. A table of such rules can be found in Spaeth's *Principles and Practice of Ophthalmic Surgery* because it will be found useful as a starting point it is worthy of emphasis.

The rules for hyperphoria must be briefly and vaguely stated. It is agreed that surgery should be directed to the hypophoric eye although it may be necessary to divide this between the two because of a great degree of hyperphoria. It

TABLE 1—RULES FOR DECIDING ON SURGICAL PROCEDURES FOR THE PHORIAS (SPAETH)

I. Phoria	Individual type	Surgery
Hyperphoria	Accommodative esotropia with myopia, convergence insufficiency near only, pre-innervational or decenter of myopia	Tucking or resection of one or both internal recti
	Convergence insufficiency esotropia for near and distance, overcorrection of prism correction shows deviation defect to be in the decentered subject line abduction action	Tucking or resection of one or both internal recti. May need recession of one external rectus as well
	Divergence excess, esotropia for both near and distance Abduction > adduction	Recession of both internal recti
Hypophoria	Convergence excess Abduction greater than adduction	Recession of both internal recti
	Divergence insufficiency	Tucking or resection of one or both internal recti

should be recalled that double hyperphoria is usually not a surgical condition but is a pure innervational defect. Operation, however should be considered at times when the double hyperphoria is decidedly unequal. One should do either a recession of the overacting muscle or tucking or the pinch operation on the underacting muscle in the hypophoric eye combined with operation on the hyperphoric eye as may be indicated. It is, indeed wise to do a little at a time in the correction of hyperphoria, rather than too much at one sitting. Sometimes one should allow an interval of time for example 3 to 5 months, between operations on the vertical muscles. During this interval orthoptic exercises may be used with advantage. The surgical correction of hyperphoria is fraught with difficulties and errors of judgment and constitutes the most difficult problem in ophthalmic surgery.

The same can be said for cyclophoria. Indeed, so easily can this condition be made worse from the patient's viewpoint, that only the most expert muscle surgeon should tackle this problem.

One can conclude therefore, by reiterating the statement that the surgical management of heterophoria depends fundamentally on the accurate diagnosis and skillful analysis of its factors, and that each case is a law unto itself. The diagnosis and not the actual performance is what counts.

TUMORS OF THE SALIVARY GLANDS, BENIGN AND LOCALLY MALIGNANT

A O SINGLETON, M D, F A C S, Galveston, Texas

SALIVARY gland tumors are probably the most debatable of all tumors and have been for many years. There are those which are definitely benign and those which are definitely malignant, but the largest group and most controversial is the mixed tumor which is benign in that it rarely metastasizes but malignant in that local recurrence is a predominating characteristic.

Parotid cysts may be congenital, but they are usually secondary to chronic infection or duct obstruction. They are often without symptoms but more often marked by the presence of swelling over the gland with pain and tenderness which may disappear with the emptying of the accumulated salivary secretion by opening of the ducts. After a time the obstruction becomes more complete with infection complicating the picture. When suppuration occurs, external drainage may be resorted to. Following drainage complicating salivary fistulas may result, therefore, every effort should be made to avoid operative interference. In several instances, we have seen these troublesome cystic glands cured by x-ray therapy. If sufficient radiation is given, the gland atrophies, becoming functionless, and the cysts give no further trouble. This is a great improvement over former attempts to dissect out the cysts.

Mikulicz's disease, because of the peculiarity of the condition and the unexplained etiology, cannot be ignored in the discussion of tumors of the salivary glands. While enlargement of the salivary, particularly the parotid, and lacrimal glands may be associated with leucemia, tuberculosis, lymphosarcoma, and toxic conditions, and has been given the name of Mikulicz's syndrome, the condition described by Mikulicz in 1888 was a definite condition without constitutional symptoms. The important part of the pathological anatomy of the disease is an extensive deposit of small round cells which seem to compress or displace the glandular parenchyma. These cells appear to be either an infiltration of leucocytes or multiplying lymphoid tissue ordinarily found in

the gland. The gland structure may be compressed or infiltrated with an excess of fibrous tissue as well. While the prognosis in these cases is difficult because of their rarity and the absence of final reports upon cases found in the literature, we think we can safely say that they are not serious and treatment is unnecessary. A case we observed exhibited no symptoms and little change in the condition over a 5 year period although the tumor of the lacrimal glands have had to be removed because of pressure upon the eyeball. Radiation should, and apparently does, have a beneficial effect in preventing the progress of the disease.

Adenolymphoma (onkocytoma) of the parotid gland is one of the rarest of tumors. It may not be directly in the salivary glands but often adjacent to them. It is composed of a lymphadenoid stroma with germinal centers with an epithelial structure in the form of tubular glands, cysts, and papillae (papillary cystadenolymphoma or papillary cystadenoma lymphomatosum). They occur in older people, are benign, encapsulated, and grow slowly. They are not usually intimately connected with the gland and may be easily removed without damage to the facial nerve or danger of recurrence.

Adenoma of the salivary gland is again one of the controversial tumors, and Warren (8) says, "Adenomas readily recognized as such are extremely rare in the salivary gland." If they do occur, it is in the parotid gland. They are always encapsulated and may be cystic or solid. The differential diagnosis between the adenoma and mixed tumor is hardly possible before operation.

Mixed tumors comprise the great majority of all tumors of the salivary glands and have been of particular interest to the profession for many years. The literature is fairly rich in discussions of this particular neoplasm. Because of the large size they may attain, years ago surgical attempts were made to remove them. I S Cutter wrote an interesting account of a controversy between the medical departments of the University of Pennsylvania and Jefferson Medical College as to priority in removal of the parotid gland. We quote

"In 1832, Dr William Gibson, professor of surgery in the University of Pennsylvania, in a lecture delivered late in the year, denied that the parotid gland had ever been extir-

pared. The founder of Jefferson, Dr. George McClellan, had already reported several cases of extirpation of the parotid and this surgical triumph had been set up as one of the household gods of the Jefferson student body. The letter to Professor Pattison was dated January 833, and concludes:

We, the students of Jefferson Medical College, feeling the honour of our Professor (McClellan) involved, and the credit of our Institution concerned, in the fact being fully established, could feel obliged to you, if you could enter into discussion of the question, *Has the Parotid Gland ever been extirpated?*

John Bell (in his *essay*) said: "The cutting out completely of the parotid gland is a thing quite impossible, since the greatest of all the arteries, viz., the temporal and the maxillary, lie absolutely imbedded in the gland."

John Bell later revised his original doctrine in his treatise on surgery stating that he had often extirpated the diseased parotid and his brother Sir Charles Bell says that he had assisted John in the extirpation of the gland ().

McClellan performed the operation successfully a number of times. Agnew recorded that Warren removed the parotid gland first in 1798 and McClellan's first case was in 1805.

The long interest in the mixed tumors has not been because of a high mortality from disease but from the fact that the embryology and pathology are without a satisfactory explanation and also because the treatment of them is still unsolved in spite of persistent effort on the part of the pathologist, the surgeon and recently the roentgenologist.

The mixed tumors are defined by Harvey Dawson and Innes as adenomas of the serous and seromucous salivary or lacrimal glands, of undifferentiated and gland-lobular types, which are very prone to a species of mucoid autolytic self-destructive transformation of their component tissues and are seldom truly malignant.

Sill, Swinton and Warren say

The frequent tendency of epithelial cells to take on spindle form has also been used to explain the apparent mesenchymal structure of certain of the elements of the so called mixed tumors. There are however certain objections: the consideration of the mixed tumors as adenomas with peculiar stromal changes. Adenomas readily recognized as such are extremely rare in the salivary gland. Moreover this particular type of change in the stroma is

almost unknown in adenomas developing elsewhere. It seems peculiar that in this group of glands alone peculiar stromal changes should develop in the adenomas which arise from them. In the very few instances of the true adenomas which have been reported there is no suggestion of the structure seen in the mixed tumor.

The concept of true mixed tumor developing from embryonic tissue is far more appealing. Distinctly in favor of this is the not infrequent occurrence of mixed tumors in diverse localities, such as the hard palate, the buccal fossa, the soft palate, the cheek, or the gum.

These tumors were at first thought to be purely epithelial in origin. Virchow thought that the cartilage was formed by pieces of metaplasia from connective tissue while Cohnheim considered it to be a remnant of the branchial arches which became displaced during fetal life. The endothelial theory set forth by Wartman has been abandoned and the epithelial generally accepted, particularly since the investigations of Kenyon and Fry.

The figures given by McFarland for the relative occurrence of mixed tumors are parotid, 93.6 per cent, submaxillary 6.1 per cent, and sublingual, 0.3 per cent. They probably represent an unselected distribution of tumor occurrence for the glands concerned. Harvey and his co-workers studied 316 mixed tumors, and the locality was given or evident in 275 of these cases: parotid gland, 230; submaxillary 21; sublingual, 2; lip, 9; palate, 6; nose, 1 and lacrimal, 6.

An analytical report of the cases of salivary gland tumor treated in the John Sealy Hospital and a study and comparative review of these tumors and others which have found their way into the Surgical Pathology Museum of the Medical Department of the University of Texas is summarized in Table I.

Of the 58 tumors arising primarily in the salivary tissues, 43 or 74 per cent were mixed tumors, and 15 or 26 per cent were carcinomas, as shown in Table II. The distribution of these tumors according to location is given in Table I. Forty five tumors were in the parotid gland alone and of these 13 were malignant.

Symptomatically in the mixed tumors, pain or tenderness was noted in an occasional case. These

however, were usually in the cases of the recurrent or very large tumors. The malignant tumors commonly caused symptoms. More than one-half of the present 15 were associated with tenderness, pain, or facial paralysis. The pain was occasionally radiating. Fixation to surrounding tissues was commonly met with.

The average age at onset for all the primary tumors was 38 0 years. Of these, the mixed tumors averaged 31 5 years, and the malignant tumors, 52 3 years. The preoperative duration of the mixed tumors averaged 5 4 years, whereas the malignant tumors averaged 1 24 years. The sharp clinical differences comparable to the two histological groups is to be noted.

The recurrence rate of the 58 salivary tumors is divided into 2 groups. That rate which recurred after excision of the tumor both elsewhere and at John Sealy Hospital and that rate recurring in the cases of patients operated on at John Sealy Hospital only. The recurrence rate should be considered in this manner because many of the cases were recurrent when first seen at this hospital. These data are available in 45 cases. Of these, 34 were mixed tumors, 10 or 33 per cent recurred. Of these mixed tumors, 2 or 8 7 per cent recurred. One of the two recurrences among the mixed tumors occurred in an elderly woman. It was widely excised, but recurred in 6 months and after 1 year had reached large proportions. It was again widely excised. The case was followed for 1 year, at which time there had been no recurrence. This tumor showed an increased cellularity in the recurrent tumor. This, considered with the marked infiltrative character noted at operation, classifies this tumor as one of the most malignant of the mixed tumors.

There is considerable controversy over the rate of recurrence in relation to the size of these tumors. The cases on which sufficient data were available were computed with this in mind. McFarland, dividing his series into tumors up to a walnut in size and a walnut or larger in size, stated that 32 per cent of the former and 16 per cent of the latter recurred. Houck, however, noted 17 and 31 per cent recurrence rates, respectively. In our series, 13 3 per cent of the smaller and 40 per cent of the larger tumors recurred. These and Houck's findings are in direct variance with those of McFarland.

One explanation for the low recurrence rate, 8 per cent, of mixed tumors of patients operated upon by us at John Sealy Hospital was the practice of wide excision. This is reflected in the high rate of postoperative complications, that is, facial paralysis. Ten cases among the mixed tumors were complicated by permanent facial paralysis. Of these, 8 were total. Facial paralysis occurred in all but 2 of the carcinomatous parotid tumors operated on. Salivary fistulas rarely occurred. Two of the present series of cases were so complicated.

TREATMENT

The diagnosis of the mixed tumors of the salivary glands is usually possible by physical examination and a history of a long duration of the tumor. A mixed tumor may be found in various parts of the orofacial region. Occasionally they are found in the lip, palate, supramaxillary border, nose, bronchi, and lacrimal gland. When the tumors are found in these locations, the diagnoses may be suspected, but usually such is not the case until microscopic study reveals the identity of the tumors.

Two years ago we stated in a discussion of these tumors of the parotid gland (6)

Though the surgical treatment of tumors in various parts of the body has been standardized, that pertaining to the parotid salivary gland tumors is still in confusion, with wide variations in the opinion of the profession as to the plan to follow. Recurrences are frequent and therefore malignancy cannot be denied, but because of the infrequency of distant metastasis and the anatomic difficulty of extensive surgery without facial nerve injury incomplete or local operations are the rule. Investigation will reveal that the early experience of the surgeon will show strenuous effort to preserve the nerve but with more experience and increasing number of recurrences, more radical procedure is preferred with less regard for the nerve. Such has been our experience in dealing with the parotid tumors.

We also advocated radical surgery for carcinoma of the parotid gland, stating

Because of the uncertainty of prognosis the frankly malignant tumors are usually treated conservatively to save the facial nerve. Therefore, we believe that conservative surgery is responsible for the high percentage of the recurrences, both in the so-called and malignant tumors. For some years we have felt that we are justified in removing large amounts of the parotid gland and even all the gland in those cases where we were convinced that sacrificing the facial nerve was necessary for cure (6)

To justify radical removal of mixed tumors because of their possible transformation into carcinoma or sarcoma is questioned by good authorities. A few cases have been reported in which such a transformation has occurred, but they are rare. In 1 of our cases this seemed undeniable, but investigation of case histories does not justify this as a reason for radical surgery. One of the most incurable malignant tumors we have found is carcinoma of the parotid gland. Even with the most radical surgery early in the course of its growth, only a very few cures are on record. We have not seen one patient who has lived 5 years after treatment. This includes 15 definitely proved carcinomas of the parotid gland which we have operated upon in a radical way. Three of these are still free of recurrence, but a 5 year period has not yet elapsed in any one of these. McFarland reported 14 cases of carcinoma of the parotid gland, 1 of questionable diagnosis, and only 2 patients were alive 5 years and these had multiple operations for recurrence.

In the case of mixed tumors of the parotid, McFarland argues against removal when they are small, claiming that the recurrences are more like

ly in the small tumors. This is not the experience of others, including ourselves.

It requires tremendous restraint on the part of the surgeon to allow an ever prominent parotid tumor to be turned away without removal. In no other large group of tumors is the attitude of conservatism considered, but the all important complication facial nerve palsy which must follow radical surgery in this region is responsible for unsatisfactory results after their treatment. Unless it becomes large the tumor is preferable to a facial palsy. Many plastic procedures are used to counteract this distressing complication, some of which are satisfactory to a marked degree, but they are far short of completely correcting the deformity. The result appears satisfactory at first, but, unfortunately due to atrophy of muscles the deformity becomes more marked with the passage of time after most plastic procedures.

At the present time we have under observation a nurse who has a parotid tumor deep in the parotid gland directly in the path of the facial nerve. The tumor is not growing rapidly and, since a facial palsy would put an end to her profession as a nurse upon which she depends for her livelihood, I cannot to this time make up my mind to disturb it. McFarland's persistent and careful clinical study of a very large series of parotid tumors resulting in the conclusion that conservatism should be emphasized in their treatment, cannot be entirely disregarded. We could emphasize that every effort should be made to save the facial nerve, at least in the initial attempt at removal. A planned sacrifice of the facial nerve is justifiable in cases of recurrence and in carcinoma. Plastic repair is of great importance but does not prevent an objectionable deformity of the face.

THE SULFONAMIDE DRUGS IN THE TREATMENT OF ACUTE SUPPURATIONS IN THE MIDDLE EAR AND MASTOID

J H MAXWELL, M D, F A C S, Ann Arbor, Michigan

THE sulfonamide drugs met with prompt and enthusiastic acceptance in the field of otolaryngology where there remained many unsolved problems of coccal infections. The acceptance of these preparations was characterized at first by overenthusiasm and favorable prejudice. Although they have found a permanent place as some of the most valuable therapeutic agents in the otologists' armamentarium, they must not at once supplant other forms of treatment of proved worth.

One of the most controversial subjects referable to the use of these preparations is that pertaining to their efficacy in the treatment of acute suppurative otitis media and mastoiditis. Most otologists are willing to admit that since the use of sulfanilamide and sulfathiazole the incidence of surgical mastoiditis, the complications of acute suppurative otitis media and mastoiditis, and the mortality rate dependent upon these conditions have been diminished greatly.

Kolmer has said that "chemotherapy is not merely the treatment of a disease with chemical agents, that is as old as the art of medicine itself. Rather it is the treatment of disease produced by living pathogenic organisms with specific chemical agents or drugs capable of selectively destroying them without serious toxic effects." When a drug is found to be efficacious in the treatment of one type of infection, it does not necessarily follow that it will be of equal benefit in all infections. Yet such a discovery is prone to bring about indiscriminate and empirical use of the compound. This has happened to a great extent in the case of the sulfonamide drugs.

The new chemotherapeutic agents are not devoid of dangers in their administration and their usage should be governed by the results of careful investigation of the patient and the disease to be treated. First, one must weigh the possible benefit to be derived from treatment, against the dangers of administration of the drug.

In reference to acute suppurations in the middle ear and mastoid the following points must be considered. First, the oral administration of the chemotherapeutic drugs in acute suppurative otitis media and acute mastoiditis, and, second, the local use of the drugs in mastoidectomy wounds.

In the case of acute suppurative otitis media, the first question that must be answered is "which patients with this disease need chemotherapy?" It has been conceded by many otolaryngologists that over 90 per cent of cases of acute suppurative otitis media proceed to spontaneous resolution after an adequate and timely myringotomy. Now since the advent of the sulfonamide drugs most encouraging reports relating the marked decrease in the morbidity from acute suppurative otitis media and the reduction in the number of cases of surgical mastoiditis have appeared. Stuart, Bowers, Clein, Lindsay, Horan and French, Baker and Bradford, Galloway, and others have reported favorably on the treatment of acute suppurative diseases in the middle ear and mastoid by the use of these compounds. Long (12) has even suggested that chemotherapy might be used for 48 to 72 hours at the very beginning of an earache in an effort to prevent the development of a suppurative otitis media. Williams and his co-workers concluded that chemotherapy afforded the greatest protection against surgical mastoiditis when used in otitis media due to pneumococci. Osgood on the other hand advised against the use of chemotherapeutic drugs in conditions in which there is little or no mortality rate, and Lindsay emphasized the statement that "the treatment for a patient who is desperately ill is not necessarily a criterion of the best policy in the early stages of these infections or in a moderate or mild type of otitic suppuration."

Babcock seemed unwilling to admit that the decrease in the number of surgical cases of mastoiditis in New York was due solely to chemotherapy, and he indicated that the effect of this treatment in otitis media is somewhat overrated. Before subscribing to the practice of giving chemotherapy to every patient suffering from acute otitis media, one should analyze some of the

From the Department of Otolaryngology University of Michigan Medical School.
Presented before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941

extremely favorable reports of drug therapy. It seems that reported reductions in the number of cases of surgical mastoiditis may be somewhat misleading since many of the reported controlled groups demonstrate an extremely high percentage of cases of surgical mastoiditis. Let us attempt to determine possible causes for the fewer cases of surgical mastoiditis other than the direct effect of the sulfonamide drugs upon middle ear infections. Kopetsky has reported a distinct periodicity in the virulence of infection of the upper respiratory tract, particularly of the middle ear and mastoid, and has stated that in different years various sub-strains of the hemolytic streptococcus may be pre-dominant. He suggested that a major cycle occurred about every 6 years.

Since chemotherapy has come to be used in a large number of patients with exudative nasopharyngitis, severe follicular tonsillitis and suppurative sinusitis with excellent results, many severe acute cases of suppurative otitis media probably have been prevented. This in itself has tended to reduce the number of surgical cases because these fulminating infections that spread to the middle ear eventuate in suppurative mastoiditis with relatively great frequency. Then there was that group of otolaryngologists who were prone to operate early in every case of severe otitis media which demonstrated fever, pain, profuse discharge, and mastoid tenderness. The more conservative aural surgeons had the courage to postpone surgical interference upon patients who demonstrated signs of uncomplicated mastoiditis in the first week of infection in the middle ear. This delay provided time for spontaneous resolution in the majority of patients and allowed walling off of the process in those who continued to develop a suppurative coalescent process in the temporal bone. Since the widespread use of chemotherapeutic agents in middle ear infections these early operations of which we know there was a tremendous number have been reduced to a minimum for the following reasons. First, the prevention of otherwise necessary operations due to the effect of the drug in the severe cases of acute suppurative otitis media. Here the acute infection in the middle ear was brought under control before extension to the mastoid had taken place. Second and the exact importance of this factor cannot be determined the prevention of unnecessary operations. The confidence in the sulfonamide drugs possessed by the patient, the general practitioner, the pediatrician, and the otologist, has acted as a deterrent to operation. The tempering of the acute symptoms has made the condition less alarming so that there has been no impatient cry for action

on the part of the patient, parents, or physician and many cases have been allowed to proceed to spontaneous resolution which might have taken the same course without the drug if sound, watchful conservatism had been practiced.

Now, since prompt and excellent response to chemotherapy in severe acute cases of suppurative otitis media has been witnessed, why should not all cases of middle ear infection be treated routinely by the administration of one of the sulfonamide drugs. In answer to this question I wish to state that chemotherapy should be used scientifically and specifically with a definite objective in view. There is a morbidity and even a mortality rate attendant upon the use of these weapons which must not be ignored. If the object is the prevention of mastoiditis we are then considering a form of treatment which should not be given to over 90 patients unnecessarily in order to treat less than 10 who need it. Even though the drug were perfectly innocuous, such empiricism does not belong to the present era of scientific medicine. If the object is, and of course it should be where possible to decrease the morbidity and to shorten the duration of the infection then a much higher percentage of patients with acute suppurative otitis media may be treated by these drugs. They should be selected on the basis of their general condition and the severity of the infection but should not be subjected to routine empirical treatment. The patient who has an infection severe enough to demand chemotherapy should be kept under close observation in order that the effect of the drug on the infection may be observed and the earliest signs of toxic reaction be detected. Those adult patients with mild acute suppurative otitis media treated by chemotherapy often insist upon remaining ambulatory and driving automobiles. The dangers attendant upon this are well known.

Finally the very significant number of patients who develop mastoiditis and intracranial complications insidiously during chemotherapy adds a new note of danger. The masking effect of the drug which allows these complications to develop without any alarming signs tends to give the physician a false impression of the patient's progress.

Allowing the sulfonamide drugs their very important place in the treatment of acute suppurative otitis media, which patients then with this disease should receive their benefits? Although it is difficult to draw any hard and fast rules, a few principles seem worth while to follow.

This treatment is best suited to those individuals in whom the disease is still a mercurial men-

brane infection, and of course to those who have established and diagnosed complications of the suppurative process in the temporal bone. Bearing this in mind, chemotherapy should be used in the following types of cases

1 Acute fulminating infections in the middle ear producing signs of mastoid involvement at the end of the second or third day and characterized by sepsis, profuse aural discharge, pain and mastoid tenderness. In this type of disease there is frequently a spread of the infection by septic thrombophlebitis of the small communicating veins of the mastoid

2 Acute infections in the middle ear, either mild or severe, but secondary to a virulent process in the throat, nasopharynx, nose or paranasal sinuses. Chemotherapy in these cases may prevent a suppurative mastoiditis by controlling the primary infection

3 Early, acute, rapidly developing middle ear suppurations characterized by a red edematous tympanic membrane and thin seropurulent or serosanguineous exudate under pressure in the tympanum. This is the type of infection which may spread rapidly to the mastoid if not brought under control promptly

4 All cases of acute suppurative otitis media from which a pneumococcus is recovered on culture

In general only those patients who have an early acute suppurative otitis media without an established suppurative mastoiditis gain the greatest therapeutic effects from the drug. If suppurative mastoiditis has already developed, treatment will be less effective. Williams stated that "on the basis of review of literature in consideration of the mode of action of the drug, it would seem that the which good blood and oxygen supply are present, one which is free of peptones and broken down leucocytes and which is not constituted of bone. The middle ear and mastoid process are essentially bony loci with a notably poor blood supply." The condition in an infected mastoid is entirely different from that in an acute osteomyelitic process in the vascular red marrow of the metaphysis of a long bone. In the latter infections chemotherapy has started to revolutionize their treatment. Badgley reported 13 cases of acute osteomyelitis in the long bones treated by sulfathiazole. In each of 3 patients incision and drainage of soft tissues only was done and in 10 patients no incisions at all were made. All of these patients made splendid recoveries. With continued chemotherapy most otologists have witnessed infection in the mastoid proceed to intracranial involvement

Although one might offer as an explanation the difference in the types of bone in the mastoid and in the long bones, it has been our experience at the University of Michigan Hospital that spreading osteomyelitis of the skull, an infection in diploic bone, is not satisfactorily managed by chemotherapy alone. We still find it necessary to remove all infected bone and to expose a wide margin of healthy dura around the osteomyelitic process.

When sulfanilamide was the only sulfonamide drug available, it was usually advisable to know what organism was responsible for the infection before instituting therapy. This was due to the toxicity and the somewhat limited effectiveness of the preparation. Culture of the infecting organisms is still important and should be performed in every disease in which chemotherapy is contemplated, yet the newer drugs with wider scope of action and decreased toxic effects may be started before the culture has been completed. At the present time sulfathiazole is the drug of choice in most instances because of its effectiveness in combating infections due to hemolytic streptococci, pneumococci, and staphylococci. Sulfadiazine, which is now available, but rather expensive, bids fair to replace sulfathiazole as the preparation of choice in most of the infections encountered in an otolaryngologic practice. Long (13) has commented on the low toxicity of sulfadiazine and has stated that it is the only one of the group of the sulfonamide drugs that can be used in the home with relative safety.

The period of time during which chemotherapy should be employed in infections of the middle ear and mastoid has been the subject of controversial discussion. Bowers, Kolmer, Osgood, Lyons, Lindsay, and Williams, have dealt with the subject in some detail. Although it has been suggested by some that it might be advisable to wait for a few days after the infection appears in order to allow antibodies to develop before giving the drug, the general opinion now seems to be that treatment should be started immediately upon the appearance of the infection and that the dosage should be very heavy during the first day in order to gain a high blood level of the drug as soon as possible. Of course by the time a severe infection becomes manifest antibodies have already been produced to a considerable extent.

Since the greatest effect of the drug is to be gained when the infection is in the mucous membrane, or when there is being produced a septic thrombophlebitis of the small communicating vessels of the temporal bone, such therapy should be used during this period and then discontinued until further indications for its use arise. This

means that treatment should be given vigorously for 4 to 10 days, at the end of which time it has probably had its complete effect upon the early stage of the infection. Earlier discontinuance is indicated, of course, if important toxic manifestations appear. Failure of the infection to respond to therapy may indicate a lack of antibodies which should be supplied by transfusions or specific sera if available.

The indications for use of chemotherapy in the early stages of severe acute suppurative otitis media are more easily defined than are the indications in infections of the middle ear and mastoid of more than a week or 10 days duration. Empiricism must again be avoided in the latter group of cases and the drug should be used only after full consideration of each individual case. Although fever may be lessened and the objective signs of manifest bone involvement within the mastoid may be partially alleviated, the disease within the temporal bone is not likely to undergo spontaneous resolution at this stage if the patient is ill enough to demand chemotherapy. Because of the masking effect of the drug which may be due as suggested by Lindsay to a limitation of the infectious process, the otologist may be confronted by the insidious development of an intra-cranial complication.

Coalescent mastoiditis can and does proceed to develop on many occasions during intensive chemotherapy. Since this may happen rather quietly an especially alert vigilance must be maintained. Signs of the surgical mastoid are almost always present but are modified due to the lack of fever, pain, severe tenderness, and leucocytosis. The characteristic granular purulent exudate, sagging of the supraposterior canal wall deafness, and progressive radiographic changes are present in most instances but are less imperative.

The local use of the sulfonamide drugs in infected and potentially infected wounds has been given a thorough trial in civilian and military surgery and has been proved to be of great value.

The postoperative care of mastoid wounds has changed from time to time in an effort to shorten the time of healing and yet assure adequate drainage. Many procedures varying from wide open drainage to primary suture after allowing the cavity to fill with blood clot have been suggested. More recently otologists have been using the sulfonamide drugs in the mastoid cavity in addition to regular gauze or rubber drains. Livingston had disappointing results from filling the mastoid wound with sulfanilamide crystals and then using the usual rubber drain and partial suture and believed that this procedure failed to shorten the

postoperative period. He reported 13 cases in which the wound was filled with either sulfanilamide or sulfathiazole and then closed tightly of which 11 showed prompt healing. Of the 11 patients so treated, the shortest healing time was 4 days and the longest healing time 9 days.

At the University of Michigan Hospital observations have been made by Dr. David DeWese on 10 simple mastoidectomy wounds treated by the local application of sulfanilamide powder at the time of operation. The wounds were nearly filled with the powder and then the usual gauze packing was inserted. Wound cultures remained negative for streptococci until after the first dressing was done on the fourth or fifth day when streptococci and staphylococci began to appear. In 8 of the 10 wounds, no pus was seen until after the packing had been changed. The highest blood sulfanilamide level obtained was 0.45 milligrams per cent following the instillation of 10 grams of drug in the mastoid wound. The next highest blood level was 0.2 milligrams per cent and the remainder showed a very small amount of the drug in the blood. Although no conclusions can be drawn from this small group of cases, it seems certain that the effect of the drug upon the wound must be local and not the result of absorption. Also it might suggest that the wounds were reinfected in dressing them in spite of the fact that aseptic technique was employed in the procedure. Reinfection of the wound at the time of dressing is not the only explanation of the postoperative suppuration although this factor is important when any wound is dressed frequently. After a well done complete mastoidectomy there remains many small infected cells which may account for the reappearance of pus after the fifth postoperative day. Since some of these infected cells do remain it would seem that primary suture of the complete mastoid wound after the local use of the sulfonamide drugs is not an entirely safe procedure because provision is not made for open drainage. The local use of the drug, partial suture of the wound, and the use of a rubber drain that can be removed gradually without having to be reinserted probably offers the best type of dressing for the average complete mastoidectomy wound.

RESULTS OF OPERATION FOR HETEROPHORIA AND HETEROTROPIA AND CAUSES OF FAILURE

WILLIAM THORNWALL DAVIS, M D, Washington, District of Columbia

THE subject of heterophoria and heterotropia may be discussed from several viewpoints I have chosen to discuss it in relation to the type of operation indicated or contraindicated according to the diagnosis There may be some who do not yet think of squints and phorias as having *definite* surgical indications, depending upon an accurate diagnosis The subject of diagnosis has already been discussed by my distinguished colleague Dr White

THE HETEROPHORIAS

The heterophorias may be divided into the esophorias and the exophorias The esophorias may be mechanical, accommodative, or mechanical plus accommodative, the mechanical or essential esophoria may be due to convergence excess or to divergence insufficiency

Essential esophoria due to convergence excess is curable by surgery, it may possibly be symptomatically alleviated by other means but not cured When due to convergence excess a lessening of the action of the median rectus or recti will result in a permanent cure If it be due to divergence insufficiency, operation upon the median rectus will not only fail to relieve the esophoria but will permanently disable the convergence and the condition will be worse than before We have found the Jameson recession operation to be eminently satisfactory, only one median rectus being recessed at a time

The cure of this form of esophoria may be achieved only by proper surgery It may require a procedure as extended as that for the cure of

convergent squint of the same type A lapse of some months should be allowed after the first operation before an operation is done upon the median rectus of the fellow eye, should this be necessary

In mechanical esophoria due to divergence insufficiency shortening of one or both lateral recti will result in a permanent cure Obviously, the extent of the shortening will depend upon the degree of the esophoria Careful study and understanding of the case enables the surgeon to judge as to the extent of the operation When properly performed as to surgical technique and with a full understanding of the surgical requirements in the particular case at hand, the result will be eminently satisfactory in a very large majority of the cases Naturally, no surgical procedure is satisfactory in all cases In a case of esophoria due to divergence insufficiency, operation upon the median recti is contraindicated

It is unfortunate to put glasses upon a patient with mechanical esophoria since they have no effect whatever upon the degree of the esophoria In a purely mechanical esophoria it will be obvious upon reflection that correction of the refraction will not alter the degree of the esophoria and hence will not relieve the patient Only if there be an accommodative factor will the degree of the esophoria be lessened

Regarding accommodative esophoria, or functional esophoria, I wish to emphasize the following statement In purely accommodative esophoria, surgery is absolutely contraindicated If operation is done, the result will be an exophoria for distance and an esophoria for near The esophoria will probably develop into a divergent squint for distance with an esophoria for near

It is improper to prescribe glasses for permanent wear. They do not cure an accommodative exophoria but correct it only while the glasses are being worn. This is symptomatic treatment only and is unsatisfactory. Accommodative exophoria can be cured by dissociation of the accommodation and convergence by proper orthoptic training.

In combined mechanical and accommodative exophoria, the mechanical factor requires surgical correction according to the suggestions made. The accommodative factor is amenable to orthoptic training as mentioned. An accurate diagnosis before treatment is attempted is essential.

The exophorias may be mechanical, accommodative, or mechanical and accommodative. In mechanical exophoria due to convergence insufficiency surgery is necessary. Proper correction of the myopia, together with orthoptic training to correct (1) the convergence insufficiency (2) to improve fusion to a wide amplitude, and (3) to obtain third degree fusion or stereopsis, may give satisfactory functional results but will not cure the exophoria.

To obtain a permanent cure, shortening of the median rectus or recti is indicated. The results are not so satisfactory as in esophoria. Relapses are more frequent. Judgment is more difficult as to the degree of shortening indicated. A primary overcorrection is desirable.

The results are often not entirely satisfactory. Bikelachowsky suggests it is better to wait until adolescence before operating in such cases. Our experience justifies this. Careful study of the patient, patience and an understanding of the many factors involved will enable the surgeon, with proper surgical measures, to obtain a satisfactory cure in the majority of cases.

It is my impression that in the presence of mechanical exophoria due to divergence excess, more brilliant successes are obtained by means of surgical treatment in this condition than in an other motor anomaly of the eyes.

Lessening the action of one lateral rectus at a sitting followed by a similar procedure on the fellow eye after the proper interval of time has elapsed results in a permanent cure more certain than does that secured by any other surgical procedure. The Jameson technique, recessing one lateral rectus 4 to 5 millimeters, appears to us to be the ideal operation. It is unsafe to recess both at one sitting, and it should not be done.

Exophoria of more than 8 prism diopters for distance prevents entrance of recruits into the commissioned personnel of the armed services, the air corps, or commercial flying. The surgical

cure is so easy and so eminently satisfactory that no person should be deprived of the inestimable benefit of correction. In selected cases and under proper conditions, the patient will not have to remain in the hospital but may resume his duties within 24 hours.

Mechanical plus accommodative exophoria is usually an exotropia and will be discussed under that heading.

Accommodative exophoria is the result of myopia. The myope of 2 or 3 diopters or more uses no accommodation for near work and hence little or no convergence. In consequence such a patient develops an exophoria which very soon becomes an intermittent exotropia at which time there begins to develop a mechanical factor.

A purely accommodative exophoria does not indicate surgery. Cure can be obtained by correction of the refraction and orthoptic training.

SQUINT

Squint may be convergent or divergent.

Convergent squint may be (1) mechanical (a) due to convergence excess, (b) due to divergence insufficiency (c) due to convergence excess plus divergence insufficiency; (2) accommodative or (3) mechanical plus accommodative.

Divergent squint may be (1) mechanical (a) due to convergence insufficiency (b) due to divergence excess, (c) due to convergence insufficiency and divergence excess; (2) accommodative; (3) mechanical plus accommodative.

Convergent mechanical squint due to convergence excess is not benefited by glasses. Orthoptic exercises alone will not correct the squint, if it does so the squint is not a mechanical one. Surgical treatment is indicated and should aim to lessen the action of the median rectus or recti. In this form of squint we have found that the Jameson recession operation, properly used, gives eminently satisfactory results. To secure a functional cure in such cases, 3 factors are necessary: (1) absolutely accurate diagnosis; (2) knowledge of how much to recess the median rectus or recti; (3) efficient orthoptic training to secure fusional amplitude and stereopsis. The causes of failure are obvious, the most important of which are incorrect diagnosis and consequent improper surgery. Uncalled for or an improper surgical procedure will result in failure. Shortening or advancement of the lateral rectus or recti is contraindicated and will result in an unsatisfactory result or failure.

The surgical treatment in mechanical convergent squint due to divergence insufficiency should be directed to the lateral recti. We seek to in-

crease their action by advancing, shortening, or both, by any operative procedure the surgeon prefers or in which he is most adept. The particular operation is of no great moment, but the choice of operation is essential to success. Error in this choice will cause failure, partially or completely. To operate upon the convergence muscular system when the divergence only is involved, will cause tragic failure since the squint will not be relieved and the convergence will be weakened. This adds to the cosmetic failure, a weakened convergence which may cause great trouble.

Surgery is absolutely contraindicated in purely accommodative convergent squint. Cure can be secured in such cases only by orthoptic training. If operation is done there will be a divergent squint for distance. The result of surgery in such cases is tragic failure and renders such eyes absolutely incurable for all time.

In accommodative mechanical convergent squint the mechanical factor should be corrected by surgical means, the accommodative, by orthoptic training. Before operation is done to correct the mechanical factor, due regard should be given to the question whether the squint is the result of convergence excess or divergence insufficiency as above discussed. Failure to observe this or failure to recognize the accommodative element will bring about unsatisfactory results.

In cases of mechanical divergent squint it is unusual to find a patient without an accommodative factor, the majority have myopia. Bielewsky advised that no operation be done to correct divergent squint before the adolescent age because of the possibility of recurrence. This judgment was no doubt formed in Germany. In our country conditions are so different that this would not seem to be proper judgment here. Because of the adverse effect on the mental development of a child, any squint should be corrected and cured at the earliest possible moment.

Mechanical divergent squint requires surgery for a cure in the following instances

a When due entirely to convergence insufficiency shortening of the median rectus or recti is necessary. Considerable experience is necessary in order to determine the degree of shortening or advancement or both that may be required. When combined with orthoptic training to overcome suppression, which is almost always present, the results are good. Recession of the lateral rectus or recti may be necessary in high degrees of divergence in addition to shortening of the median rectus. Overcorrection is required since there is a strong tendency for the squint to recur. In our experience correction of a mechanical divergent

squint is more difficult and less satisfactory than that of convergent squint. The patient should be informed that recurrence may occur and that further surgery may be required. Suppression which is likely to be intermittent is difficult to overcome, consequently extended orthoptic training may be required and the case kept under observation over a long period.

b Surgery is necessary in mechanical divergent squint due entirely to divergence excess. One rarely finds such a case. Often exophoria is due purely to divergence excess but by the time it has become an exotropia there is usually added convergence insufficiency. In a case with pure divergence excess, recession of one or both recti gives a most satisfactory cure which is often permanent, provided there is no convergence insufficiency or the anatomical anomaly is not so great that recurrence is likely. Obviously orthoptic training and correction of the refraction are concomitant necessities in obtaining a cure. May I emphasize the word *cure* which means binocular vision with stereopsis. Without this the case is only cosmetically corrected not cured.

In the great majority of cases of divergent squint due to divergence excess plus convergence insufficiency, a high degree of resection and advancement of both median recti may be required, possibly combined with recession of the lateral recti. A cure is not always possible though a cosmetic correction may be secured. The advanced muscle detracts from the cosmetic result. Limitation of abduction may result even though both eyes are operated upon. This is undesirable but may be necessary in correction of ocular deformity.

The causes of failure of correction appear frequently to be an insufficient degree of resection and advancement primarily to overcorrect the eye. Extreme limitation of movement of one eye may result from too great shortening of the median rectus with or without recession of the lateral rectus. The correction necessary in the higher degrees of squint should be equally distributed between the two eyes. An excess correction may result in convergent squint which may cause an annoying and possibly an insuperable diplopia. One should proceed with caution in high degrees of alternating divergent squint. Correction of the deformity may result in diplopia, so annoying to the patient that it cannot be endured. We believe such cases to be very rare and have not hesitated to correct such squints. We have had no case of serious diplopia following surgical correction.

Accommodative divergent squint differs in many respects from accommodative convergent

squint. It is the beginning of the mechanical form and results from myopia. The child is myopic and uses no accommodation for near vision consequently no convergence. He fixes with one eye and the other is relatively divergent. Hence suppression occurs for near vision which is therefore intermittent suppression. Slight amblyopia may occur which later becomes more marked as the squint progresses from an intermittent to a continuous one.

The child has a divergent squint only for near at the beginning, hence it is functional i.e. accommodative. The child, however, only squints when he is looking down, that is, in near work. Consequently it is not observed by the parents. Very likely his myopia will not be discovered until he goes to school. By this time the squint will probably have a mechanical factor in addition to the accommodative factor.

It is obvious that we rarely see a purely accommodative divergent squint. It is equally obvious

that surgery is not indicated if the case be entirely accommodative. Correction of the refraction and orthoptic training will be adequate to establish a cure in such a case.

In mechanical plus accommodative squint surgical correction and in addition orthoptic training and correction of the refraction are required. Surgery properly adapted to the particular case is usually satisfactory and a cure is accomplished in conjunction with the other treatment mentioned. The degree of squint is usually not great and there should be no failures in such cases. Failure could come only from improper diagnosis and poorly conceived or improperly performed surgery.

OTOLOGICAL SYMPTOMS OR COMPLICATIONS OF CRANIOCEREBRAL INJURY

W E GROVE, M D, F A C S, Milwaukee, Wisconsin

WITH the accelerated pace of our industrial life and with war rampant in the world, there are an ever increasing number of head injuries. With the exception of headache, the most frequently encountered symptoms of head trauma lie in the field of otology.

The anatomical considerations are briefly these: the external ear, external canal and membrana tympani, the middle ear, the cochlea and vestibule, the cochlear and vestibular nerves, the facial nerve, the first way stations of cochlear and vestibular nerves in the floor of the fourth ventricle and brain stem, and the central cochlear and vestibular connections.

In the production of intracranial damage the head may strike an object, be struck by an object or be violently jarred against the vertebral column. In considering the mechanics of such an injury there are three distinct phases: (1) the moment of impact, (2) the movement of skull and brain, (3) the cessation of skull movement. As the brain floats freely in the cerebrospinal fluid and as there is a certain element of inertia in its movement, it can be damaged by impact against the inside of the skull in either the first or the third phase of the injury. Such damage, when it occurs in the third phase, is of the *contre coup* variety.

As to the type of pathology produced, there may be fractures of the skull with concomitant brain injury or brain injury without any demonstrable skull fracture. Fractures of the skull may involve the facial bones, the vault, the base, or any combination of these. Fractures of the base constitute from 60 to 80 per cent of all skull fractures. They may involve the anterior, middle or posterior fossae, but those involving the middle fossa predominate. They may be of the bending or bursting type.

Fractures of the temporal bone, which is very loosely fitted into the base and which constitutes a large portion of the middle fossa, occur whenever the middle fossa is fractured. Transverse fractures of the temporal bone, which cross it more or less at right angles and destroy its con-

tents, are initiated in the posterior fossa. The contents of the temporal bone may also be damaged by violent swinging movements of the temporal bone without any fracture having taken place. In the vast majority of cases, a transverse fracture of the temporal bone causes a complete cochleovestibular paralysis, but there are a few well authenticated cases in which a portion of either the cochlear or the vestibular function is spared.

Another type of injury of interest to the otologist is injury to brain tissue, particularly pathology involving the brain stem and the region of the floor of the fourth ventricle where it can damage the cochlear and vestibular nuclei and their central connections. Such pathology consists of contusions and petechial hemorrhages, the tearing of blood vessels, the tearing, stretching, and laceration of cranial nerves, and damage to the vasomotor center and vasomotor nerves resulting in irritation of the vestibular nuclei.

A third type of injury which is of peculiar interest to the otologist is the direct injury to the cochlear and vestibular end organ. This is occasioned by transverse fractures of the otic capsule which actually destroy the sensory epithelium, by longitudinal fractures of the temporal bone which do not of themselves invade the capsule but which are associated with bleeding into the basal coil of the cochlea, by the tearing or stretching of the eighth nerve at the internal auditory meatus and by wave movements of perilymph and endolymph caused by violent swinging movements of the entire pyramid.

Careful history taking is of importance in evaluating a head injury. In general it may be said the older the patient the more serious are the effects of the injury and vice versa. The baby's skull, because of its great elasticity, absorbs the effects of trauma very well. The question of unconsciousness is an interesting one. In general it may be said that the longer the period of unconsciousness the more serious the injury. And yet we encounter rather serious intracranial damage in cases in which no loss of consciousness occurred. A truck driver walked into my office a few weeks ago complaining of headache. Ten days before, while closing the rear doors of his truck he fell

backward, striking his head against the pavement. He continued his work as a truck driver until he consulted me. Examination revealed a linear fracture of the occipital bone about 4 centimeters long. At no time was he unconscious.

Bleeding from the mouth, nose, or ears generally indicates a basal fracture. It may come on immediately but in some cases it may be delayed for a couple of days or even up to a 2 week period. The history of any previous injury to the head is of value in evaluating the signs. Any information as to the previous condition of the cochlear or vestibular apparatus is of vital importance.

In the examination of the patient, the importance of team work between the surgeon, neurologist, ophthalmologist, and otolaryngologist cannot be stressed too strongly. Otolological examination divides itself into immediate, as soon after injury as possible and subsequent examinations.

The immediate examination of the patient should concern itself with the following points: presence or absence of consciousness; presence or absence of facial paralysis or weakness; presence or absence of ptosis or strabismus; condition of the pupils and pupillary reflexes. The otoscopic examination will disclose any blood or cerebrospinal fluid in the external canal, any bloody crusts, fissures or cracks in the canal wall, any rupture of the drum or the presence of hematotympanum. Rough hearing tests should be made as soon as the sensorium of the patient permits to determine qualitatively if hearing is present. The presence or absence of spontaneous nystagmus in different positions of the eyes should be noted, especially if there is a complaint of dizziness. If the patient is unconscious, a conjugate deviation of the eyes can often be seen. This has the same significance as a spontaneous nystagmus in the conscious patient.

Subsequent examinations will concern themselves with a study of all the cranial nerves. The sense of smell should be investigated. The eyes should be studied in regard to pupil size and reaction, action of the extraocular muscles, media and fundi, diplopia and the field of vision. The action of the facial nerve should be carefully investigated. The hearing function should be examined by the voice, tuning fork reactions, and the audiometer preferably in a sound proof room. A study of the vestibular mechanism should include all the spontaneous signs of vestibular disturbance as well as the induced vestibular reactions, both thermal and rotatory.

SIGNS AND SYMPTOMS

The signs and symptoms which especially concern the otologist are tinnitus, loss of hearing,

dizziness, the escape of blood or cerebrospinal fluid from the ear, the presence of facial paralysis or weakness, the presence of fracture lines in the external auditory canal, and the development in 4 to 5 days of Battle's sign, ecchymosis over the mastoid process.

Spontaneous vestibular vertigo is subdivided into turning or rotatory vertigo and tactile vertigo. In turning vertigo the patient will indicate in some way that either he feels himself turning, the more common variety or that objects in his environment are rotating, not so common. There is no more certain sign of vestibular disturbance than turning vertigo. Tactile vertigo is again divided into (1) errors of sensation and (2) lateropulsion. In lateropulsion, which is not very common, the patient feels himself being pushed to one side.

The patient with an error of sensation has a feeling of tilting or tipping, of uncertainty or unsteadiness, or he complains of faintness or spots before his eyes. He does not experience any sense of rotation. His vertigo is not accompanied by spontaneous nystagmus, but his vestibular mechanisms usually show unequal responses to thermal stimulation.

Unless there has been a complete cochleovestibular paralysis caused by a labyrinthine fracture the vertigo is not constant but comes on in bursts initiated by sudden movements of the head, bending, lifting, exposure to sun and heat, elevation above ground level and indulgence in alcohol.

The spontaneous signs of vestibular disturbance are of more importance in checking for brain stem pathology than are the induced reactions, induced by either the caloric test or the rotation chair. These spontaneous signs are nystagmus, post pointing, drift in the deviation test, gait deviations, the Romberg test, and the girdle reactions.

Spontaneous nystagmus due to vestibular disturbance is a jerky nystagmus. It is usually rotary and horizontal. If vertical or diagonal in character it may be due to a brain stem lesion but it is not vestibular in origin. After a total exclusion of the labyrinth, it is continuous but if due to pathology in the region of the vestibular nuclei, it is intermittent. It may appear in all three positions of the eyes, but if mild in degree, will only be seen if the eyes are turned in the direction of the quick component. It should be searched for in every position of the head and eyes with the head erect, head tipped backward and then forward, and with the head tipped to either shoulder the so-called positional nystagmus. If no nystagmus is seen in these positions, it can sometimes be made to appear by rapidly

shaking the head, the so-called "head movement test." This test will not produce a spontaneous nystagmus in a normal individual. If a spontaneous nystagmus is intermittent in character, do not expect to find it on every examination and do not make the mistake of saying that there is no spontaneous nystagmus present in a patient from one single examination. The nystagmus will only be present on those occasions when the central vestibular nuclei are being irritated and when the patient has a subjective sense of rotation. This also applies to the other spontaneous signs of vestibular disturbance.

If a patient has a subjective sense of rotation, he will past point when the pointing test is made in the vertical plane, his outstretched arms will drift to the right or left in the deviation test of Fischer and Wodak and he will deviate to one or the other side when he walks forward or backward with eyes closed.

If the patient has a sense that he is tipping or tilting, he may past point if the pointing test is made in the horizontal plane.

The falling reaction is best tested by the Romberg test. I shall not try to describe to you the technique of performing the Romberg test. Suffice it to say that when making the test in a medicolegal case, every effort should be made to divert the attention of the patient while the test is made. If a falling tendency is due to a peripheral labyrinth lesion, the fall will be in the direction of the slow component of the existing spontaneous nystagmus, no matter which way the head is turned. If the lesion producing the positive Romberg is central, it may still be vestibular in origin and then the fall will be in the direction of the quick component. If the lesion is cerebellar, the fall will be always backward or forward if the vermis is affected and always to the same side if one of the hemispheres is affected, and this fall bears no relation to the position of the head or any pre-existing nystagmus.

As I mentioned previously, I consider the spontaneous vestibular signs as more important than the induced reactions, but at times it is necessary to employ the induced tests. One can use either the turning chair or thermal stimulation, the caloric test. The turning chair has the disadvantage that it stimulates both labyrinths at the same time and, for this reason, I prefer the caloric test. Unless I am testing the peripheral labyrinth for total exclusion, I prefer to use the so called minimal stimulation method. I slowly introduce 5 cubic centimeters of water at 80 degrees F into the external canal after having tipped the head back 60 degrees. This co-called optimum posi-

tion is used because the horizontal canals are thus put into a vertical position and we know that the horizontal canals stimulate thermally more easily than do the vertical canals. In anywhere from 10 to 25 seconds a nystagmus appears while the patient is looking straight forward, which nystagmus lasts from 1 to 2½ minutes. If the two ears exhibit a greater difference in the latent period than 5 seconds, or if there is more than 30 seconds difference in the duration of the induced nystagmus, we feel that the two vestibular mechanisms are not in balance. Fixation on the part of the patient should be prevented by the use of strong convex lenses. This minimal stimulation serves very well for studying the induced nystagmus, but is not strong enough to study induced pointing and falling reactions. It rarely produces nausea or vertigo except in the hysterical type of patient. It is needless to say that the caloric test cannot be used when there is a pre-existing spontaneous nystagmus in the central position of the eyes, nor is it of any value under these conditions.

The hearing of the patient should be tested by the voice, tuning forks, and audiometer. Bone conduction should be investigated in the Rinne and Schwabach tests. The audiometric test should preferably be done in a sound proof room. Qualitative hearing tests should not be made until the sensorium of the patient has cleared and preferably not until he is up and about. The audiometer has the advantage that it produces relatively uniform and relatively pure tones and that a graph can be made of the entire range of hearing, which can be compared to subsequent graphs and also, to some extent, to audiometric examinations made by another. Its disadvantage is that a diagnosis of the type of deafness cannot be made by its use alone. For this it must be supplemented by the use of tuning forks.

Loss of hearing due to head trauma can result from the effects of brain contusion alone, without any fracture of the cranial bones. It may result from a longitudinal fracture of the temporal bone, which courses along its anterior edge and projects itself into and through the tympanic cavity. It may also result from a transverse fracture of the pyramid which destroys the sensory epithelium of the cochlea and causes complete loss of cochlear function. Unless there has been an actual fracture of the labyrinth, in which case the loss of hearing is usually complete, the predominant type of deafness produced by a blow to the head is a perceptible or high tone deafness, associated with shortened bone conduction and a strongly positive Rinne reaction. Even in those cases in which there has been a fracture of the cranial bones

ther than a direct fracture of the labyrinth this type of hearing loss is due in large measure to the effects of hemorrhage into the labyrinth and not to the actual fracture itself. It has been proved in experimental animals that a blow to the head of insufficient force to fracture the skull will produce hemorrhages into the perilymph spaces of the basal coil of the cochlea and the harder the blow the further up in the cochlea will these hemorrhages extend. Some of this blood will absorb, but often it produces a perceptive type of deafness.

When a fracture courses through the middle ear ruptures a drum, and damages the intra-tympanic structures in addition to producing the previously mentioned high tone loss, a combined type of deafness might be expected. However when the ruptured drum closes and the fracture through middle ear heals, recovery of hearing in lower and middle tone ranges is often truly remarkable.

ROENTGENOGRAPHY

The roentgenographic delineation of basal skull fractures in general, with one exception, is very difficult even when the skull is photographed from every conceivable angle. The roentgenographic examination should include antero-posterior, lateral, oblique, vertex, mental, and Stenvers' exposures. Stereoscopic views are very useful. Even when all of these views fail to reveal a basal fracture one is not justified in saying that it does not exist. Hemorrhage from the mouth or nose, suffusion about the eyes and the roof of the nose, a slowly developing ecchymosis over the mastoid, the escape of blood or cerebrospinal fluid from the ear and the presence of hemato-tympanum are suggestive of basal fracture even in the absence of roentgenographic confirmation.

The presence of a large amount of endocranial bone in the otic capsule, bone which shows little or no tendency to regenerate permits of the roentgenographic delineation of a labyrinth fracture many years after its occurrence. So it may be said, in contradistinction to the usual failure to demonstrate basal skull fractures roentgenologically, that fractures through the petrous pyramid can almost always be demonstrated.

FACIAL PARALYSIS

Facial paralysis may be caused by longitudinal or transverse fractures, by nerve injury by stretching or tearing at the internal auditory meatus, or by hemorrhage into the fallopian canal. It may come on immediately or be delayed as long as a couple of weeks. It may be complete or partial. It complicates 10 to 15 per cent of all longitudinal fractures and about 50 per cent of all

transverse fractures of the pyramid. Surgery is not indicated for this condition. Unless this complication has been caused by a transverse fracture of the petrous pyramid recovery is the rule.

PROGNOSIS AND COMPLICATIONS

The immediate mortality from basal skull fractures is high, amounting to as much as 53 per cent according to various statistics. Late meningitis accounts for from 7 to 8 per cent mortality. The fractures of the otic capsule do not close by bony callus and, therefore the late development of meningitis is encouraged when a mild otitis media ensues, even many years after the injury.

Most of the cases presenting a blood or cerebrospinal discharge from the ear recover without the development of meningitis unless the otic capsule itself has been fractured, and unless suppuration ensues.

TREATMENT

The principles in the therapy of craniocerebral injuries can be rapidly summarized. The first consideration after injury is the treatment of shock by bed rest, elevation of the foot of the bed, warmth, the use of shock cabinets, etc. The appearance of cerebral edema is discouraged by dehydration. This is accomplished by the limitation of fluid intake by the use of magnesium sulphate, and by intravenous injections of glucose or sucrose. Morphine tends to increase cerebral edema and should not be used. Craniotomy should not be encouraged unless there is evidence of increasing cerebral edema or a lapse into unconsciousness after a lucid period, indicating hemorrhage from the middle meningeal artery.

Any manipulation of an ear discharging blood or cerebrospinal fluid should be discouraged as it may result in suppuration and subsequent meningitis. This cannot be stressed too strongly. Such an ear should be covered by sterile dressings which should not be disturbed for several days.

If a bleeding ear suppurates and there is no evidence of a capsular fracture, it may safely be treated as any other otitis media. A fracture of the otic capsule will be recognized by the total deafness produced. If a fracture occurs through a chronically discharging ear a radical mastoid operation should be done as soon as patient is out of shock and fracture line should be exposed. If ever after a transverse fracture of the pyramid, a middle ear suppuration should supervene, a radical mastoid operation should be done at once.

Needless to say the advent of chemotherapy has markedly brightened the prognosis of ear suppuration developing after basal skull fractures involving the temporal bone.

INTRACRANIAL INFECTIONS AND THEIR SPREAD FROM THE EAR AND THE NASAL ACCESSORY SINUSES

A C FURSTENBERG, M D, F A C S, Ann Arbor, Michigan

IT always seemed poignantly dramatic in our student days to be told that there were seven-teen pathways along which infection might travel from the temporal bone to the meninges and we trembled with fear at the thought of germs in the tympanum or mastoid that could choose so many avenues of attack. On an anatomical basis the unfortunate individual with a suppurative process in the middle ear and mastoid bone had a poor chance for his life. With the intracranial cavity the terminus of seventeen routes through the temporal bone, it appeared inevitable that the invading organism would find its way to the meninges and there establish a process that only a decade ago was a little less than 100 per cent fatal.

But as our clinical experience grew and furnished us practical information on the behavior of temporal bone infections, we discovered that our fears were unnecessarily exaggerated and largely unfounded. Experience did not confirm the supposition derived from anatomical study. Infection did not usually extend without restraint along the many avenues of approach to the brain but on the contrary frequently remained within the middle ear and mastoid for weeks and even months without evidence of spread beyond the confines of bone.

The usual course pursued by an inflammatory process in the temporal bone or within the nasal accessory sinuses that gives rise to an intracranial complication is one which causes a destruction of tissue by continuity of infection and ultimately reaches the subarachnoid space by direct extension through the dura mater. To be sure, there are common exceptions to this rule. We have all witnessed the tragedy of a meningitis following on the heels of a fulminating acute ear or sinus infection several hours or a few days after the onset of the disease. Or, we have witnessed the development of a septic thrombus in the lateral sinus and rapid invasion of the meninges from this source within 4 or 5 days after the first signs of an inflammatory process in the middle ear. Intracranial complications of this type are obviously due

to a hematogenous dissemination of infection either in the form of a rapidly developing arteritis or phlebitis or the dissemination of septic emboli to the vessels of the meninges.

In discussing this precipitous variety of meningeal infection which, as has been implied, occurs less frequently than the more insidious and delayed form, particular emphasis should be given to the intracranial complications of the swimmer. From my point of view the acute fulminating sinusitis which develops after swimming is fraught with dangerous potentialities. There is an inordinate tendency in these cases for the infection to spread rapidly within 2 or 3 days to the intracranial tissues and to establish a diffuse meningitis or brain abscess. The precise mechanism of such an invasion is the subject of ethical differences of opinion to autopsy, it was obviously due to a retrograde thrombosis of the veins of the mucous membrane of the frontal sinuses which communicate with the dense plexus of veins in the coverings of the brain.

In the cases of acute sphenoiditis there were instances of cavernous sinus thrombosis with the characteristic signs and symptoms of this disease and subsequent involvement of the meninges or brain. The point is that sinusitis in the swimmer is a dangerous disease, when it invades the intracranial structures it is prone to do so rapidly and to produce a complication of serious proportions in an uncommonly short period of incubation.

All of which has given rise to a great deal of speculation and considerable acrimonious dispute on the therapeutic management of these cases. There exists a school that, for reasons which appear sound to its advocates, recommends immediate tapping of the frontal sinus with a drill through its floor or anterior wall in an effort to establish early drainage of the purulent collection. There is another group who for equally good reasons is unalterably opposed to this point of view. As for myself, I have long held to the dictum, avoid bone work in the presence of a green infection. Do not interfere surgically with a sinus involved in an acute inflammatory process. The rationale of this admonition would give rise to a discussion that is beyond the scope of this paper, suffice it to say that we are alarmed at the frequent occurrence of

Presented in the symposium, Neurological Surgery as Related
to the Eye and Ear before the Clinical Congress of the American
College of Surgeons Boston November 3-7 1941

diffuse osteomyelitis of the skull after surgical attack upon an acute nasal accessory sinus disease. In our series of 84 cases of osteomyelitis of the calvarium, the disease developed after bone work had been done in 52 cases of acute sinusitis or acute exacerbations of a chronic infection. The high incidence of this devastating disease under these circumstances would seem to point to some error of commission or omission on the part of the surgical procedure rather than to a matter of mere accident or coincidence. Consequently it is axiomatic in our clinic to treat an acute sinusitis conservatively and to limit our surgical efforts to soft tissue drainage when the infection has perforated the walls of the sinus. Bone interference is resorted to only in the subacute or chronic stages of the disease. It is amazing and likewise gratifying to observe how frequently the acute sinus sufferer will recover spontaneously if he is given a narcotic for his pain, a shrinking solution for his nose and incision for the purulent collection that occasionally develops in neighboring tissues.

But there is another cogent reason for skepticism concerning the value of early sinus drainage by drilling through its walls, namely the doubt that the operation can be instituted before the intracranial complications intervene. Reference has already been made to the rapid occurrence of meningitis in the sinusitis of the swimmer. There are instances by no means rare when the sinus disease and the meningeal infection seem to occur almost simultaneously. One follows the other at such a rate as to preclude the possibility of instituting a surgical measure in time to prevent invasion of the meninges. At the risk of evoking bitter criticism, I should like to pose the opinion that when the surgeon opens a frontal sinus in the acute sinus disease of the swimmer he is usually too late to prevent an intracranial complication that was destined to occur from the onset; moreover, if the patient who has been subjected to surgical drainage does not develop a meningitis or brain abscess, there is still no justification for the assumption that the operation served as a preventive measure. Specifically I do not believe that the end justifies a surgical means.

Come now to the discussion of another method of spread of infection to the intracranial structures, attention is called to extension by continuity and contiguity of tissue. In our experience this would appear to be the common form of invasion when the inflammatory process has progressed to the subacute or chronic stages. The infection remains active within the sinuses or temporal bone for weeks or even months, destroys the surrounding osseous tissues, and finally reaches

the coverings of the brain. The dura, although a highly resistant connective tissue membrane may ultimately succumb to the ravages of the disease. Its invulnerability to infection, however is often amazing. An inflammatory process of uncommon virulence may grow on its surface for many months producing a large extradural abscess with pressure retention beneath the inner table of the skull without invasion of the intracranial cavity. Finally however the fibers of the dura may liquefy and open the subarachnoid space, an intracranial sinus, or the brain to the inflammatory process.

It is interesting to observe that a brain abscess derived from a nasal accessory sinusitis, a temporal bone infection, or an osteomyelitis of the calvarium that has passed beyond the acute stages is usually the result of direct extension to the cerebral cortex. An abscess stalk marks the line of invasion, within which it is clearly seen that the brain is attacked through a perivascular infiltration. The stalk is the result of a fibrous connective tissue proliferation and many new formed blood vessels. An infiltration of the perivascular spaces is much in evidence and it is by means of this pathological process that the infection is carried into the deeper parts of the brain.

Thrombosis of the cerebral vessels is occasionally observed in postmortem material but it is by no means the predominant method of spread. Infection from chronic inflammatory processes in neighboring bone does not frequently extend to the brain in this manner. A thorough search of many brain abscesses derived from such sources seems to indicate that the prevailing method of diffusion of infection is by perivascular infiltration and not through the migration of septic thrombi within the pial and cerebral veins.

It is to be remembered however that the point of entrance of infection into the cranial cavity may be widely removed from the primary focus within the temporal bone or nasal accessory sinuses. Anatomically it may be clearly demonstrated that the veins of the mucous membranes of these regions communicate directly with the dural sinuses. It can be shown further that these veins may become involved in a septic thrombophlebitis which tends to distribute infection to remote regions of the dura. The typical pathological change is that of a septic exudate spreading over the surface of the dura beneath the intact inner table of the skull and frequently extending far beyond the original site of infection. Occasionally this exudate is found in one or more isolated patches under the calvarium and separated from the primary focus in the accessory sinuses or the mastoid bone by a

zone of healthy dura. Notwithstanding this mode of diffusion access to the intracranial cavity, when gained, is usually by direct extension from the extracranial abscess which is virtually an extradural abscess through the fibers of the membranous coverings of the brain.

TREATMENT

that have a specific effect upon bacteria, there was always some question in my mind as to the value if any, of a mastoid or a sinus operation upon the victim of meningitis. Because it seemed to be in accord with the best principles of surgery and to hold out the only hope for a cure, we routinely operated upon these patients in the early years of our experience. But the results were most discouraging. Death was inevitable in spite of our efforts and after many disappointments the utility of this practice was realized and operative procedures abandoned.

With the advent of chemotherapy and surprising recoveries from meningitis, there has been a revival of the orthodox method of treatment and renewed confidence in the practicability of surgical intervention. Once there appeared to be some hope for the life of the patient there came a strong resurgence of interest in the time-honored principle of eradicating a focus of infection that was the cause of a complication. Cut off the source of supply of the infection and chemotherapy will do the rest. So the cry and this practice seems to have captured the approval of otologists everywhere today. So we now advocate the eradication of an infective process and mass drainage of the products of inflammation by the radical removal of necrotic and necrotic bone in conjunction with adequate doses of the sulfonamide drugs.

Reference has already been made to the pre-dominating method of diffusion of infection to the brain by perivascular infiltration and in this connection we find a lesson, I believe, of some practical value. Where brain abscess is suspected it is rational to assume that the pathology of spread has been direct and therefore to search for the area of softened dura through which the disease has passed. Careful and meticulous removal of the exudate from the dura will frequently disclose the portal of entrance and give access to the pathway along which the infection has traveled. Gentle penetration of this region with a brain cannula often produces a drop of pus and reveals the identity of the inflammatory stalk. Thus we may enter and drain the abscess through a tract along which the infection has migrated and in so doing respect a surgical principle which in no other part of the body can be more advantageously applied.

At the risk of pointing out the obvious, your attention is called to the great value of chemotherapy in the treatment of ear and sinus complications. The literature is replete with references to this subject, but perhaps I may be permitted to throw a few suggestions into the hopper particularly as they pertain to the otologist's point of view.

Turn now to the treatment of the intracranial complications of ear and sinus infections, reference must be made to the important matter of prevention. This has become doubly significant since the advent of chemotherapy, first, because of the masking effect of the sulfonamide drugs upon the lesions that give rise to intracranial infections and, second, for the reason that these specific chemical substances have greatly altered the prognosis of meningitis and brain abscess. It goes without saying that a surgical mastoiditis or an osteomyelitis of the skull secondary to nasal accessory sinus disease must be recognized and adequately eradicated if we are to give proper attention to our first lines of defense. Heretofore, this was not a difficult task. Years of practical experience acquainted the rhinologist with clinical pictures that were more or less typical of surgical lesions and clearly indicated the optimum time for intervention. But the introduction of the sulfonamide drugs has altered the situation somewhat in that we now encounter atypical and protein forms of inflammatory processes within bone which often keep us much in the dark concerning their surgical or nonsurgical character. Under the influence of chemotherapy, particularly its prolonged administration, a mastoid disease may run a bizarre and deceptive course characterized by remissions and a singular absence of the usual signs and symptoms. Its insidious development and peculiar growth give rise to osteomyelitic lesions that do not conform to customary patterns and herein lies one of our difficult problems in the diagnosis of surgical mastoiditis in patients who have been treated with the sulfonamide drugs.

Masking, perhaps, is the word that expresses it best. It refers categorically to otological parlance to an infectious process in the mastoid bone that proceeds to its terminal stages with concealed identity. It is this quality of disguise or concealment that makes it a much feared lesion and a serious menace to its neighboring structures.

Turn now to the second influence of chemotherapy to which reference has already been made, it is a matter of verity that the sulfonamide drugs have greatly reduced the mortality of the intracranial complications of ear and sinus infections. Before the discovery of toxic chemical substances

It is highly probable that sulfadiazine will replace the other sulfonamide drugs in otological practice. It is a specific toxic substance for the *Streptococcus viridans*, *Streptococcus hemolyticus*, *pneumococcus* (II types) *meningococcus*, and *Friedländer's bacillus*. While sulfathiazole is believed to be somewhat superior for staphylococcus infections, there is good scientific evidence that sulfadiazine also has a specific effect upon this organism. It is true that we frequently find a mixed infection in the ear and sinuses with the staphylococcus in great numbers but I am inclined to believe that this organism is usually a "hanger-on." The germ that puts in its first appearance, the one that is isolated with the inception of the disease and can usually be found in pure culture in the early stages is probably the real offender and the one upon which the attack should be made.

In addition to its specific effect upon all of the organisms listed above including the staphylococcus, sulfadiazine is less toxic than its related agents. It is much less likely to produce a dermatitis, fever, vomiting, anemia, a peripheral neuritis, psychosis, acidosis, or a hepatitis than either sulfanilamide, sulfathiazole or sulfapyridine. It may therefore be given with little risk in the home provided the patient is seen daily by the physician who will inquire into his state of health and make at least a cursory examination for the common clinical manifestations of a toxic reaction.

It is exceedingly important to commence chemotherapy at the earliest moment in the course of infection and to strike with heavy initial doses. An early knockout is the objective and to this end sulfadiazine is given intravenously in severe infections. The drug is absorbed rather slowly from the gastrointestinal tract and several precious hours may be lost if given by mouth. The initial dose should be 0.1 to 0.15 grams per kilogram of body weight of a 5 per cent solution in freshly distilled water (7 to 0.5 grams for 150 pound man). The preparation should not be autoclaved or boiled. For maintenance dosage by the intravenous route 0.05 grams per kilogram (5 to 7 grams for 150 pound man) is recommended and should be ad-

ministered every 12 to 16 hours. If oral administration is utilized for a maintenance dose 1.0 grams should be given every 4 hours. The blood level should be kept at 10 to 15 milligrams per cent.

Even when large doses of sulfadiazine are given intravenously a proportionately small quantity of it is found in the cerebral spinal fluid. This is in direct contrast to sulfanilamide which is rapidly taken into the spinal fluid and found there in rather high concentration. This observation has led to the supposition that sulfadiazine is less desirable than sulfanilamide in the treatment of meningitis. However it must be borne in mind that in meningitis we are not treating the spinal fluid. We are treating the meninges and experience with sulfadiazine although still meager is promising enough to indicate that it will probably replace its allied preparations in the treatment of intracranial complications of otitic and sinus origin.

CONCLUSIONS

1. While the hematogenous spread of infection from the ear and sinuses to the intracranial structures does occur particularly in the sinusitis of the swimmer, the usual method is by continuity and contiguity of tissue, when the primary lesion has reached the subacute or chronic stages.

A dictum to which we sedulously adhere is, avoid bone work in the presence of a green infection. It is admitted, however that the exigencies of the disease make surgical intervention imperative in some cases. It may be necessary to sacrifice bone early in the acute process in order to find and drain brain abscesses.

3. Meningitis and brain abscess are occasionally changeable to an intracranial yet extradural infection which spreads in the form of a confluent or patchy exudate over the surface of the dura beneath the inner table of the skull.

4. Treatment calls for the eradication of the primary focus of infection by surgical means and adequate doses of the sulfonamide drugs. Recent experience would seem to indicate that sulfadiazine gives promise of supplanting its allied preparations in the field of otolaryngology.

SURGICAL ANATOMY OF THE EYE

F BRUCE FRALICK, M D, F A C S, Ann Arbor, Michigan

UNDERSTANDING the anatomy of the eye is essential to any ophthalmic surgeon in performing the various surgical procedures on the globe. It familiarizes him with normal relationships, thereby giving confidence when corrective operations are undertaken in complicated cases. A knowledge of anatomy also includes an understanding of the variations from the normal and the effect these variations play on the functioning of the part. This aids the surgeon when he encounters anomalous relationships.

For instance, it is known that the rectus muscles are covered by fascial sheaths continuous with Tenon's capsule. The connection between the muscle fibers and the sheath is especially strong at the point where the two fuse. Because of this, the muscles retain their attachment to the capsule and do not retract extensively after tenotomy or enucleation of the globe. It is this anatomical arrangement which permits us to obtain some movement of the prosthesis after enucleation and implantation of a foreign substance within Tenon's capsule.

A rather uncommon, but troublesome, complication following enucleation with implantation is a tendency for the implant to migrate in the orbit as if extruded from Tenon's space. This complication may be accounted for on an anatomical basis. If we recall that Tenon's capsule and the conjunctiva are fused with the sclera for a distance of 1 to 2 millimeters about the limbus, and that the cornea has a diameter between 11 and 12 millimeters, we realize that about 16 millimeters of the circumference of Tenon's space has been lost in doing an enucleation and thus the insertion of a glass or metal ball the diameter of the normal eye made impossible. We are able to compute the exact size of ball which can be inserted into the reduced space of tenon following enucleation by subtracting the lost circumference from the circumference of the eyeball. In an adult we find that an implant of more than 18 millimeters will stretch Tenon's capsule and promote its expulsion. Those surgeons recommending a 20 to 21 millimeter diameter implant are forgetting the

size of Tenon's space after enucleation. Upon severance of the optic nerve, a perforation of the capsule is made posteriorly through which an implant is easily forced if too large a one is inserted. These are minor, but important, features to remember in enucleations in which one not only attempts to get the highest percentage in retention of implant, but also to prevent migration of the implant.

In growing subjects, Tenon's capsule is easily separated from the overlying conjunctiva in the anterior segment of the globe, but in adults they are more or less fused. We rely upon the loose capsular and subconjunctival tissue as the bed for absorption of the aqueous in trephine operations for glaucoma. If the conjunctiva and capsule are separated from one another, as in Elliot's original description of the trephine operation, a rather dense scar tissue replaces the normal loose connective tissue resulting in a thin, localized, honeycombed cicatrix at the site of the trephine opening or in no bleb at all. The incision should be through the conjunctiva and capsule, and the relationship between the two should not be disturbed at any step in the operation. This has recently been emphasized by Benedict.

When iridencleisis for glaucoma is performed, it is important to remember that the conjunctiva and Tenon's capsule are fused to the sclera for a distance of 1 to 2 millimeters about the cornea. The fistulizing opening will be under a heavier and looser cushion with less chance of delayed infection, if no attempt is made to dissect the conjunctiva and capsule from the sclera further limbalward than this point of fusion before the keratome incision is performed, since the overlying tissues closer to the cornea are denser and thinner. The sclera has very few blood vessels, and those present consist of branches of the anterior and posterior ciliaries. These form a network almost entirely confined to the episcleral tissues. This episcleral network is extremely attenuated except in the anterior region near the limbus. A close capillary system is formed here which can be evidenced clinically as ciliary injection in inflammatory conditions. This scarcity of blood supply in the sclera partially accounts for the slow healing of scleral wounds. Most of the reparative process advances from the subconjunctival and uveal tissues.

From the Department of Ophthalmology University of Michigan
Presented in the symposium Principles of Ophthalmic Surgery
before the Clinical Congress of the American College of Surgeons
Boston November 3-7 1941

This slow healing of the sclera promotes the possibility of expulsion of the glass or metal ball when it is implanted in the sclera as in Mules operation. A variable amount of oozing from the perforating vessels, posteriorly and anteriorly may result in the accumulation of a clot which exerts pressure upon the suture line. Tendency for expulsion of the implant is greatly lessened by using silk mattress sutures for closure of the scleral wound anteriorly together with electro-coagulation of the perforating vessels on the inner surface of the sclera. It is essential for one to choose the size of implant which will permit an easy closure of the sclera without tension. Our experience in this type of treatment of the eyeball, when possible, has given a far better cosmetic result than simple enucleation or enucleation with implant in Tenon's capsule. We believe there is no more danger here of sympathetic ophthalmia than in any other form of treatment in this surgical condition. Not all cases, however, are suitable for a Mules operation. It is reserved for panophthalmitis, freshly lacerated globes, hydrophthalmos, etc., and should not be used when tumor is suspected, or in chronically inflamed eyes.

The thickness of the sclera varies considerably with age and sex. It is thinner in children and in females. The sclera has a thickness of from 0.3 to 0.5 millimeter behind the insertion of the rectus tendon but grows thicker posteriorly. In recession operations, Jameson's directions for inserting the scleral needle should be followed explicitly. One should also remember that the tendons of the rectus muscles become thicker and denser as they approach the sclera. Therefore, if we cut these tendons as close as possible to the sclera, we will retain the densest portion and be assured that our sutures will not tear out after tying.

The limbus offers many anatomical features of clinical importance in fact too many to be considered entirely at this time. Schlemm's canal is commonly thought of as a single lumen. However it is seldom a single elongated lumen, but more often consists of two or more lumina lying side by side or over one another in the scleral furrow. Salzmann describes it as resembling a great stream which flows along undivided for a stretch, then becomes divided into several branches, and thus differs in various sections of the eye. Therefore Barkan's operation for glaucoma might fail if the incision did not happen to open the lumen, but instead passed between several branches of the canal.

The filtration angle in hydrophthalmos presents many congenital anomalies, no two being exactly alike. These congenital anomalies possibly ac-

count for the poor results obtained in the various operations most commonly used in other forms of glaucoma. In chronic noninflammatory glaucoma the filtration angle is often blocked by anterior root synechia, thus the iris does not herniate into the wound when the scleral button is removed, and no aqueous is lost. In this instance in order to form a communication with the posterior chamber it is necessary to grasp the iris tissue with fine forceps and excise the iris. Undoubtedly all who have performed many trephine operations, on rare occasions have experienced buttonholing of the conjunctival flap at the limbus. I have found Verhoeff's operation for glaucoma well adapted when this has occurred. The buttonhole incision at the limbus above can be continued on either side to make a short conjunctival flap. The epithelium is denuded from the upper pole of the cornea and a trephine opening is made at the usual position on the limbus. The conjunctival flap is drawn down over both the trephine opening and denuded portion of the cornea and, as in the Van Lindt flap, is sutured on either side of the cornea. In this, as in other instances, in which it is desirable to cover a portion of the cornea, the anatomical structure of the conjunctiva is such that it lends itself admirably.

The blood supply of the conjunctiva comes from the superior and inferior tarsal arcades of the eyelids and the anterior ciliary arteries. The superior tarsal arcade at the upper border of the tarsus and between the two portions of the levator tendon gives off perforating branches, which pass through the muscle of Mueller to reach the conjunctiva. Here branches are sent downward over the tarsus and upward as the posterior conjunctival vessels to form a superficial pericorneal plexus, after receiving anastomotic branches from the anterior conjunctival arteries. The anterior ciliary artery comes from the muscle branches of the ophthalmic. Each muscle artery gives off two anterior ciliary arteries with the exception of the external rectus which gives only one. The anterior ciliary arteries, after giving off the anterior conjunctival arteries, pass through the sclera at a point just in front of the muscle insertion to enter the base of the iris and form the major arterial circle. The anterior conjunctival vessels are deep to the conjunctiva and do not move with it. They anastomose with the posterior conjunctival vessels, pass on to form the deep pericorneal plexus in the episcleral tissue, and to send vascular loops into the corneal limbus. In cataract extractions, deep incisions into the limbus cut across many of these vascular loops and can cause troublesome bleeding. To a old this trouble some prefer to

perform corneal sections entirely in the cornea. These limbal vascular anatomical findings are of considerable clinical interest. In conjunctivitis and inflammations of the superficial portions of the cornea, it is the superficial pericorneal plexus which is injected. In addition, these vessels move with the conjunctiva but do not fade when pressure is applied. The deep pericorneal plexus is hyperemic in infections of the iris, ciliary body, and deeper corneal stroma. The deep pericorneal plexus is injected in the form of a ciliary flush and it is noted that this flush disappears on pressure but the vessels do not move with the conjunctiva. In interstitial keratitis the new vessels invading the cornea come from the anterior ciliary arteries as they pass through the sclera to reach the iris and ciliary body.

The central third or optical zone of the cornea is spherical. Toward the periphery, especially on its nasal side, it becomes flattened. This explains, in part, the poor visual results obtained with optical iridectomies since it is often necessary to do them behind the flattened zone of the cornea. The optical effect in reducing vision is similar to that obtained in cornea plana.

Wandering cells, corneal corpuscles, and corneal lamellae make up the *substantia propria* of the cornea. The corneal lamellae are broad bands of fibrils which run the entire length of the cornea and nearly parallel to its surface. The bands of fibrils are in alternate layers which crisscross at approximately 90 degrees. This anatomical arrangement offers a line of cleavage in a plane parallel to the corneal surface for resection of corneal scars.

Many believe, in performing an iridectomy for glaucoma, that freeing the filtration angle is the purpose of the operation and that they are successful only in those cases in which the base of the iris has been freely excised from its attachment to the ciliary body. In order to remove a broad portion of the iris base it is necessary that the corneal section be made properly. Meller advises that a sufficiently peripheral position of the section can be obtained if the knife or keratome enters the sclera $1\frac{1}{2}$ millimeters from the limbus and passes approximately parallel to the plane of the iris. This places the inner portion of the incision very close to the base of the iris and allows it to be excised entirely. When the inner portion of the incision is more centrally placed, the iris base is more likely to be left intact and only that portion of the iris central to the incision is removed. These faulty incisions and the iris base left fastened to the inner margin of the wound are often seen in eyes removed after unsuccessful glaucoma opera-

tions. It is best to pick up the base of the iris, push it away from the angle with the iridectomy forceps, and thus produce an iridodialysis when the incision is known to be faulty or if it is thought desirable to retain the sphincter action if subsequent miotic therapy should be needed. The base of the iris is then excised horizontally producing a large peripheral coloboma, but retaining sphincter action. Because some of the patients might need miotic therapy as an accessory aid in reducing the intraocular tension, I can see no advantage in producing a complete coloboma in either iridectomies or trephines.

The iris has a few interesting anatomical characteristics. One is its absence of hemorrhagic tendency after cutting, and another, its failure to heal following iridectomy. However, when there is inflammatory tissue on its surface or new formed blood vessels of inflammatory origin, we do find a tendency for bleeding and secondary proliferation following the trauma produced by surgery. The blood vessels in this inflammatory membrane are entirely different in character from those of the normal iris. Their walls are much thinner and contain much less contractile element, thereby giving them less hemostatic effect.

In the posterior uvea we find the choriocapillaris supplied by the posterior ciliary arteries. Anterior to the equator the blood comes from the recurrent branches of the long posterior ciliary arteries. The relatively few anastomoses between these two sources have been sited as the cause for circulatory failure of the intermediate zone at the equator in certain cases, that is, in producing the ring scotoma of pigmentary degeneration of the retina. However, ring scotoma in retinitis pigmentosa is at about the 20 to 30 degree meridian, which is in the zone of the posterior ciliary circulation and thus posterior to this junction. Ring scotoma at the equator is seen in luetic disease of the arteries and can thus be used as a differential point in diagnosing these two clinical conditions.

Between the sclera and the choroid is the choroidal space, a potential cavity across which the fine lamellae of the superficial layer of the choroid stretch to blend with the lamina fusca of the sclera. This space, which is traversed by the vessels and nerves supplying the choroid, stretches between the scleral spur and the optic scleral foramen. The choroid is easily detached from the sclera during cataract or glaucoma surgery because of the delicate nature of lamellae stretching across it. Torn lamina heals without residual visual loss after absorption of subchoroidal edema fluid. On the other hand, the inner surface of the choroid is very intimately related to the outer lay-

ers of the retina indeed, the basal membrane separating the two structures is partly derived from each, and the pigment epithelium of the retina is very closely associated with this membrane. When the retina is detached, the split occurs between the neural layers of the retina and the retinal epithelium the latter structure remaining behind and adhering to the choroid.

Salzmänn finds that the suprachoroid is at length completely lost in the meridional portion of the ciliary muscle. The majority of the lamellae enter the posterior border of the ciliary muscle with the result that the most anterior portion of the suprachoroidal space must be entirely free of suprachoroidal lamellae. Because of the density of the lamina and the absence of the suprachoroid beneath at least the anterior half of the width of the ciliary region, I would suggest that the scleral opening be at least 5 millimeters from the limbus in doing a cyclodialysis for glaucoma. This would connect the channel made to the anterior chamber with the looser suprachoroidal space behind the midpoint of the ciliary muscle.

The anatomy of this area of the globe has another important clinical application when we recall that the ciliary body has a width of about 5 to 6 millimeters (Salzmänn) as measured on the inner surface of the sclera or 7 to 8 millimeters as measured on the outer surface of the sclera. Let us recall also, that the corona ciliaris is about 2 millimeters broad, or when measured on the outer surface of the sclera 3 to 3.5 millimeters, and that the orbicularis ciliaris has a width of 4.5 to 5 millimeters on the outer scleral surface. The orbicularis ciliaris of the ciliary body contains a vascular layer much like that of the choroid with which it is continuous. It is not, however so wide and there is no choriocapillaris. This is the least vascular structure or area of the eyeball outside of the cornea. Since the arterial supply to the whole anterior region of the uvea passes through the ciliary muscle, the vessels in the orbicularis ciliaris consist almost entirely of veins which run backward meridionally and parallel to each other to empty into the vena vorticosus. These anatomical considerations seem to point to the orbicularis ciliaris of the ciliary body as the most optimum site of entrance to remove intraocular metallic foreign bodies by the posterior route. There is no danger of detachment of the retina if a hinged scleral trephine button is made just anterior to the ora serrata and the underlying uvea incised meridionally with a cataract knife. This might occur if the opening were made further posteriorly. There is a minimum of hemorrhage since the least vascu-

lar zone of the posterior segment is entered. The postoperative reaction is surprisingly slight. The wound heals readily and without tendency for staphyloma. I can see no reason for fearing sympathetic ophthalmia. This approach has been used with much satisfaction in the University Clinic for over 10 years (1).

By recognizing the structure of the retina it is easy to understand that hemorrhage occurring in the nerve fiber layers are the flame shaped type of hemorrhages. More irregularly spreading or punctate hemorrhages are seen when they occur in the nuclear or plexiform layers. It must be borne in mind that the anatomical structure of even the largest branches of the central retinal artery resembles that of the arterioles in the thinness of their walls and in the absence or slight development of the muscular coat. Those designating the branches of the central artery of the retina in the first and second order as arteries, and the finer divisions, as arterioles, are basing this view upon the marked differences in their clinical manifestations in hypertension, rather than upon differences in anatomical structure. Anatomically there is little if any difference, in the various branches of the central retinal artery.

The functional retina extends to within 7 millimeters of the ora. Structurally the nonfunctional retina is frequently degenerate and thus after the age of 30 it almost constantly shows a varying number of cysts which may in some cases atrophy to such a degree that vitreous is allowed to extend through it and cause retinal separation. Once the retina is separated, its full functions are never restored following reattachment. This is especially true when the macular area is detached in that central vision seldom, if ever is restored to its former acuity. Most patients complain of metamorphopsia and marked disturbances in reading vision.

The peripheral retina to the extent of about 4 millimeters is seldom visible with the ophthalmoscope even with a widely dilated pupil. This must be remembered in order to determine the distance of retinal tears from the ora in retinal separation. In less widely dilated pupils, of course, not even this much of the periphery is visible. Since the ora is considered to be 8 millimeters from the limbus as measured on the sclera, the anterior limits of the usual ophthalmoscopic field are approximately 1 millimeter from the limbus. It is convenient to remember that the optic nerve head is 14 millimeters in diameter and to estimate the distance of the retinal tears from the ora in disc diameters. With these measurements available at the time of operation, the

position of the retinal tears may be projected to the scleral surface with fair accuracy.

The central retinal artery and vein enter the optic nerve 5 to 15 millimeters behind the eyeball on its lower and mesial aspect. The artery usually goes directly through the subarachnoid space to reach the center of the optic nerve, where it turns at right angles to send a recurrent branch backward, while the central retinal artery goes toward the optic disc. The vein enters the subarachnoid space and courses anteriorly a short distance through it before turning at right angles to reach the center of the optic nerve, where it in turn sends its recurrent branch, and then goes toward the optic disc as the central retinal vein. Thus, it is seen that the veins can be affected by any rise in pressure to which the fluid in the subarachnoid space is subjected, and papilledema may result, as in the case of increased intracranial pressure.

Fincham has demonstrated that the thickness of the lens capsule varies in different portions, and gradually thickens with increasing years. The thickest portion of the capsule is found to be limited to a zone running around concentrically with the equator and just central to the insertion of the zonular fibers on both the anterior and posterior surface of the lens. The fact that the zonular fibers weaken with age and the lens capsule thickens with age accounts for the greater ease of intracapsular extractions in elderly people.

As the anterior ciliary arteries and veins pass through the scleral emissaria anterior to the muscle attachments, they are sometimes accompanied by aberrant intrascleral nerve loops from the long ciliary nerves in the perichoroidal space. On occasions, because these nerve loops are so pigmented, they give the appearance of subconjunctival metallic foreign bodies and unless the patient is well anesthetized excruciating pain is experienced upon attempting to remove them.

During external ethmoid operations it is of importance to remember the length of the optic nerve. The average length of the optic nerve is 25 millimeters between the globe and the optic foramen, while the average distance between the posterior pole of the eye and the optic foramen is 18 millimeters. This allows a possible forward displacement of the globe 7 millimeters before the nerve is put on a tension that might produce optic atrophy. In order to obtain better exposure during external ethmoid operations, I have seen a few instances in which too much traction on the globe has resulted in immediate and complete loss of vision.

SUMMARY

A few anatomical features of the eyeball have been presented in the hope of rationalizing various surgical procedures, and only with such knowledge is the surgeon capable of carrying out operative technique with the greatest finesse and with the least possible complications. A thorough understanding of the structures involved in a surgical problem will greatly influence the choice of method used, if several methods of approach are possible. No new operative methods have been presented, but a review of a few of the known anatomical features has been given in an attempt to draw attention to certain pitfalls in present surgical methods used on the eye which might be avoided through a better knowledge of anatomy.

ers of the retina indeed, the basal membrane separating the two structures is partly derived from each, and the pigment epithelium of the retina is very closely associated with this membrane. When the retina is detached the split occurs between the neural layers of the retina and the retinal epithelium the latter structure remaining behind and adhering to the choroid.

Salzmann finds that the suprachoroides is at length completely lost in the meridional portion of the ciliary muscle. The majority of the lamellae enter the posterior border of the ciliary muscle with the result that the most anterior portion of the suprachoroidal space must be entirely free of suprachoroidal lamellae. Because of the density of the lamina and the absence of the suprachoroides beneath at least the anterior half

of the width of the ciliary region, I would suggest that the scleral opening be at least 5 millimeters from the limbus in doing a cyclodialysis for glaucoma. This would connect the channel made to the anterior chamber with the looser suprachoroidal space behind the midpoint of the ciliary muscle.

The anatomy of this area of the globe has another important clinical application when we recall that the ciliary body has a width of about 5 to 6 millimeters (Salzmann) as measured on the inner surface of the sclera, or 7 to 8 millimeters as measured on the outer surface of the sclera. Let us recall also, that the cornea ciliaris is about 2 millimeters broad, or when measured on the outer surface of the sclera 3 to 3.5 millimeters, and that the orbicularis ciliaris has a width of 4.5 to 5 millimeters on the outer scleral surface. The orbicularis ciliaris of the ciliary body contains a vascular layer much like that of the choroid with which it is continuous. It is not, however so wide and there is no choriocapillaris. This is the least vascular structure or area of the eyeball outside of the cornea. Since the arterial supply to the whole anterior region of the uvea passes through the ciliary muscle the vessels in the orbicularis ciliaris consist almost entirely of veins which run backward meridionally and parallel to each other to empty into the vena vorticosus. These anatomical considerations seem to point to the orbicularis ciliaris of the ciliary body as the most optimum site of entrance to remove intraocular metallic foreign bodies by the posterior route. There is no danger of detachment of the retina if a hinged scleral trephine button is made just anterior to the ora serrata and the underlying vena incised meridionally with a cataract knife. This might occur if the opening were made further posteriorly. There is a minimum of hemorrhage since the least vascu-

lar zone of the posterior segment is entered. The postoperative reaction is surprisingly slight. The wound heals readily and without tendency for staphyloma. I can see no reason for fearing sympathetic ophthalmia. This approach has been used with much satisfaction in the University Clinic for over 10 years (1).

RETROBULBAR NEURITIS IN RELATION TO SINUS DISEASE

JAMES B. COSTEN M.D. F.A.C.S., St. Louis, Missouri

NO subject in the entire field of otolaryngology has been capable of exciting such perennial interest and controversy as the relationship of retrobulbar neuritis to sinus disease. Many such cases had been reported as relieved by opening of the nasal sinuses but close anatomical relationship was revealed in the studies of Onodi in 1908. He demonstrated how frequently the optic nerve passes along the upper and outer wall of the sphenoid and posterior ethmoid cells, covered only by a thin bone or membrane. To remove the effects of direct absorption of pus or the pressure from thickened membranes seemed merely to require resection of this posterior group of sinuses.

Hajak, Sluder, Sauer, Loeb and others of that era reported many successful cases in which the blindness was relieved after such surgery. The recognition of multiple sclerosis as the commonest cause of retrobulbar neuritis discounted many of the early successful cases and incited further interest in the etiology of the disease.

It was recognized as a lesion of the papillomacular bundle with enlargement of the blind spot and central scotoma without visible change in the appearance of the eye grounds. Gracie ascribed this to the involvement of the central vein of Vossius, secondary to the involvement of the perosteal or dural veins adjacent to the diseased sinuses.

L. White (20) made most important studies, beginning in 1913, on the relationship of the diameter of the optic canal to the prognosis, finding that 50 per cent of patients with optic nerve involvement having 4 millimeter canal measurements were unimproved, regardless of the type of treatment. He showed that extensive pneumatization of the sphenoid next to the canal is usually associated with a smaller caliber canal and thinning of its bone. He urged the search for an elimination of all distant foci (3) becoming more and more conservative with regard to the surgical drainage of posterior sinuses.

As the preponderance of multiple sclerosis gave it first place in etiology of this type of optic neur-

itis, toxic effects from chemicals, alcohol, and tobacco from diabetes, nephritis, and virus diseases became recognized as next in frequency, revising the figures of toxic absorption from the sinuses to the bottom of the list. Authentic reports revealing sinus disease clearly as the cause had been made by Oliver and Crowe in 1917 and Peter in 1918. Ellett in 1929 reported cases of prompt recovery of vision after drainage of sinuses as well as after removal of teeth. He emphasized the need of careful analysis of the case before selecting treatment. Benedict and Lillie in similar reports found the incidence of proved sinus infection so low in the study of large series of retrobulbar neuritis that they both considered its importance negligible. Campbell, after a comprehensive review of numerous authors giving discouraging opinions, conceded that there is in a small percentage of cases an actual indication for surgical drainage of the sinuses in retrobulbar neuritis. The study of Kennedy in 1936, definitely established allergy as an important cause of retrobulbar neuritis to be considered in every case until any possible allergic factor has been removed from contact.

Early stages of visual disturbance in retrobulbar neuritis may be only vague subjective symptoms such as blurring which clears up rapidly. It is unlikely that many in this stage are examined. To proceed with diagnosis, multiple sclerosis must be ruled out by its numerous neurological signs and differentiated from syphilis by the use of both blood and spinal fluid serological tests. Any preceding acute febrile disease or chronic exposure to chemicals, nicotine, or alcohol is sought in the history. Foci such as diseased tonsils and teeth are carefully examined and elaborate study of the paranasal sinuses is made. Besides routine x-ray positions, lipiodol plates, made by puncture of maxillaries and by Proets (16) displacements into sphenoids, are of great value. Laminograms made at 5, 6 and 7 centimeter levels in the coronal plane of the head, recently described by Cone, Dean, and Moore, aid greatly in the estimation of density in the posterior group of sinuses, in this district superimposed cells can be truly analyzed by this method only.

In 1939 a personal series of 13 cases (5) as presented before the Southern Medical Association,

From the Department of Otolaryngology, Washington University School of Medicine, and the Oscar Johnson Institute, St. Louis, Missouri.
Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

to Barnes Hospital in 1 of which a diagnosis of retrobulbar neuritis was made. The principal contributing factors noted in the 27 cases of retrobulbar neuritis were remote foci in 6 cases, alcohol in 3 cases, brain tumor in 2 cases, sinus disease in 8 cases, systemic disease in 3 cases, complicating allergy in 2. Of the 27 patients with a diagnosis of retrobulbar neuritis, the condition of 8 was improved by sphenothmoidectomy, 1 after 2 years, 6 were improved by typhoid and fever therapy, 2 made a spontaneous recovery with no treatment. One is reviewed in detail with the permission of Doctors Cone and Votaw. It is of particular interest because there is an unproved allergy in the history, prompt recovery of the patient after surgery of diseased sinuses and a follow-up for 2½ years with no further visual disturbance.

CASE 6 W W R, aged 22 years, a white female, entered Barnes Hospital April 7, 1939, with failing vision of 3 weeks which had followed a left frontal headache with no preceding throat or nose obstruction. She gave a history of hives and angioneurotic edema in January, 1939 after eating shrimp, but no likely causative agent was taken before this attack. Examination by Dr. Lawrence Post showed vision 20/60 in the left eye with an eccentric scotoma. Nose and throat examination was entirely negative except for delayed emptying of the left posterior noid. Laminagrams had shown blurring of the left sphenoid section of the left sphenoid and ethmoid cells was done with marked improvement of vision in the left eye in 3 days. Section of tissues from the sinuses showed marked inflammatory change. The vision on May 10, 1939, in the left eye was 20/25-2.

Whatever is done for the relief of retrobulbar neuritis or for extensive acute retinal lesions, in the way of sinus surgery or removal of foci, should be promptly carried out, damage to the optic nerve being rapid and commonly followed by permanent residual atrophy. The opportunity to demonstrate improvement after surgery is limited because the cases showing indications are few in number, and the surgery is done concurrently with all forms of general therapy. When used there are various theories regarding the value of surgery of the sinuses.

- 1 Drainage of infectious material away from direct contact with the optic nerve
- 2 Removal of a negative pressure effect within the sinuses which produce an emigration of toxins and bacteria to the tissues about the optic nerve (White, 20)
- 3 Decompression of the nerve by free incision of blood and lymphatic vessels when engorged tissues are removed (Proetz, 17)
- 4 Production of hyperemia, restoring blood supply to the nerve, anemic from swelling within

the bony canal or by thrombosis of small vessels supplying them. Benedict and Lillie believe that the same thing may be accomplished by the use of stimulating chemicals within the nose. A most elaborate survey by Duggan, 1941, takes a strong stand against removal of foci except for the sake of removal as a toxic source—and not that such removal would influence an angiospastic lesion to which he thinks retrobulbar neuritis belongs, he considers it a localized tissue anoxia, a histamine effect, and “vasodilating therapy directed toward these pathological changes is both logical and effective—that nasal sinasal surgery is nonspecific in mode of action—and that improvement of vision is more rapid and more marked (with vasodilator treatment) than when other types or no therapy at all is used.”

CONCLUSION

Even though the question should remain open because of so many qualifying factors, surgery of any diseased sinuses seems to be indicated when the condition occurs in its rare association with retrobulbar neuritis. The presence of allergy increases the indication for surgery according to our experience. Study of the records certainly confirms the stated importance of removal of foci distant from the optic nerve, such as teeth and tonsils. The use of laminagrams is a valuable addition to the x-ray study of posterior sinus disease.

TABLE I.—CASES OF RETROBULBAR NEURITIS (27) ADMITTED TO BARNES HOSPITAL FROM 1929 TO 1939

Age	Sex	Eyes involved	Concurrent disease	General therapy	Local therapy	Course
73	M	Both	Multiple sclerosis	Not treated		Not improved
88	F	Both			Sphenothoracicductomy (bilateral)	Improved
98	M	Both	Alveolar abscess	Not treated		Not improved
	M	Both		Intravenous typhoid		Improved
97	M (Col.)	Both	Diabetes	Insulin		Improved
37	M	Both	Alcohol and tobacco amblyopia	Intravenous typhoid	Tonsillectomy	Improved
43	M	Both	Alcohol arteriosclerosis	Lamb alcohol		Improved
68	M	Both	Nephrectomy 6 months before			Not treated
98	M	Both			Tonsillectomy	Improved
34	F	L			Sphenothoracicductomy (bilateral)	Improved
98	M	Both	Prostatic disease	Intravenous typhoid	Tonsillectomy	Improved
44	M	Both	Central nervous system syphilis	Fever therapy hypothermia		Not improved
53	F	Both	Hypothyroidism		Displacement arthrograms	Improved
60	M	Both	Rheumat?			Not treated
34	M	Both			Tonsillectomy	Improved
98	M (Col.)	Both			Sphenothoracicductomy Astrum windows	Improved
33	M	R.	Sphenosinus paranasalis		Sphenothoracicductomy right	Improved
61	M	Both	Cystitis of bladder right	Not treated		Not improved
51	M	Both	Brain tumor, anterior of sphenoid	Cranectomy	Tonsillectomy	Not improved
33	F	Both	Brain tumor cholesteatoma	Cholecystectomy craniotomy (1)		Improved
98	M	Both		Intravenous typhoid	Sphenothoracicductomy (unilateral)	Improved 75% cranial nerve, dark
30	F	L		Intravenous typhoid		Improved
34	F (Col.)	L		Intravenous typhoid	Cases not found	Improved
64	M	Both	Alcohol exogenous hypertension	Yodium therapy		Improved
48	F	Both	Psychomotor		Sphenothoracicductomy (bilateral)	Improved
80	F	Both	Allergy		Sphenothoracicductomy (bilateral)	Improved
79	F	L	Allergy, lewis		Sphenothoracicductomy, left	Improved

is a variety of retinal lesions, all seen during an acute stage and all responding more or less promptly to surgical drainage of sinuses, and removal of tonsils. Cases 1 and 5 had definite allergy the latter patient becoming very sensitive to drugs used in the eye. Although she had responded to fever therapy with remission of symptoms, the longest period of improvement began at once after clearing out the maxillary sinuses and she is more comfortable now than at any period of her complicated eye history. Case 1 belongs to

the group classified as lactation amblyopia (Imachi and Marooka, and Sautter) for which Sautter's treatment was salicylate sweats, high doses of vitamin B₁, and calcium preparations.

In review of all patients with optic neuritis admitted to Barnes Hospital in the past 10 years—85 in number not including records of our patient dispensary of Washington University—it is noted that in 27 a diagnosis of retrobulbar neuritis was made (Table I). During the same period there were 195 cases of multiple sclerosis admitted

COSTEN RETROBULAR NEURITIS AND SINUS DISEASE

597

to Barnes Hospital in 1 of which a diagnosis of retrobulbar neuritis was made. The principal contributing factors noted in the 27 cases of retrobulbar neuritis were remote foci in 6 cases, alcohol in 3 cases, brain tumor in 2 cases, sinus disease in 8 cases, systemic disease in 3 cases, complicating allergy in 2. Of the 27 patients with a diagnosis of retrobulbar neuritis, the condition of 8 was improved by sphenothmoidectomy, 1 after 2 years, 6 were improved by typhoid and fever therapy, 2 made a spontaneous recovery with no treatment. One is reviewed in detail with the permission of Doctors Cone and Votaw. It is of particular interest because there is an unproved allergy in the history, prompt recovery of the patient after surgery of diseased sinuses and a follow-up for 2½ years with no further visual disturbance.

CASE 6 W W R, aged 22 years, a white female, entered Barnes Hospital April 7, 1939, with failing vision of 3 weeks which had followed a left frontal headache with no preceding throat or nose obstruction. She gave a history of hives and angioneurotic edema in January, 1939, after eating shrimp, but no likely causative agent was taken before this attack. Examination by Dr. Lawrence Post showed vision 20/60 in the left eye with an eccentric scotoma. Nose and throat examination was entirely negative except for delayed emptying of lipiodol from the left sphenoid. Laminagrams had shown blurring of the left posterior section of the left sphenoid and ethmoid cells was done with marked improvement of vision in the left eye in 3 days. Section of tissues from the sinuses showed marked inflammatory change. The vision on May 10, 1939, in the left eye was 20/25-2.

Whatever is done for the relief of retrobulbar neuritis or for extensive acute retinal lesions, in the way of sinus surgery or removal of foci, should be promptly carried out, damage to the optic nerve being rapid and commonly followed by permanent residual atrophy. The opportunity to demonstrate improvement after surgery is limited because the cases showing indications are few in number, and the surgery is done concurrently with all forms of general therapy. When used there are various theories regarding the value of surgery of the sinuses.

- 1 Drainage of infectious material away from direct contact with the optic nerve
- 2 Removal of a negative pressure effect within the sinuses which produce an emigration of toxins and bacteria to the tissues about the optic nerve (White, 20)
- 3 Decompression of the nerve by free incision of blood and lymphatic vessels when engorged tissues are removed (Proetz, 17)
- 4 Production of hyperemia, restoring blood supply to the nerve, anemic from swelling within

the bony canal or by thrombosis of small vessels supplying them. Benedict and Lillie believe that the same thing may be accomplished by the use of stimulating chemicals within the nose. A most elaborate survey by Duggan, 1941, takes a strong stand against removal of foci except for the sake of removal as a toxic source—and not that such removal would influence an angiospastic lesion to which he thinks retrobulbar neuritis belongs, he considers it a localized tissue anoxia, a histamine effect, and “vasodilating therapy directed toward these pathological changes is both logical and effective—that nasal sinus surgery is nonspecific in mode of action—and that improvement of vision is more rapid and more marked (with vasodilator treatment) than when other types or no therapy at all is used.”

CONCLUSION

Even though the question should remain open because of so many qualifying factors, surgery of any diseased sinuses seems to be indicated when the condition occurs in its rare association with retrobulbar neuritis. The presence of allergy increases the indication for surgery according to our experience. Study of the records certainly confirms the stated importance of removal of foci distant from the optic nerve, such as teeth and tonsils. The use of laminagrams is a valuable addition to the x-ray study of posterior sinus disease.

MANAGEMENT OF OPHTHALMOLOGICAL SURGICAL COMPLICATIONS

THOMAS D ALLEN M D F.A.C.S Chicago, Ill. on

In its broadest sense surgical complications imply not only the complications of the actual surgical procedure, but also the undesirable and unlooked for reactions to surgery on remote parts of the body. These can be divided roughly into three large groups. The first group comprises conditions in which surgery is attended by grave risks the second, cases in which the eyes themselves have given evidence of intolerance to any surgery. The third group is made up of cases in which one would naturally expect a good result but complications arise through fortuitous circumstances such as the patient falling out of bed or becoming delirious and pulling off the bandages and injuring the eye.

First let us consider that group of cases in which life expectancy is short, i.e., malignancy or advanced senility or great physical depression. Only the most necessary of operations should be done. Sometimes however even in advanced senility one obtains very favorable results. I remember operating on a patient at the clinic who was 96 years old and had a tumor of the iris. It seemed to be well localized but was growing. He came of a long lived family his father being 100 years of age at the time of death and his mother well along in years. He himself was in very good health considering his years. He recovered from the iridectomy and apparently there were no metastases. A year and a half later I removed the lens of the eye because the vision had deteriorated to less than 20/300. He recovered in the usual time without complications with vision of 20/40. There was very slight macular degeneration. He read large printed matter for several years. He lived to the age of 103 years.

In systemic diseases such as advanced tuberculosis great care should be taken not to do unnecessary surgery particularly such surgery as will require the patient to lie quietly on his back for a day or two. In diabetes one does not worry as much as one used to. Our practice is to put the patient in the hospital for several days or a week before operation—sometimes longer—so that the diabetic service will be able to control the situ-

ation we do not operate until that service tells us to go ahead. In acute infections such as diphtheria, scarlet fever or acute colds one must be exceptionally careful. All but the most urgent surgery should be postponed. I recall a little Chinese boy who was brought in with a bad laceration of the eye. He had fallen on a milk bottle. The cornea had to be sewed up immediately although he had a fever of 101 degrees and a bronchitis that was very evident. In this case intravenous anesthesia was given, the eye was sewed up the conjunctival flap was brought over and the patient then put on the medical service. There were no serious complications.

Infections around the teeth and gums, to my mind, constitute contraindications for any but immediate surgery. The mouth should be cleaned up first and any pockets of pus or infected roots should be treated or the teeth removed. We are more apt to see these patients in the clinic than in private practice and therefore are apt to overlook the obvious.

Let us next take that group of cases in which we have learned to expect only grief for instance an acute inflammation in the sympathizing eye of sympathetic ophthalmia.

CASE REPORT

Mr. Joon, No C 5553, 74 years of age, was brought to me with a history that nearsightedness had begun 19 months before. A diagnosis of cataract had been made and the left eye was operated upon in December 1933, about 8 months before I saw him. Apparently there was post-operative prolapse of the iris. He left the hospital 5 days after the operation and the eye began to pain him very greatly. His doctor told him he had an infection and sent him to dentist. He found good many of his teeth in bad condition. Nearly all of these were extracted during the succeeding several months but there was no improvement in his eyesight. At times there was very great pain which began to affect the right eye about 3 months before I saw him, that is, in May. This right eye had been perfectly normal before the operation according to his story and he had been advised that no operation would be necessary upon that eye.

I found his left vision was 0, the tendon -3. The eye was markedly inflamed and shrunken. The cornea was waxy and wrinkled and the eyeball was abnormally tender. The right eye was not particularly inflamed, the vision counting fingers at 6 feet in dim light. The pupil was unobscured and vertically oval, about 3.5 by 4 millimeters. There was gray reflex in the pupil. The anterior chamber was of fair depth. There were few precipitates

on the lower portion of the cornea and several pupillary synechiae. Considerable pigment was present on the anterior capsule and there was clouding of the cortex. No cycloplegic or mydriatic had been used in this eye according to the patient's statement.

After atropine was used in the right eye, 3 rather firm adhesions were found and there was a marked opacity on the posterior pole of the lens so that it interfered considerably with the view of the fundus. A faint view of one artery only was seen in the fundus.

In order to relieve him of pain the left eye was enucleated, and the routine medical treatment for sympathetic uveitis of the right eye instituted, salicylates, typhoid vaccine intravenously, local heat and cycloplegia. The iris rather promptly subsided, but it would recur from time to time, lasting for a few days. The tension of this eye was within normal limits for some weeks but it gradually increased and neither cycloplegics nor miotics helped. He was carried along with a tension in the 30's for about 6 months, when the tension rose to 60 millimeters of mercury, at which time he was hospitalized and a paracentesis done. Following this the eye remained quiet for a month, when suddenly there developed considerable pain in the eye and I found a spontaneous rupture of the anterior capsule of the lens, just below the center. Cortex was found in the anterior chamber. The tension was considerably increased but the eye was too tender for us to use the tonometer.

In consultation with both Dr. Gradle and with Dr. Brawley it was decided to attempt an immediate removal of the lens and the capsule if possible. The lens could not be removed in the capsule naturally because the capsule had already ruptured. After VanLint aknesia and a retrobulbar anesthesia of the ciliary ganglion and 1 per cent cocaine subconjunctivally was used to assure complete anesthesia, I dissected a conjunctival flap down from about 4 millimeters from the limbus and placed the sutures before making a corneal section. The corneal section was then done, a complete root iridectomy was obtained, the nucleus and cortex were expressed and the chamber irrigated without complications. It was impossible to remove much of the anterior capsule.

At first dressing the pupil was found filled with an exudate and the iris was quite thick. The pupil remained fairly large but the anterior chamber did not form. Connected with the pupillary exudate was a yellowish white thick mass which lay on a portion of the iris and in the colobomatous area and there was a distinct tumefaction of the iris at 11 o'clock. He was markedly sensitive to atropine and scopolamine so duboisine was used. The tumefaction in the iris gradually subsided and the cornea seemed to become more normal. As the anterior chamber reformed it was filled with exudate so that there was no aqueous interval seen with the slit lamp beam. Two months after the operation there were minute hemorrhages present on the lens capsule and iris. Later the cornea became quite vascularized, the projection was very poor, the tension became minus and the sclera began to shrink. The vision of course was 0.

I cite this case for several reasons. In the first place, the time to begin to handle surgical complications is *before surgery is attempted*. This man's teeth did not suddenly become worse after the cataract operation was done. The teeth should have been put in order before the first cataract operation was done. One should also anticipate possible complications of a prostatic nature or a gall bladder nature or a bowel nature.

My uncle was operated upon unsuccessfully in Florida for cataract because the doctor had not recognized a habitual cough that he could not control. This cough racked him at least twice an hour during his waking hours. Naturally he had a prolapse of the iris and a detachment of the retina. It is easier to manage these surgical complications before we attempt surgery rather than afterward.

Another reason I have cited this case in such length is because of the short period of hospitalization following the cataract extraction. The operation was done on December 3, and he left the hospital on December 8. It is true that cataracts used to be done in the doctor's office and the patient allowed to go home the same day, possibly 8 or 10 miles into the country in a farm wagon, but you would not wish to have yourself or your relatives so treated. One of the most careful surgeons in the United States keeps his patients flat on their backs for several days, occasionally 2 weeks, after the operation and practically never lets them leave the hospital under 2 weeks. Some years ago I was impressed by the action of a general surgeon who removed my wife's gall bladder. It was a beautiful operation, clean anatomical dissection, clean anatomical removal. I marvelled that he did not look at the wound for 10 days. He was sure of his surgery. He was sure of his technique. I wonder how many of us can keep our hands off an eye that has been operated upon for cataract for 3 or 4 or 5 days after operation.

Another reason I quoted this history was the fact that the patient's right vision was normal, so he said, and he quoted the doctor as saying that no operation would have to be done on the right eye. Seldom do we need to operate for cataract when the vision of the other eye is good. Very occasionally we will find an overripe cataract or a cataract beginning to become overripe in one eye and no opacity or only an immature cataract in the other eye, the vision in the second eye being nearly normal.

Still another reason is that the doctor apparently lost interest in the case at a most critical time merely turning him over to the dentist who was in a distant city. Also, he did not recognize over a period of 2 months, the beginning signs of sympathetic ophthalmia or he would not have rested until the exciting eye had been removed.

I cannot emphasize too strongly. First, the most important thing in the management of complications is to *avoid having them* by careful preoperative study of the case and by refusing to operate upon patients unless there is definite

indication therefor. Second, consultation is always in order. The patients may protest that they think highly of us but they know that none of us is all wise and seldom do we find a patient who will not welcome consultation. The patient must have thorough confidence in the surgeon and the surgeon in himself.

One of the most difficult and one of the most usual complications after cataract extraction is prolapse of the iris. This problem has been met in several ways. The usual preventive measures have been peripheral or complete iridectomy and careful toilet of the wound, but occasionally one finds a small knuckle of iris appearing at the wound even when this is accomplished. We were taught in Vienna that prolapses usually occurred on the third or fourth day. Therefore it was not unusual to have the patient, after cataract operation, get off of the table and be led not carried, to his room. He was allowed to sit up in

chair until the second or third day when he was put to bed for a few days. I saw many prolapses on this regimen. Canthotomy on unruly patients, on patients with prominent eyes or on those who are deaf or cannot understand the language is a very valuable procedure as Dr. Gräfe has recently shown. Also complete anesthesia and proper akinesia are of prime importance.

On our service at the Illinois Eye and Ear Infirmary we have found that since our technique has been slightly changed prolapses are very much fewer than they used to be. On our service there are two first assistants who alternate in the operating room, changing off every 3 months. One is a staunch advocate of the Verhoeff radiating limbal suture with conjunctival suture. The other uses parallel corneoscleral sutures with conjunctival suture. Otherwise their techniques are quite similar and include culture from the conjunctiva taken 48 hours before the operation and at the operation, akinesia and ciliary ganglion anesthesia, iridectomy (peripheral or complete), careful extraction, careful postoperative toilet and a preliminary canthotomy if the patient is unco-operative or the eyeball is rather prominent. Their desire is to produce nonleaking close approximation of the wound. Dr. Leech examines his patients after 48 hours, Dr. Nethercut and I, after 96 hours. In case pain or suggestive fever occurs before the time for the regular dressing naturally our routine calls for immediate investigation of its cause. The first dressing is the most important as at that time careful handling will avoid prolapses that careless handling would produce. The careless removal of the dressings or raising of the upper lid with the thumb placed

over the supraorbital notch has caused more than one prolapse. The thumb should be placed temporal to the supraorbital notch and the lid should be very gently raised.

But once a prolapse occurs, it should be recognized and notations of its first appearance made upon the record. I am not inclined to touch it for nearly a week unless it occurs within 48 hours as I wish the wound to be as firmly healed in the rest of its extent, as is possible. At the end of a week, depending upon its size and whether or not it is covered with conjunctiva, the treatment begins. If it is a small prolapse and covered entirely with conjunctiva, after anesthetizing with pontocaine, we touch the prolapse with a very small applicator dipped in trichloroacetic acid. This treatment is repeated daily. It is important immediately before this treatment, to dry the area to be treated. The trichloroacetic acid is a saturated solution. A dry cotton-tipped applicator should then be applied so that the trichloroacetic acid will not touch other parts of the eye. This treatment is repeated daily for a week, then 3 times a week for 3 weeks. It is remarkable how many of these prolapses will flatten out under this treatment without further complication.

Larger prolapses and those not covered with conjunctiva have to be handled surgically. It is my opinion that as a rule we do not spend enough time planning our course of action, and certainly not enough time to get complete anesthesia when operation is decided upon. Also we are too anxious to get through with the operation, to cover up the eye to hide our errors of technique with a bandage. One must be exceedingly delicate as the tissues are very thin and undue haste or pressure will cause disastrous loss of vitreous. The part must be thoroughly anesthetized by retrobulbar and subconjunctival injection as well as topical application so that there will be absolutely no feeling. This anesthesia is decidedly more difficult than at the time of the first operation. One must remember also that unless the eyeball is soft before it is opened, as soon as the prolapsed iris is cut, vitreous will present. Therefore in the retrobulbar injections, enough adrenalin must be used with the anesthetic to cause a tension of -1 to the finger within 10 minutes. We wait until that softening occurs before opening the wound.

Some sort of a conjunctival flap must be prepared before the prolapse is excised. This can be a sliding flap or a simple cover. Sutures must be placed in the cornea and/or the scleral tissue. If one bears in mind the histological relationship in a case of prolapse he will better understand

how to handle the situation. A prolapse means that there is very little tissue between the contents of the eye and the outside world. At the edge of the prolapse the cornea and/or sclera are shelved to almost infinitesimal thinness. If the prolapse is large how can one expect to provide protection with only a conjunctival flap? It is essential to have the edges of cornea or sclera meet in such a way that they will grow together and be firm enough to withstand the postoperative intraocular tension. This may be aided by doing a cyclodialysis immediately after the prolapse is excised. Canthotomy will relieve postoperative pressure from without; this is imperative in the so-called "squeezers."

The actual excision is to my mind best preceded by a very light cautery, either chemical or thermal, of the epithelial structures that cover the prolapse and the nearby tissues, that is, for *at least* 2 millimeters beyond the prolapse. When the eyeball is thoroughly softened and after the conjunctival flap is prepared, one should carefully dissect down until the iris is reached at the root on both ends and on the scleral side of the prolapse. The iris is then grasped and an attempt made to free it very delicately from the *corneal* adhesions. This can usually be done with the fine forceps but occasionally a spatula is necessary. The prolapsed iris should be pulled out away from the adhesions to both distal and proximal edges and carefully excised so that the part remaining will retract. The corneoscleral edge is then very carefully prepared with the scissors in such a way that the drawing up of the sutures will cause an exact approximation of the two edges. Interrupted fine silk sutures threaded on small corneal needles are placed perpendicular to the wound so as to hold the edges together and make it watertight; they penetrate only the anterior layers of stroma. The sutures are then drawn up to demonstrate this and before being tied, their ends are passed through the conjunctival cowl. The sutures should be tied snugly but not so tightly as to invert or evert the edges. When they are tied we therefore have accurate approximation of an appreciable thickness of cornea and an appreciable thickness of sclera from the anterior surface of which all epithelium has been removed for at least 2 millimeters. The raw surface of the conjunctiva therefore has a chance to send down into these tissues new-formed blood vessels. Such an eye should be immediately treated with atropine and bichloride ointment and both eyes bandaged. It should not be re-examined for *at least* 4 days. Our recurrences are due to meddlingness inquisitiveness which should not be tolerated.

If we do our surgery well, we do not have to be meddling. If we do not do our surgery well, we should quit doing surgery. Prolapses sometimes occur in the best of hands but too many of them indicate poor surgery.

One of the most embarrassing complications which we encounter is an inability to extract the lens before loss of vitreous has taken place. This may be due to an improper corneal section. Recently one of the residents who had had some experience, inserted the cataract knife back of the iris. The anterior chamber in this case was particularly shallow and a corneal section should not have been attempted in the usual way. The knife was withdrawn and the section was completed by the attending surgeon with the aid of scissors. Fortunately the Verhoeff sutures had been previously placed and were ready to be tied before the attempted removal of the lens. When the iridectomy was done vitreous presented. The speculum was removed and the eye was closed for 5 minutes. The upper lid was raised with the suture which had previously been placed in it and a DeMarr retractor was inserted. The vitreous had replaced itself, the blood was washed out of the anterior chamber and on attempting to grasp the capsule with the forceps, again vitreous presented. To go after the lens in the usual way would have invited certain disaster. Consequently a thin probe with a very smooth knob at its end was used to break a few zonular fibers at a time. In order to do this the corneal lip had to be raised very gently. The fact that vitreous presented in the wound meant that some of the zonular fibers had already ruptured. Therefore the first to be ruptured intentionally were the lower ones, then those on each side, a few at a time, until nearly all of them were ruptured, after which the lens was easily removed with the loop. The Verhoeff sutures were pulled up and before being tied, the prolapsed vitreous was very carefully excised. (One must be cautious in this maneuver as the sutures can be cut so easily.) The sutures were then tied, and with a spatula, the iris was freed from the wound.

The removal of a lens freely floating in the vitreous presents many difficulties. Particularly is this so when it does not disappear into the vitreous until after the section has been made. This can best be handled by the use of a focussed fluorescent light, or by locating the lens with the ophthalmoscope, using a fluorescent light. Great care must be taken not to injure the retina as a hole is very often produced and detachment of the retina invariably results. It is considered better surgery to leave it alone unless it can be floated

indication therefor. Second consultation is always in order. The patients may protest that they think highly of us but they know that none of us is all wise and seldom do we find a patient who will not welcome consultation. The patient must have thorough confidence in the surgeon and the surgeon in himself.

One of the most difficult and one of the most usual complications after cataract extraction is prolapse of the iris. This problem has been met in several ways. The usual preventive measures have been peripheral or complete iridectomy and careful toilet of the wound, but occasionally one finds a small knuckle of iris appearing at the wound even when this is accomplished. We were taught in Vienna that prolapses usually occurred on the third or fourth day. Therefore it was not unusual to have the patient, after a cataract operation, get off of the table and be led not carried, to his room. He was allowed to sit up in a chair until the second or third day when he was put to bed for a few days. I saw many prolapses on this regimen. Canthotomy on unruly patients, on patients with prominent eyes or on those who are deaf or cannot understand the language is a very valuable procedure as Dr Gräfe has recently shown. Also complete anesthesia and proper akinesia are of prime importance.

On our service at the Illinois Eye and Ear Infirmary we have found that since our technique has been slightly changed prolapses are very much fewer than they used to be. On our service there are two first assistants who alternate in the operating room, changing off every 3 months. One is a staunch advocate of the Verhoeff radiating limbal suture with conjunctival cowl. The other uses parallel corneoscleral sutures with conjunctival cowl. Otherwise their techniques are quite similar and include culture from the conjunctiva taken 48 hours before the operation and at the operation, akinesia and diaphy ganglion anesthesia, iridectomy (peripheral or complete), careful extraction, careful postoperative toilet and a preliminary canthotomy if the patient is unco-operative or the eyeball is rather prominent. Their desire is to produce nonleaking close approximation of the wound. Dr Leech examines his patients after 48 hours, Dr Vetterli and I after 96 hours. In case pain or a suggestive fever occurs before the time for the regular dressing naturally our routine calls for immediate investigation of its cause. The first dressing is the most important as at that time careful handling will avoid prolapses that careless handling would produce. The careless removal of the dressings or raising of the upper lid with the thumb placed

over the supraorbital notch has caused more than one prolapse. The thumb should be placed temporal to the supraorbital notch and the lid should be very gently raised.

But once a prolapse occurs, it should be recognized and notations of its first appearance made upon the record. I am not inclined to touch it for nearly a week unless it occurs within 48 hours as I wish the wound to be as firmly healed in the rest of its extent, as is possible. At the end of a week, depending upon its size and whether or not it is covered with conjunctiva, the treatment begins. If it is a small prolapse and covered entirely with conjunctiva, after anesthetizing with pontocaine, we touch the prolapse with a very small applicator dipped in trichloroacetic acid. This treatment is repeated daily. It is important immediately before this treatment, to dry the area to be treated. The trichloroacetic acid is a saturated solution. A dry cotton-tipped applicator should then be applied so that the trichloroacetic acid will not touch other parts of the eye. This treatment is repeated daily for a week, then 3 times a week for 2 weeks. It is remarkable how many of these prolapses will flatten out under this treatment without further complication.

Larger prolapses and those not covered with conjunctiva have to be handled surgically. It is my opinion that as a rule we do not spend enough time planning our course of action, and certainly not enough time to get complete anesthesia when operation is decided upon. Also we are too anxious to get through with the operation, to cover up the eye, to hide our errors of technique with a bandage. One must be exceedingly delicate as the tissues are very thin and undue haste or pressure will cause disastrous loss of vitreous. The part must be thoroughly anesthetized by retrobulbar and subconjunctival injection as well as topical application so that there will be absolutely no feeling. This anesthetization is decidedly more difficult than at the time of the first operation. One must remember also that unless the eyeball is soft before it is opened, as soon as the prolapsed iris is cut, vitreous will present. Therefore in the retrobulbar injections, enough adrenalin must be used with the anesthetic to cause a tension of ± 1 to the fingers within 10 minutes. We wait until that softening occurs before opening the wound.

Some sort of a conjunctival flap must be prepared before the prolapse is excised. This can be a sliding flap or a simple cowl. Sutures must be placed in the corneal and/or the scleral tissues. If one bears in mind the histological relationship in case of prolapse he will better understand

how to handle the situation. A prolapse means that there is very little tissue between the contents of the eye and the outside world. At the edge of the prolapse the cornea and/or sclera are shelved to almost infinitesimal thinness. If the prolapse is large how can one expect to provide protection with only a conjunctival flap? It is essential to have the edges of cornea or sclera meet in such a way that they will grow together and be firm enough to withstand the postoperative intraocular tension. This may be aided by doing a cyclodialysis immediately after the prolapse is excised. Canthotomy will relieve postoperative pressure from without, this is imperative in the so-called "squeezers."

The actual excision is to my mind best preceded by a very light cautery, either chemical or thermal, of the epithelial structures that cover the prolapse and the nearby tissues, that is, for *at least* 2 millimeters beyond the prolapse. When the eyeball is thoroughly softened and after the conjunctival flap is prepared, one should carefully dissect down until the iris is reached at the root on both ends and on the scleral side of the prolapse. The iris is then grasped and an attempt made to free it very delicately from the *corneal* adhesions. This can usually be done with the fine forceps but occasionally a spatula is necessary. The prolapsed iris should be pulled out away from the adhesions to both distal and proximal edges and carefully excised so that the part remaining will retract. The corneoscleral edge is then very carefully prepared with the scissors in such a way that the drawing up of the sutures will cause an exact approximation of the two edges. Interrupted fine silk sutures threaded on small corneal needles are placed perpendicular to the wound so as to hold the edges together and make it watertight, they penetrate only the anterior layers of stroma. The sutures are then drawn up to demonstrate this and before being tied, their ends are passed through the conjunctival cowl. The sutures should be tied snugly but not so tightly as to invert or evert the edges. When they are tied we therefore have accurate approximation of an appreciable thickness of cornea and an appreciable thickness of sclera from the anterior surface of which all epithelium has been removed for at least 2 millimeters. The raw surface of the conjunctiva therefore has a chance to send down into these tissues new-formed blood vessels. Such an eye should be immediately treated with atropine and bichloride ointment and both eyes bandaged. It should not be re-examined for *at least* 4 days. Our recurrences are due to meddlesome inquisitiveness which should not be tolerated.

If we do our surgery well, we do not have to be meddlesome. If we do not do our surgery well, we should quit doing surgery. Prolapses sometimes occur in the best of hands but too many of them indicate poor surgery.

One of the most embarrassing complications which we encounter is an inability to extract the lens before loss of vitreous has taken place. This may be due to an improper corneal section. Recently one of the residents who had had some experience, inserted the cataract knife back of the iris. The anterior chamber in this case was particularly shallow and a corneal section should not have been attempted in the usual way. The knife was withdrawn and the section was completed by the attending surgeon with the aid of scissors. Fortunately the Verhoeff sutures had been previously placed and were ready to be tied before the attempted removal of the lens. When the iridectomy was done vitreous presented. The speculum was removed and the eye was closed for 5 minutes. The upper lid was raised with the suture which had previously been placed in it and a DeMarr retractor was inserted. The vitreous had replaced itself, the blood was washed out of the anterior chamber and on attempting to grasp the capsule with the forceps, again vitreous presented. To go after the lens in the usual way would have invited certain disaster. Consequently a thin probe with a very smooth knob at its end was used to break a few zonular fibers at a time. In order to do this the corneal lip had to be raised very gently. The fact that vitreous presented in the wound meant that some of the zonular fibers had already ruptured. Therefore the first to be ruptured intentionally were the lower ones, then those on each side, a few at a time, until nearly all of them were ruptured, after which the lens was easily removed with the loop. The Verhoeff sutures were pulled up and before being tied, the prolapsed vitreous was very carefully excised. (One must be cautious in this maneuver as the sutures can be cut so easily.) The sutures were then tied, and with a spatula, the iris was freed from the wound.

The removal of a lens freely floating in the vitreous presents many difficulties. Particularly is this so when it does not disappear into the vitreous until after the section has been made. This can best be handled by the use of a focussed fluorescent light, or by locating the lens with the ophthalmoscope, using a fluorescent light. Great care must be taken not to injure the retina as a hole is very often produced and detachment of the retina invariably results. It is considered better surgery to leave it alone unless it can be floated

indication therefor. Second, consultation is all ways in order. The patients may protest that they think highly of us but they know that none of us is all wise and seldom do we find a patient who will not welcome consultation. The patient must have thorough confidence in the surgeon and the surgeon in himself.

One of the most difficult and one of the most usual complications after cataract extraction is prolapse of the iris. This problem has been met in several ways. The usual preventive measures have been peripheral or complete iridectomy and careful toilet of the wound but occasionally one finds a small knuckle of iris appearing at the wound even when this is accomplished. We were taught in Vienna that prolapses usually occurred on the third or fourth day. Therefore it was not unusual to have the patient after a cataract operation, get off of the table and be led, not carried, to his room. He was allowed to sit up in a chair until the second or third day when he was put to bed for a few days. I saw many prolapses on this regimen. Canthotomy on unruly patients, on patients with prominent eyes or on those who are deaf or cannot understand the language is a very valuable procedure, as Dr. Gräfe has recently shown. Also complete anesthesia and proper akinesia are of prime importance.

On our service at the Illinois Eye and Ear Infirmary we have found that since our technique has been slightly changed prolapses are very much fewer than they used to be. On our service there are two first assistants who alternate in the operating room, changing off every 3 months. One is a staunch advocate of the Verhoeff suturing limbal suture with conjunctival cowl. The other uses parallel corneoscleral sutures with conjunctival cowl. Otherwise their techniques are quite similar and include culture from the conjunctiva taken 48 hours before the operation and at the operation, akinesia and ciliary ganglion anesthesia, iridectomy (peripheral or complete), careful extraction, careful postoperative toilet and a preliminary canthotomy. If the patient is unco-operative or the eyeball is rather prominent. Their desire is to produce an airtight close approximation of the wound. Dr. Leech examines his patients after 48 hours, Dr. Nettercut and I, after 96 hours. In case pain or a suggestive fever occurs before the time for the regular dressing naturally our routine calls for immediate investigation of its cause. The first dressing is the most important as at that time careful handling will avoid prolapses that careless handling would produce. The careless removal of the dressings or raising of the upper lid with the thumb placed

over the supraorbital notch has caused more than one prolapse. The thumb should be placed temporal to the supraorbital notch and the lid should be very gently raised.

But once a prolapse occurs, it should be recognized and notations of its first appearance made upon the record. I am not inclined to touch it for nearly a week unless it occurs within 48 hours as I wish the wound to be as firmly healed in the rest of its extent, as is possible. At the end of week, depending upon its size and whether or not it is covered with conjunctiva, the treatment begins. If it is a small prolapse and covered entirely with conjunctiva, after anesthetizing with pontocaine we touch the prolapse with a very small applicator dipped in trichloroacetic acid. This treatment is repeated daily. It is important immediately before this treatment, to dry the area to be treated. The trichloroacetic acid is a saturated solution. A dry cotton-tipped applicator should then be applied so that the trichloroacetic acid will not touch other parts of the eye. This treatment is repeated daily for a week, then 3 times a week for 3 weeks. It is remarkable how many of these prolapses will flatten out under this treatment without further complication.

Larger prolapses and those not covered with conjunctiva have to be handled surgically. It is my opinion that as a rule we do not spend enough time planning our course of action, and certainly not enough time to get complete anesthesia when operation is decided upon. Also we are too anxious to get through with the operation, to cover up the eye to hide our errors of technique with a bandage. One must be exceedingly delicate as the tissues are very thin and undue haste or pressure will cause disastrous loss of vitreous. The part must be thoroughly anesthetized by retrobulbar and subconjunctival injection as well as topical application so that there will be absolutely no feeling. This anesthetization is decidedly more difficult than at the time of the first operation. One must remember also that unless the eyeball is soft before it is opened, as soon as the prolapsed iris is cut, vitreous will present. Therefore in the retrobulbar injections, enough adrenalin must be used with the anesthetic to cause a tension of -1 to the fingers within 10 minutes. We wait until that softening occurs before opening the wound.

Some sort of a conjunctival flap must be prepared before the prolapse is excised. This can be a sliding flap or a simple cowl. Sutures must be placed in the corneal and/or the scleral tissues. If one bears in mind the histological relationship in a case of prolapse he will better understand

how to handle the situation. A prolapse means that there is very little tissue between the contents of the eye and the outside world. At the edge of the prolapse the cornea and/or sclera are shelved to almost infinitesimal thinness. If the prolapse is large how can one expect to provide protection with only a conjunctival flap? It is essential to have the edges of cornea or sclera meet in such a way that they will grow together and be firm enough to withstand the postoperative intraocular tension. This may be aided by doing a cyclodialysis immediately after the prolapse is excised. Canthotomy will relieve postoperative pressure from without, this is imperative in the so-called "squeezers."

The actual excision is to my mind best preceded by a very light cautery, either chemical or thermal, of the epithelial structures that cover the prolapse and the nearby tissues, that is, for *at least* 2 millimeters beyond the prolapse. When the eyeball is thoroughly softened and after the conjunctival flap is prepared, one should carefully dissect down until the iris is reached at the root on both ends and on the scleral side of the prolapse. The iris is then grasped and an attempt made to free it very delicately from the *corneal* adhesions. This can usually be done with the fine forceps but occasionally a spatula is necessary. The prolapsed iris should be pulled out away from the adhesions to both distal and proximal edges and carefully excised so that the part remaining will retract. The corneoscleral edge is then very carefully prepared with the scissors in such a way that the drawing up of the sutures will cause an exact approximation of the two edges. Interrupted fine silk sutures threaded on small corneal needles are placed perpendicular to the wound so as to hold the edges together and make it watertight, they penetrate only the anterior layers of stroma. The sutures are then drawn up to demonstrate this and before being tied, their ends are passed through the conjunctival cowl. The sutures should be tied snugly but not so tightly as to invert or evert the edges. When they are tied we therefore have accurate approximation of an appreciable thickness of cornea and an appreciable thickness of sclera from the anterior surface of which all epithelium has been removed for at least 2 millimeters. The raw surface of the conjunctiva therefore has a chance to send down into these tissues new-formed blood vessels. Such an eye should be immediately treated with atropine and bichloride ointment and both eyes bandaged. It should not be re-examined for *at least 4 days*. Our recurrences are due to meddling and inquisitiveness which should not be tolerated.

If we do our surgery well, we do not have to be meddling. If we do not do our surgery well, we should quit doing surgery. Prolapses sometimes occur in the best of hands but too many of them indicate poor surgery.

One of the most embarrassing complications which we encounter is an inability to extract the lens before loss of vitreous has taken place. This may be due to an improper corneal section. Recently one of the residents who had had some experience, inserted the cataract knife back of the iris. The anterior chamber in this case was particularly shallow and a corneal section should not have been attempted in the usual way. The knife was withdrawn and the section was completed by the attending surgeon with the aid of scissors. Fortunately the Verhoeff sutures had been previously placed and were ready to be tied before the attempted removal of the lens. When the iridectomy was done vitreous presented. The speculum was removed and the eye was closed for 5 minutes. The upper lid was raised with the suture which had previously been placed in it and a DeMarr retractor was inserted. The vitreous had replaced itself, the blood was washed out of the anterior chamber and on attempting to grasp the capsule with the forceps, again vitreous presented. To go after the lens in the usual way would have invited certain disaster. Consequently a thin probe with a very smooth knob at its end was used to break a few zonular fibers at a time. In order to do this the corneal lip had to be raised very gently. The fact that vitreous presented in the wound meant that some of the zonular fibers had already ruptured. Therefore the first to be ruptured intentionally were the lower ones, then those on each side, a few at a time, until nearly all of them were ruptured, after which the lens was easily removed with the loop. The Verhoeff sutures were pulled up and before being tied, the prolapsed vitreous was very carefully excised. (One must be cautious in this maneuver as the sutures can be cut so easily.) The sutures were then tied, and with a spatula, the iris was freed from the wound.

The removal of a lens freely floating in the vitreous presents many difficulties. Particularly is this so when it does not disappear into the vitreous until after the section has been made. This can best be handled by the use of a focussed fluorescent light, or by locating the lens with the ophthalmoscope, using a fluorescent light. Great care must be taken not to injure the retina as a hole is very often produced and detachment of the retina invariably results. It is considered better surgery to leave it alone unless it can be floated

into the anterior chamber and incarcerated there by contracting the pupil behind it.

Intraocular hemorrhage on the fourth or fifth postoperative day is usually not of great import but occasionally small vessel will repeatedly bleed even after a simple iridectomy. Thorough study of the vitamin K and vitamin C content of the blood should be made. The patient's blood should be typed; we have found that small transfusions of blood repeated 2 or 3 times are usually followed by very satisfactory results. The opposite treatment—preoperative bleeding—is also occasionally successful, especially if the blood pressure is elevated. Undoubtedly preoperative bleeding of the patient used to be done too frequently. I remember Dr. Casey Woods preoperative orders were frequently "Be ready to take 100 cubic centimeters of blood just before the operation."

I recall the case of a friend of mine who had a glaucoma in its early stages. He very much wished to be relieved of the necessity of using drops and as the drops did not perfectly control the tension at all times, it was felt wise to operate. A simple iridectomy was done without complications. On the second night he hit the eye with his hand while asleep and this was followed by some pain. The next morning a small amount of blood was found in the anterior chamber. The bleeding continued until the chamber was nearly filled with blood and on the fourth day a small transfusion was given him before the chamber was opened to irrigate. The transfusion was repeated and he had no further complications.

This matter of postoperative bleeding that occurs spontaneously is often of grave concern and calls for the co-operation of an internist who is studying hematology. Small transfusions of 100 cubic centimeters or thereabouts repeated daily are often of great benefit. I have not found calcium therapy as beneficial as some have claimed it to be. Should the blood remain in the anterior chamber for any length of time there results a blood staining of the cornea. I make it a practice to evacuate it about the seventh day unless by that time it seems to be disappearing.

Postoperative glaucoma is a condition that we would see less often if we would study our cases thoroughly from the standpoint of unearthing a very early glaucoma. If we find an early glaucoma I believe that it is a point of wisdom to do a deep root iridectomy preliminary to a cataract extraction. The iridectomy should be complete if it is found that the pupil will not dilate well during the preliminary study. I believe that the tonometer is not used one tenth as much as it

should be in our preliminary examinations. In this paper we cannot take up what constitutes a thorough examination of the eyes but suffice it to say that we cannot make such an examination in 1 or 2 days. When we do find that there is a postoperative glaucoma, naturally there are counteracting measures which should be taken. One of the necessary procedures is to examine the iris first with the slit lamp and a very fine beam and second, with a gonioscopic contact glass. Gonioscopy is coming into its own slowly but surely. Just as one learns microscopy first with a low power instrument, so one should learn gonioscopy first with a simple loupe and a good spot light. The higher the magnification and the more knife-like the beam of light naturally the greater the detail.

As a rule a postoperative glaucoma shows up within a month or 6 weeks after the operation. Sometimes it is brought on by continued instillation of atropine. Occasionally it can be adequately controlled by the use of a miotic. Often, however, operative measures are necessary. These measures will depend upon what one sees with the gonioscope. If the iris angle is well open and there are no peripheral synechiae goniotomy may be tried. This is a very simple operation and can be repeated many times. Often a single operation is effective. It need not necessarily be done under a contact glass but the eye must be thoroughly studied with a contact glass before it is attempted.

If a pillar of the iris is caught in the corneal wound and particularly if the anterior chamber is rather shallow, cycloodialysis seems to me to be the logical operation. This also can be repeated a number of times. We occasionally use air injections in the anterior chamber after this operation. The air should not be under great pressure but this procedure pushes the iris and vitreous away from the cornea. Occasionally a trephine is in order or an iridectomy with or without sclerectomy.

In colored people we are more apt to have complications; therefore our technique must be extraordinarily accurate and delicate. In colored people we find that it is better to do no unnecessary operating.

Occasionally we have so much postoperative reaction that the pupillary area is occluded or we have had loss of vitreous and the iris is drawn well up into the wound where it is incarcerated. We like the technique of making a meridional incision in the lower iris in all cases, but moderate amount of vitreous has been lost. This can be best done with the de Wecker or other very fine scissors and we do it just before the lachrym

is closed. It should be carried well down toward the root of the iris. When this has not been done and the pupil is obstructed by exudate or by the iris being drawn well up toward the wound, after the eye is quiet a small subconjunctival incision into the anterior chamber can be made from below and the iris root caught in a small iris forceps and drawn out so that an iridectomy can be done. The less done the less is the subsequent reaction. There should be sufficient adrenalin used before the operation so that there will be little or no bleeding into the anterior chamber.

Delirium is one of the bugbears we must all deal with. Recently a graduate of Rush Medical College, class of 1894, our history No. D-4107, a man of astonishing vitality, asked us to remove one of his cataracts. When he became delirious we removed the patch from the eye not operated upon, got him out of bed, and had his wife stay in the room with him, but all to no avail. Then I found he had been getting a barbiturate. The resident had just come on service and did not know that barbiturates occasionally cause a psychosis, particularly in elderly people. When paraldehyde by rectum was substituted he slept like a child and awoke refreshed and in his right mind.

We believe it important also to push fluids in elderly people, chipped ice, ginger ale, and often soda in small doses reduce the tendency to nausea and the tendency to dehydration. Infection is more easily prevented than combatted. We always take a culture 48 hours before any intra-ocular surgery. Small colonies of streptococci are occasionally overlooked on a 24 hour culture plate.

We lost an eye some years ago because of this and since then insist on a 48 hour culture. One or two colonies of nonhemolytic staphylococcus do not cause us concern if the eyelids look normal and if we use 1 per cent silver nitrate just before the surgical procedures are begun. It precipitates the protein in the conjunctival sac if left in the eye for 30 seconds, it can then be washed out. It tends to cloud the cornea temporarily.

We always test the patency of the lacrimal passages during our preliminary survey. Appropriate measures are taken when necessary. Should the patient have a fever or should the eye be uncomfortable during the first 48 postoperative hours we do not hesitate to remove the bandage. We first examine the dressing and secretion at the lid borders. If this examination suggests infection or if the upper lid is not normally wrinkled we carefully inspect the eye. Smears and cultures are made. Atropine and a mild antiseptic such as 1 per cent aqueous mercurochrome and bichloride ointment are used, the eyes are rebandaged and milk injections are given. With the advances in chemotherapy our methods will undergo revision, I am sure. We have given one patient sulfathiazol, another had massive doses of x-ray, the former recovered, the latter did not.

I realize that many situations can arise that are not covered by these scattered remarks. The main idea that I would wish to leave with you is that surgery should be preceded by most careful study of the patient and when surgery is attempted one should bear in mind that the eye is a most delicate structure and reacts badly to carelessness.

INFLAMMATION OF THE SALIVARY GLANDS

AUGUST L. BECK, M.D. F.A.C.S. New Rochelle, New York

AT the risk of being accused of reverting to old-fashioned nomenclature the term *inflammation*, rather than *infection*, is used in the title of this paper for the reason that some of the inflammatory conditions are caused by drugs and are not primarily caused by micro-organisms. The chief purpose of the paper is to discuss the various types of infection of the salivary glands. Until I began to realize that infection of the salivary glands ties up with and is really a part of, infection of the cervical fascia my conception of infection of these glands was indeed vague.

The process may be primary and limited to the salivary glands, or the glands may become involved secondarily in the course of a systemic disease. In the latter instance the involvement constitutes a complication, and if it occurs during an attack of typhoid fever it is none the less a case of typhoid fever and the record is filed under that heading; likewise it is none the less a case of parotitis. This makes literary investigation difficult and the witticism "always a bridesmaid never a bride" applies.

It should be remembered that there is a close anatomical relationship of the salivary gland and lymph nodes. In the case of the parotid gland some lymph nodes are situated on the capsule and some are enmeshed in the gland itself. In the case of the submaxillary gland the lymph nodes lie on the capsule. This relationship suggests that it is possible that there may be inflammatory swelling at the location of the salivary gland which may at first be wholly a lymphadenitis. I have observed inflammatory swelling over the site of these glands, parotid and submaxillary from infection in the lymph nodes without marked involvement of the salivary gland proper. Infection may involve the gland secondarily.

Some inflammations of the salivary glands, particularly the parotid, are metastatic. Osler designated these complicating and metastatic inflammations, symptomatic parotitis or parotid bubo. They are usually acute.

There are several specific types of salivary gland inflammation, chiefly mumps, mumps-parotid fever and Mikulicz's disease or syndrome.

MUMPS—EPIDEMIC PAROTITIS

A full discussion of this disease is not considered necessary but a few remarks are in order. In the first place mumps is a virus disease and is definitely epidemic. All the salivary glands may be involved or only those of one side either simultaneously or in succession. Only one gland may be involved. It is usually acute but occasionally becomes chronic due to hypertrophy. There is no suppuration. In the diagnosis it is important to ascertain the existence of any cases of mumps which the patient may have contacted within 3 weeks. An inquiry at the health department will obtain information as to the existence of known cases of mumps. It should be remembered that mumps often develops in patients after hospitalization for other reasons. In our records there are a number of instances of the development of mumps during the convalescence from injuries and operation. Obviously the contact occurred before the patients were admitted to the hospital. When the patient is in the hospital for a longer period of time the contact may be made by visitors.

It is difficult to find the records as it would necessitate perusal of thousands of histories. I was able to find the following. One case developed the day after tonsil and adenoid operation, and I am quite certain there were more. One case developed after fracture of the femur. One case after knee injury. and one 11 days after an acute upper respiratory infection. Two other cases, sisters, who were admitted to be treated for an upper respiratory infection with swollen cervical glands, developed typical signs of mumps on the day after admission.

A complicating orchitis is fairly frequent. Sometimes the lacrimal glands are involved. Rarely symptoms referable to the pancreas appear. During the convalescence of one of my deep neck infection cases, a young man at home after healing was complete, swelling of the region of the parotid gland on the same side occurred with elevation of temperature. At first it was thought that a recurrence of the deep neck infection was in progress, but in 48 hours an orchitis appeared, followed in a day or two by epigastric pain and tenderness, nausea and vomiting which were ascribed to pancreatitis. The proved contact was by a sick room visitor while in the hospital. This and the

following case history are recited to demonstrate that the complications of mumps may be formidable and may bring about severe life-long handicaps. Every otologist recognizes the importance of mumps as a cause of deafness, usually bilateral. From involvement of the testicles there may come sterility, from involvement of the ear labyrinths there may come deafness, from involvement of the nervous system—brain, or meninges—there may come death. If death occurs it is most frequently from cerebral complications.

Nervous system involvements should be accorded all the care and respect that are due any involvement of the central nervous system. The following is an example. During the past year one patient with a cerebral complication caused by mumps was treated at the New Rochelle Hospital. An adult male about 45 years of age was admitted to the hospital 10 days after the onset of an attack of mumps and 1 day after he had been allowed out of bed. On the day of admission he was suddenly taken with severe headache and vomiting which continued during the day with increasing severity. The morning temperature was normal, climbing rapidly during the day to 103 degrees F when admitted to the hospital. At this time there was also rigidity of the neck and inflammatory areola at Stenson's duct orifices. The spinal fluid showed 721 cells, 94 per cent lymphocytes, 6 per cent polynuclears, no organisms on smear or culture. By the third day the temperature had gradually come down to normal with subsidence of symptoms, and the patient was discharged at the end of 2 weeks. This patient was much depressed mentally and was considerably more ill than his chart indicated. The diagnosis was mumps virus meningitis. A prolonged rest of 3 months was prescribed.

UVEOPAROTID FEVER

Textbooks describe a condition called uveoparotid fever in which, as its name implies, there is a painless enlargement of both parotid glands with inflammation of the uveal tract of each eye. The etiology is unknown. The mortality is about 5 per cent. The swelling is firm and nodular, and usually subsides after some weeks or months. Also there is a low grade fever. Sometimes there is present one or more of the following: polydipsia, polyuria, polyneuritis, facial paralysis, burning sensation in the tongue, swelling of the lacrimal glands, and general adenopathy with splenomegaly. Visual defects are apt to be prominent and permanent. It occurs in the second and third decades of life. Tuberculosis has been accused of being the cause but this has not been proved. Treatment is purely symptomatic. The sulfo-

namide drugs might be tried. I have never seen a case of uveoparotid fever, and have based my description on what I have read in the books. My conclusion is that it is not common.

MIKULICZ'S DISEASE OR SYNDROME

Any reference to Mikulicz's disease without an expression of admiration for the masterly scientific description by Mikulicz in his original paper would be a regrettable omission. A delightful experience is in store for the physician who will take the trouble to read that paper in the original as translated in *Medical Classics*, vol. 2, October, 1937. To add to the wonder of the description, microscopic characteristics and blood count examinations were included when it was written, about 53 years ago, between 1888 and 1892.

The syndrome consists of symmetrical enlargement of the lacrimal and salivary glands and sometimes also of the accessory glands in the hard palate and tongue. Enlargement of the lacrimal glands is usually the first to appear but occasionally the enlargement of the salivary glands appears first, and sometimes only the lacrimal glands are involved. The swelling is firm, smooth, painless, not tender, and not adherent to the surrounding structures. Cecil states that sometimes there is splenomegaly and local or general lymphadenosis. Microscopic characteristics resemble lymphoma. The same source also states that in one of two cases observed there was general lymphadenosis with biopsy showing lymphosarcoma, the other patient recovering after antiluetic medication. It has occurred in diabetes. Hypothyroidism has also been observed with recovery after thyroid medication. The facial appearance is rather characteristic, almost grotesque, with the swollen eyelids, the prominent jaws and the head thrown backward for vision. Naturally the patient is not pleased with his appearance, but he complains mostly of the interference with vision caused by the ptosed and puffed out eyelids. In no instance has a definite cause been ascertained. Surgical removal in selected cases has been successful, and so also has roentgen-ray therapy.

The following is a much abbreviated summary of Mikulicz's original paper: (1) The lacrimal glands are usually involved first, followed later by involvement of the submandibulars and parotids, (2) the patient runs an afebrile course, (3) the lymphatics are not involved, (4) the spleen is not enlarged, (5) there is no leucocytosis nor other change in the blood count, (6) the disease is not a new growth, (7) the parenchymal cells (secretory) are not involved, (8) the disease is charac-

Fig. A, Manner of introducing the traction sutures. B Traction sutures in position not slit shape of orifice. C, Canalculus kind in position for slitting of duct. D Appearance after duct has been slit open, exposing calculus. E, Instrument.

terized by a round cell (lymphocytic) infiltration in the interstitial connective tissue structure, with increase in the amount of connective tissue (9) it is essentially a chronic low grade, and not an acute process, (10) it is not systemic—Mikulicz did not consider it hematogenous in origin (11) he believed the causative factor to be "an infectious or parasitic process in the broadest sense of the word.

The editors of *Medical Classics* wrote the following summary:

"We know only that the disease seems to be a low grade infection of the lacrimal and salivary glands, extending over a long period with possible spontaneous termination and never causing death.

Little has been added to the subject since Mikulicz's contribution and the problem admits of further enlightenment. Apparently all the cases which Mikulicz observed were chronic or at

least nonacute, and the patients were otherwise apparently healthy.

Several years ago I observed a patient, a married woman aged 58 years, with a low grade nonsuppurative involvement of the lacrimal and salivary glands, but with rather acute abnormalities of their systems. I regarded the lacrimal and salivary manifestations as Mikulicz's syndrome occurring in the course of an acute illness ushered in by a severe acute suppurative and ulcerative tonsillitis.

The illness extended over a period of 4 weeks during which time there were periods of great distress, later attributed epigastric pain attributed to the biliary mechanism, and pain in the lower right chest region. There was throughout an extreme dryness of the mouth, or xerostomia, which symptom was not mentioned by Mikulicz as having been present in any of his cases. There was oral sepsis not caused by the teeth. For during the early acute stage of the tonsillitis the temperature did not go over 101.4 de-

grees, the pulse running between 90 and 110. Both tonsils were riddled with multiple crypt abscesses, all probably connecting with each other and containing purulent exudate. There was also a vesicular rash, later becoming pustular, on the hands, chest, neck, scalp, and feet caused by *Monilia albicans* infection which yielded readily to treatment consisting of local application of gentian violet, by the dermatologist. No fungus forms were observed in the smear or the culture taken from the tonsils. Tonsil culture showed *Staphylococcus aureus* and *Micrococcus catarrhalis*. On admission to the hospital the blood indicated sepsis, with count as follows: leucocytes, 21,650, polymorphonuclears, 81 per cent of which young forms numbered 28 per cent, lymphocytes, 16.5 per cent, eosinophiles, 1.5 per cent, large mononuclears, 10 per cent, 1 metamyelocyte, toxic granules in an occasional polymorphonuclear cell, no anemia. The sepsis was attributed to the severe throat infection. It gradually subsided. Roentgenographic examination of the biliary tract after intravenous injection of dye showed failure to outline or visualize a gall bladder shadow and seemed to indicate a pathological process the identity of which was never determined. I suspect it might have been pancreatic.

On several occasions patient complained of pain in one knee joint. Blood sugar was 138 milligrams. Wassermann reaction was negative, blood culture, negative, urine sugar-free. The patient received a variety of therapy including potassium iodide, small stimulating doses of insulin, salicylates, bismuth, mixed vitamins, caroid and bile, no part of which can be said to be wholly responsible for her recovery. At first the tonsils were so swollen that they touched each other in the midline, giving rise to a type of noisy breathing with some dyspnea and at times some cyanosis. This was completely relieved by insertion of a pharyngeal airway. When the tonsillar inflammation and swelling had subsided the swelling of the lacrimal and salivary glands began to subside. She was discharged from the hospital at the end of about 4 weeks with some lacrimal and salivary swelling still present. The xerostomia was still present, but had diminished considerably. This was the driest mouth I have ever seen. It distressed the patient very much.

One month after discharge from the hospital the tonsils were removed, and since then there has been no return of the syndrome. The family doctor states that the tonsillectomy cured her. The laboratory was not requested to section and examine these tonsils, an oversight which I regret very keenly. At the time of the tonsil operation there was still present a mild xerostomia.

In the literature the ophthalmologist is the most frequently found author on the subject of Mikulicz's syndrome. This will probably continue to be the case, as the swelling of the lacrimal glands constitutes the most annoying manifestation, and ophthalmological examination is sought early. Occasionally the lacrimal glands are involved in mumps, but a diagnosis of Mikulicz's syndrome is usually justified when the lacrimal and salivary glands are simultaneously involved with nonpainful and nontender swelling. If occurring during an epidemic of mumps it should be treated as mumps. Until further enlightenment on the cause of the disease is forthcoming one cannot be more definite. Because of its microscopic resemblance to lymphoma and lymphosarcoma it has been characterized as a new-growth

Fig 2 Roentgenogram of typical small calculus in Wharton's duct on intraoral film

The evidence is otherwise against it. A point of differentiation from mumps is that with mumps there is leucocytosis with lymphocytosis. Another point is that in the absence of other conditions Mikulicz's syndrome is afebrile. Simultaneous acute inflammatory involvements elsewhere, as for example tonsillitis, would be expected to alter the blood count. For the present it may be stated that simultaneous swelling of the lacrimal and salivary glands without acute inflammation, fever, or pain, and with no related general pathology may be regarded as Mikulicz's syndrome.

INFLAMMATION OF THE SALIVARY GLANDS CAUSED BY DRUGS

Inflammation of the salivary glands caused by drugs may be acute or chronic. The parotid is most frequently involved. Involvement of the salivary glands is manifested by swelling, discomfort, and alteration of function. References to this condition in the books are found under the captions, ptyalism, salivation, sialosis, sialorrhea—synonyms for increased quantity of secretion, and xerostomia, aptyalism, oligosialia—synonyms for decreased quantity of secretion. In these cases the intensity of symptoms in the mouth from the stomatitis overshadows the symptoms in the glands. Mercurialism is the best example. As an entity it rarely needs consideration. The treatment is symptomatic and abstinence from the drug. Among the drugs that cause an increased output of saliva are mercury, gold, copper, iodine, jaborandi, muscarine, tobacco, bromides, arsenic, potassium chlorate, pilocarpine, bismuth, and lead. Among those that decrease the secretion are opiates and belladonna. Personally I have had no experience with drug poisoning. Years ago I

Fig. 3. Roentgenogram showing two small calculi in the parotid gland. Cyst shown in Figure 4, as not visible in this exposure.

Fig. 4. Roentgenogram showing large cyst in right parotid gland. About cubic centimeters of radiopaque solution as injected into Stenson's duct. Later 5 cubic centimeters of cystic fluid as aspirated, from the buccal side. Photograph slightly retouched. The cyst as excised from the mouth side.

frequently saw cases of accidental and intentional mercurial salivation: the one from continuing the use of calomel for too long periods and the other in obtaining the full effect of mercury in the treatment of syphilis. Calomel was then a household remedy and many cases of salivation and stomatitis resulted from its indiscriminate use by the layman.

ACUTE INFECTION OF THE SALIVARY GLANDS

The specific types of infection, notably mumps, are not here alluded to. There are three important types of acute infection of the salivary glands: (1) acute inflammation; (2) deep neck infections; (3) acute exacerbation of the chronic inflammation wherein calculus formation occurs. (4) acute infection occurring during the course of a systemic disease or after injury to or surgical operation on abdominal or pelvic viscera. This includes severe acute pathology in the abdomen or pelvis.

There is a rare type of acute primary suppurative inflammation, usually involving the parotid gland. It occurs in infants and young children and even in the newborn. I have never observed a case. Bock and Pacella and others have reported it in the newborn.

ACUTE INFECTION ACCOMPANYING NECK AND DENTAL INFECTIONS

In my experience acute infection in the presence of neck and dental infections is the most

common type of acute infection of the salivary glands. Its place in the picture is decidedly subordinate to the deeper cervical infection. The parotid and the submaxillary glands lie in their own compartments of the cervical fascia and are separated from each other by a union of the enveloping fascia between the glands. The external layer of the parotid fascia is very tightly fastened to the overlying superficial fascia and it is difficult to dissect the two apart. It is attached above to the zygoma for which reason swelling which involves only the parotid gland or its fascia is limited above to the zygoma. The internal surface is in relation with the sheath of the vessels, particularly the external carotid and some of its branches. The parotid gland also is in relation with small veins which enter into the formation of the common facial and external jugular veins, and less intimately with the internal jugular vein. There are a number of lymph nodes both on its capsule and enmeshed in its structure. Because of this contiguous vascularity and the rich distribution of lymphatics early sepsis is to be expected when it is severely involved. When infection of the parotid and submaxillary glands accompanies deep cervical fascia infection this may not be appreciated because of the already existing severe

sepsis The retromandibular process or extension of the gland forms part of the external wall of the pharyngomaxillary fossa and at its end is devoid of fascia The pharyngomaxillary fossa is divided into two unequal parts or compartments by the structures attached to the styloid process That part situated in front of these is the anterior compartment, and that behind is the posterior compartment The great vessels and their sheath are situated in the posterior compartment Infection in the pharyngomaxillary fossa quickly involves the parotid gland and when this occurs the infection is both within and without the capsule Infection in the anterior compartment of the pharyngomaxillary fossa gives an unmistakable triad of signs, viz, swelling of that lateral pharyngeal wall with protrusion inward of the tonsil fossa and tonsil, trismus, and swelling of the parotid gland If, during the course of a deep parapharyngeal infection, swelling of the parotid gland region occurs with these other signs one may be sure of infection in the pharyngomaxillary space The inflammatory swelling of the parotid gland increases the trismus and intensifies the pain on chewing because of its relationship with the neck and ramus of the jaw Otalgia is not an uncommon symptom, and for the same reason In primary inflammation, like mumps, limited strictly to the parotid gland I have never observed swelling of the lateral pharyngeal wall Swelling of contacting or neighboring lymph nodes is present and if those in the upper adjacent cervical regions are involved the parotid swelling is continuous with the cervical swelling lower down Tenderness is present over the whole area of swelling It frequently happens that abscess in and about the parotid gland ruptures into the external auditory canal I have seen this twice in deep neck infections and once when the parotid gland abscess occurred during severe inflammatory disease of the colon Simpson has reported the occurrence in pharyngomaxillary infection Sometimes a suppurative otitis media is the cause of suppurative parotitis

The treatment consists of drainage of the pharyngomaxillary abscess This is followed by subsidence of the parotid and cervical swelling, though occasionally a cervical gland abscess will form and require drainage I have not observed a facial nerve paralysis in these acute infections, though it is appreciated that such an event is possible I have seen and drained primary abscess of the parotid gland which I strongly suspected to have been entirely lymph node in origin Such infections are strictly localized The submaxillary salivary glands are more commonly involved with

lymph node abscesses than are the parotid glands In relation with the capsule of the submaxillary gland there are several lymph nodes which receive drainage from the tongue, floor of the mouth, teeth, and alveolar process of the mandible When these nodes are inflamed and swollen the appearance is the same as when the salivary gland is inflamed and swollen, in fact some inflammation of the salivary gland itself is unavoidable In practically all cases of the Ludwig's angina type the submaxillary salivary glands are involved, and sometimes during the convalescence after incision and drainage the glands are literally lying in a pool of pus Infection in the submaxillary region from whatever cause practically always involves the submaxillary salivary glands, one or both This gland is much more loosely held in its recess than the parotid gland, and as its posterior end is bent around the posterior border of the mylohyoid muscle, part of the gland is located in the mouth floor above the muscle It is to be seen that the gland may thus be a direct avenue of infection from mouth to neck From this it is also seen that it is a direct avenue of approach in the search for pus Excision of the gland is practiced as a drainage measure especially, as will be mentioned later, when there are calculi in the gland Occasionally one sees an acute infection of the sublingual salivary gland, but it is not so common It occurs with or without calculus formation The cause is not always ascertainable It may be secondary to dental infection I recently treated a patient with abscess of the sublingual gland, and no calculus nor dental pathology could be demonstrated by roentgenograms or otherwise Cyst formation, or ranula, occurs in the sublingual glands or ducts, and is probably caused by low grade chronic inflammation In Ludwig's angina with the pronounced inflammation in the floor of the mouth these glands are always involved, but this involvement is completely overshadowed Acute and chronic inflammation of the salivary glands may be caused by disease of the dental region I have seen chronic inflammation of the parotid gland, with swelling persisting for several years, accompanying dental disease for which a third mandibular molar had been extracted There occurred osteomyelitis of the alveolar process and on several occasions acute exacerbation of the chronic inflammation in the gland Figures 3 and 4 show a small calculus in the posterior part of the gland and a large cyst in the anterior part on the buccal aspect The latter shows the large cyst and the duct outlined by injected radiopaque material

I have been somewhat impressed by observance of the frequency with which dental extraction has

Fig. 3. Roentgenogram showing two small calculi in the parotid gland. Cyst above. In Figure 4, as not visible in this exposure.

Fig. 4. Roentgenogram showing large cyst in right parotid gland. About cubic centimeters of radiopaque solution, as injected into Stenson's duct. Later, 5 cubic centimeters of cystic fluid, as aspirated, from the buccal side. Photograph slightly retouched. The cyst, as excised from the mouth side.

frequently saw cases of accidental and intentional mercurial salivation, the one from continuing the use of calomel for too long periods and the other in attaining the full effect of mercury in the treatment of syphilis. Calomel was then a household remedy and many cases of salivation and stomatitis resulted from its indiscriminate use by the layman.

ACUTE INFECTION OF THE SALIVARY GLANDS

The specific types of infection, notably mumps, are not here alluded to. There are three important types of acute infection of the salivary glands: (1) acute inflammation in deep neck infections; (2) acute exacerbation of the chronic inflammation wherein calculus formation occurs; (3) acute infection occurring during the course of a systemic disease or after injury to or surgical operation on abdominal or pelvic viscera. This includes severe acute pathology in the abdomen or pelvis.

There is a rare type of acute primary suppurative inflammation, usually involving the parotid gland. It occurs in infants and young children and even in the newborn. I have never observed a case. Bock and Pacella and others have reported it in the newborn.

ACUTE INFECTION ACCOMPANYING NECK AND DENTAL INFECTIONS

In my experience, acute infection in the presence of neck and dental infections is the most

common type of acute infection of the salivary glands. Its place in the picture is decidedly subordinate to the deeper cervical infection. The parotid and the submaxillary glands lie in their own compartments of the cervical fascia and are separated from each other by a union of the enveloping fascia between the glands. The external layer of the parotid fascia is very tightly fastened to the overlying superficial fascia, and it is difficult to dissect the two apart. It is attached above to the zygoma for which reason swelling which involves only the parotid gland or its fascia is limited above to the zygoma. The internal surface is in relation with the sheath of the vessels, particularly the external carotid and some of its branches. The parotid gland also is in relation with small veins which enter into the formation of the common facial and external jugular veins, and less intimately with the internal jugular vein. There are a number of lymph nodes both on its capsule and enmeshed in its structure. Because of this contiguous vascularity and the rich distribution of lymphatics early sepsis is to be expected when it is severely involved. When infection of the parotid and submaxillary glands accompanies deep cervical fascia infection this may not be appreciated because of the already existing severe

tion Crile and Manning suggest that these changes, described by Bessey and Wolbach, may account to some extent for the infection in the gland

A single parotid gland is usually involved. The reasons given for the fact that the submaxillary glands are not involved are that the normal and constant motility of the tongue and floor of the mouth tends to keep the duct clear of accumulations, and also because the secretion from the submaxillaries contains mucin, a substance which has bactericidal action. The occurrence of a complicating symptomatic parotitis is always of serious significance and immediately calls for a guarded prognosis. It occurs not infrequently in the wards of a general hospital. Cecil states that the mortality is from 30 to 50 per cent. Crile and Manning had a mortality of 43 per cent in 23 cases requiring surgical drainage. In 37 patients not operated upon the mortality was 11 per cent. In 3 cases death was attributed directly to the parotitis, in 2 cases the parotitis was contributory, in the 10 remaining cases it had very little to do with the death.

The onset is sudden with increased elevation of temperature and toxemia. There is local swelling, tenderness, and pain, sometimes painful swallowing and otalgia. Crile and Manning state that "pain in the temporomandibular joint on opening the mouth is commonly the initial symptom, occurring as early as 6 or 8 hours before swelling of the gland." If not aborted at this stage there occurs redness of the skin and fluctuation from abscess formation. In 1 of my cases this redness took on a rustiness of color almost like iron rust. I have wondered whether this is to be explained on the basis of its closeness to the overlying skin just below and in front of the lobe of the ear. In another place I have referred to the difficulty of dissecting the fascia of the gland away from the overlying superficial fascia, the 2 being quite adherent. In some cases suppurative localization takes place very slowly. In others abscess formation is rapid. When abscess has formed, large incisions are not necessary provided they go through the capsule. Incision should be withheld until one is certain that there is suppuration. Spontaneous rupture through the overlying skin and occasionally into the canal of the ear occurs if incision is delayed too long. Crile and Manning state that if roentgen therapy is applied as soon as any symptoms are recognizable the prognosis is much better in that many will not go on to suppuration. They consider the x-ray treatment very important in the earliest stage, day or night. Later its efficacy is much diminished or nullified.

Fig. 5. Chart showing sulfathiazol concentration in the saliva with a blood concentration of 5 to 8 milligrams per cent. Note that the greatest amount appears 15 minutes after the dose was given.

Radium has also been advocated. Preoperative and postoperative oral hygiene is of the greatest importance. Cleansing of the mouth and teeth by muscular action and stimulation of the free flow of saliva, by the use of chewing gum is also of considerable value. Administration of vitamins, especially vitamin A, is also recommended because of its influence on the metabolism of epithelium. Otherwise the treatment of the parotid gland condition consists of the same measures, surgical or nonsurgical, used for any localized suppuration, but tremendously influenced by factors imposed by the primary condition. It is very advisable to begin the administration of a sulfonamide preparation 48 hours before the performance of the abdominal or pelvic operation, especially one on the colon, and to continue the administration at least that long after the operation. Since the advent of the sulfonamide derivatives, many of these dire clinical conditions should be much ameliorated, if not actually controlled, by chemotherapy.

I was able to find records of 5 cases of symptomatic parotitis in our hospital files. Our filing records do not include complications, which makes it necessary to rely somewhat upon recollection. The antecedent conditions were as follows: (1) gastric ulcer, died, (2) cesarean section with subsequent infection, died, (3) acute hemorrhagic nephritis, recovered, (4) colitis with ileostomy—parotid abscess ruptured spontaneously and healed, patient still living but very ill, (5) salpingo-oophorectomy, bilateral, also subtotal hysterectomy and appendectomy, recovered. Two of the five died.

In summing up one may reasonably state that the development of symptomatic parotitis is often contributory to the death of the patient, and always renders the prognosis of the source disease graver.

been the forerunner or instigator of infection in the salivary apparatus. Two cases, one in the parotid and one in the submaxillary gland, come to mind. They differ in no essential way from those not so provoked and are subject to the same indications so far as treatment is concerned. It is also possible that a latent dental infection, when interfered with or lighted up by dental extraction, may be the cause of the acute exacerbation. The relationship should be borne in mind. In the differential diagnostic relationship, diagnostic roentgenograms of both the ducts and glands and films of the jaw to exclude beginning osteomyelitis should be made.

ACUTE SECONDARY PAROTITIS

Ossler called acute secondary parotitis symptomatic parotitis or parotid bubo. It is never primary and is always a complicating parotitis. It occurs during the severe febrile diseases such as typhoid, typhus, pneumonia, and septicemia. Now that typhoid fever is a comparatively rare disease in this part of the world, it occurs most frequently after severe debilitating abdominal or pelvic disease or injury. Ossler stated that it sometimes occurs after injury, disease, or temporary derangement of the genital organs, and that by temporary derangement is meant slight injuries or natural processes—a slight blow on the testis, introduction of a pessary, menstruation, or pregnancy. In such cases the exact mode of involvement is obscure. In fact, knowledge of the exact pathway of involvement from the primary pelvic or abdominal disease to the gland is not yet established. Two pathways come under consideration—the blood stream and the duct system of the gland. That the blood stream is not always the pathway is indicated by the fact that the kind of infecting organisms recovered from the abscess in the gland is not always the same as the kind of organisms found in the provocative source as for example, pneumococci. Payne has made the following observation: "There is nothing in the available evidence to suggest that pneumococcal parotitis is specially prone to arise in patients with proved pneumococcal infections. When acute parotitis develops during the course of pneumococcal infection of the lung it is almost invariably caused by the *Staphylococcus aureus* and not by the pneumococcus. If the infection originates in the mouth, and it is quite likely that it does in most cases, the explanation becomes simple, but even in that event something must happen to the gland which greatly lowers its resistance and renders it more susceptible to any infection which may be present in the mouth. It is well known that in

severe debilitating illness of any kind the mouth becomes septic even when it was not septic before the illness.

BACTERIOLOGY

Members of the pyogenic group of organisms are the most frequent invaders. The staphylococcus group is found most commonly especially the *Staphylococcus aureus*. The streptococcus group is the next in order of frequency also the pneumococcus. This is to be expected as this pyogenic group is most commonly present in the mouth. The typhoid bacillus would be more commonly found if typhoid fever were now more prevalent. By way of digression I should like, while on the subject of bacteriology to refer to the types of organisms which are found in primary infections. In addition to the pyogenic group there are sometimes found fungi of which the ray fungus of actinomycosis is of particular importance in agricultural districts. In my experience here in the East actinomycosis in the mouth is very rare but it is possible that I have overlooked some cases. The tubercle bacillus and the spirillum of syphilis are occasional invaders. Because of their frequent presence in the mouth the fusil-spirochete organisms of Vincent's angina are possible invaders, though I have never actually demonstrated them in salivary infection.

That there is an element of selectivity in the occurrence of parotitis from the numerous types of abdominal and pelvic disease is suggested by the fact that it seems to be more common after surgery of the colon. Crile and Manning, in one of the best papers on this subject, reported that over half of the cases of complicating parotitis occurred after colon surgery. The incidence of parotitis in general surgery at the Cleveland Clinic was 1 in 1,500 cases. In colon surgery the incidence was 1 in 125 cases. After abdominoperitoneal resections of the rectum the incidence was 1 in 20 cases. They also make the statement with regard to etiology that "modern opinion favors the ductogen theory."

Vitamin A deficiency has been shown to cause atrophy of the epithelial lining cells of many of the epithelial structures, including the salivary glands, genitourinary tract, respiratory tract, and cornea of the eye. Following the atrophy there is metaplasia from the normal stratified columnar cells into keratinized cells which desquamate and accumulate in the ducts and acini forming mucus which cause obstruction. A diminished secretion and excretion of saliva results and there is dryness of the mouth. In the presence of bacteria which are present in the duct this is the start of infec-

The orifice of the duct is inflamed and prominent, and in most cases a stone in Wharton's duct can be palpated with the finger. In the case of Stenson's duct this will depend on its proximity to the duct orifice. Farther back than where the duct goes through the buccinator muscle it would probably not be palpable unless very large. Roentgenography, including exposure on an intraoral film, in my opinion is very valuable. In former years before the development of the precise roentgen technique of today it was often disappointing. Sialograph after injection of radiopaque solution, 1 to 3 cubic centimeters, has in my experience helped to differentiate between a duct and a gland calculus. It should not be done during an acute exacerbation. It is particularly helpful in the parotid duct and gland cases. I see no objection to careful probing except during acute exacerbations. It may be done in both Stenson's and Wharton's ducts, and is sometimes very helpful. If the duct is traumatized by rough manipulations an acute inflammation may be precipitated. I have recently considered the feasibility of injecting 1 to 3 cubic centimeters of a sulfonamide solution into Stenson's or Wharton's duct for these inflammatory conditions in which the calculus is in the gland or in which there is no calculus in the duct. To date I have not done so.

PATHOLOGY

Sometimes a calculus is extruded by erosion and formation of fistula, usually into the mouth but occasionally through the skin. It was submaxillary in all reported cases. If it occurs externally branchial and thyroglossal fistulas must be excluded. Calculi usually occur singly but may occur in numbers. Most of them are smooth but in one of my cases it was so rough and so firmly attached to the walls of the duct that it was necessary to detach it by sharp dissection. It had a surface similar to the rough irregular surface of an inferior turbinate bone. If the obstruction is complete, cystic dilatation of the duct behind it occurs, and congestion followed by atrophy takes place in the gland structure. In the duct itself there occur congestion, petechial hemorrhages, granulations, and fibrosis.

The following is a pathological report from one of my cases of chronic inflammation of the right submaxillary gland with calculi in the gland. I quote from pathologist's report:

"Gross examination. A submaxillary gland 6 by 4 by 2 centimeters in size. It has been cut in the longitudinal plane, exposing two small calculi deep in the substance of the gland. The cut surface is pinkish yellow in color and has coarsely lobular markings.

"Histologic examination. Sections show acute and chronic inflammatory changes in submaxillary gland with proliferation of small ducts and compression and distortion of the gland alveoli. Many small ducts contain purulent exudate. The uniform lobulation, the marked inflammatory changes and the presence of calculi make it appear proper to classify the growth as a salivary duct adenoma.

"Diagnosis. (1) submaxillary gland duct adenoma, (2) acute and chronic inflammation, submaxillary gland, (3) submaxillary gland calculi."

Another of our cases carries the following histological report. No calculi were present in this one.

"Sections show greatly distorted submaxillary gland, with obliteration of gland units and productive inflammatory products between atrophic gland units. There is no evidence of tumor. Diagnosis. Chronic inflammation, submaxillary gland."

Citation of more examples would be needless repetition, as these serve to show the typical pathology. Henke and Lubarsch, quoted by New and Harper described these two types of chronic inflammation of the salivary glands, designating them chronic exudative and chronic productive, respectively. Fibrosis is as good a name for the latter variety and is more descriptive. Cysts, quite large, also form occasionally. I now have under observation one such case in which the cyst was excised from the inside of the mouth. It was situated in the anterior part of the parotid gland.

TREATMENT

Treatment is in most instances surgical but should not be done during acute exacerbations. If there is acute inflammation hot fomentations externally with hot saline mouth wash are valuable. Administration of the sulfonamide derivatives, preferably sulfathiazol or sulfadiazine, is advisable, and otherwise any symptomatic treatment that may be indicated. Probing should not be done during acute exacerbations. When the acute attack has completely subsided, usually after several weeks, the calculus may be removed or the gland excised as indicated. For probing the duct (Wharton's) or removing a calculus I prefer to immobilize the duct at its orifice in the papilla with two silk retraction sutures as suggested by me in 1934 and here illustrated in Figure 1. Immobilizing the calculus against the inner side of the jaw with the finger, and cutting down upon it directly is the most commonly employed method of removal. When the calculus is small it is not always easily palpated, in which case cutting directly down upon it is sometimes difficult. When traction is made with properly placed silk sutures the orifice is converted into a long slit into which it is extremely

CHRONIC INFLAMMATION OF THE SALIVARY GLANDS

In the majority of instances nonspecific chronic inflammation occurs with calculus formation, and acute exacerbations take place frequently. Except during such exacerbations it causes no trouble except swelling and slight discomfort. Specific types of chronic inflammation may be caused by mumps, tuberculosis, syphilis, actinomycosis and chemicals. These also cause acute inflammations. One or more of the glands may be involved. A type of gaseous tumor formation sometimes occurs in glass blowers and wind instrument musicians. These gaseous tumors may contain purulent material.

That type of chronic inflammation occurring with calculi, either in the glands or in the ducts, is the most common. It is possible that calculus formation may be the primary condition as, for example the formation of solid concretion around a foreign body such as a seed, piece of tooth-pick, piece of fish bone, etc. In such cases chronic inflammation of the duct and gland is inevitable and sooner or later as the concretion increases in size, more or less constant or intermittent obstruction to the outflow of secretion results. The signs of obstruction are intensified during meal time when an increased amount of secretion is called forth. The signs are increased swelling of and discomfort in the gland. Sometimes there also occurs sudden filling of the mouth with a gush of released secretion. There is also swelling and discomfort in the floor of the mouth. Acute inflammation may occur suddenly with marked increase in the severity of the symptoms. Sudden obstruction in the presence of duct stone does the same.

Calculi may form during the course of a chronic inflammation and as an incident in the process. In other words it may be secondary. The same type of inflammation may not be accompanied by the formation of any calculi. It may in some instances be likened to the age-old problem of the priority of the hen or the egg. Clinically it may be regarded as the same condition whether or not calculi are present. It is probable that sometimes there is actually calculus formation present when it has not been demonstrated by diagnostic roentgenogram prior to surgery.

New and Harper have published valuable statistics on this subject. They found that in only 63 per cent of 110 cases of nonspecific chronic inflammation could they demonstrate the presence of calculi. Forty-two per cent of these were removed from the duct, 18 per cent from the gland through the floor of the mouth, and in 4 per cent the gland was excised with its calculus con-

tent. They state that clinically the condition is the same whether or not a stone is present. Statistics vary somewhat as to the relative frequency of involvement of the several glands and ducts with and without calculi. New and Harper report the following percentage of incidence of salivary calculi according to the gland or duct involved. Submaxillary gland or duct, 92.9 per cent, the parotid gland or duct, 4.3 per cent, the sublingual gland or duct, 2.8 per cent. Wakeley reported as follows submaxillary 63.2 per cent, parotid, 20.6 per cent sublingual, 16.3 per cent. Caryan reported 37 cases as follows Wharton's duct, 59.4 per cent submaxillary gland tissue, 10.8 per cent, Stenson's duct, 13.5 per cent, parotid gland tissue, 2.7 per cent, sublingual duct, 10.8 per cent Bartholin's duct, 2.7 per cent. Blair stated that the most common location of salivary calculi is in the submaxillary (Wharton's) duct, being more frequent there than in all other locations combined. That about sums it up. It occurs in middle aged people, and according to various writers, from two to five times as frequently in men as in women. Curiously the right submaxillary gland and duct are more frequently involved than the left.

In those cases of chronic inflammation without stone New and Harper report that the submaxillary gland was the most commonly affected. The incidence was as follows submaxillary gland, 80 per cent parotid gland 12.5 per cent, sublingual gland 7.5 per cent. Of the 40 there were 27 males and 13 females. In all of them tuberculosis, syphilis, and actinomycosis had been excluded as etiological factors. It should be possible to demonstrate nearly all salivary calculi by roentgenogram because they are composed mostly of calcium carbonate and calcium phosphate. It has been stated that the saliva of the submaxillary salivary glands has a higher percentage of solids and organic matter which should permit the calcium salts in these glands to be seen more distinctly than those in the calculi of the other glands. The factors which make tartar prone to form on the lingual surface of the lower incisors may also favor the formation of calculi in the submaxillary ducts and glands. A history of previous attacks, sometimes dating back years, is commonly elicited. The most prominent symptom or complaint is intermittent pain and swelling of the gland caused by acute exacerbations. Pus can be expressed from the duct by making pressure on the gland during acute exacerbations and nearly always when no acute inflammation is present if there are calculi in Wharton's duct. The same with regard to the parotid and its duct.

The orifice of the duct is inflamed and prominent, and in most cases a stone in Wharton's duct can be palpated with the finger. In the case of Stenson's duct this will depend on its proximity to the duct orifice. Farther back than where the duct goes through the buccinator muscle it would probably not be palpable unless very large. Roentgenography, including exposure on an intraoral film, in my opinion is very valuable. In former years before the development of the precise roentgen technique of today it was often disappointing. Sialograph after injection of radiopaque solution, 1 to 3 cubic centimeters, has in my experience helped to differentiate between a duct and a gland calculus. It should not be done during an acute exacerbation. It is particularly helpful in the parotid duct and gland cases. I see no objection to careful probing except during acute exacerbations. It may be done in both Stenson's and Wharton's ducts, and is sometimes very helpful. If the duct is traumatized by rough manipulations an acute inflammation may be precipitated. I have recently considered the feasibility of injecting 1 to 3 cubic centimeters of a sulfonamide solution into Stenson's or Wharton's duct for these inflammatory conditions in which the calculus is in the gland or in which there is no calculus in the duct. To date I have not done so.

PATHOLOGY

Sometimes a calculus is extruded by erosion and formation of fistula, usually into the mouth but occasionally through the skin. It was submaxillary in all reported cases. If it occurs externally branchial and thyroglossal fistulas must be excluded. Calculi usually occur singly but may occur in numbers. Most of them are smooth but in one of my cases it was so rough and so firmly attached to the walls of the duct that it was necessary to detach it by sharp dissection. It had a surface similar to the rough irregular surface of an inferior turbinate bone. If the obstruction is complete, cystic dilatation of the duct behind it occurs, and congestion followed by atrophy takes place in the gland structure. In the duct itself there occur congestion, petechial hemorrhages, granulations, and fibrosis. The following is a pathological report from one of my cases of chronic inflammation of the right submaxillary gland with calculi in the gland. I quote from pathologist's report:

Gross examination. A submaxillary gland 6 by 4 by 2 centimeters in size. It has been cut in the longitudinal plane exposing two small calculi deep in the substance of the gland. The cut surface is pinkish yellow in color and has coarsely lobular markings.

"Histologic examination. Sections show acute and chronic inflammatory changes in submaxillary gland with proliferation of small ducts and compression and distortion of the gland alveoli. Many small ducts contain purulent exudate. The uniform lobulation, the marked inflammatory changes and the presence of calculi make it appear proper to classify the growth as a salivary duct adenoma."

"Diagnosis (1) submaxillary gland duct adenoma, (2) acute and chronic inflammation, submaxillary gland, (3) submaxillary gland calculi."

Another of our cases carries the following histological report. No calculi were present in this one.

"Sections show greatly distorted submaxillary gland, with obliteration of gland units and productive inflammatory products between atrophic gland units. There is no evidence of tumor. Diagnosis. Chronic inflammation, submaxillary gland."

Citation of more examples would be needless repetition, as these serve to show the typical pathology. Henke and Lubarsch, quoted by New and Harper described these two types of chronic inflammation of the salivary glands, designating them chronic exudative and chronic productive, respectively. Fibrosis is as good a name for the latter variety and is more descriptive. Cysts, quite large, also form occasionally. I now have under observation one such case in which the cyst was excised from the inside of the mouth. It was situated in the anterior part of the parotid gland.

TREATMENT

Treatment is in most instances surgical but should not be done during acute exacerbations. If there is acute inflammation hot fomentations externally with hot saline mouth wash are valuable. Administration of the sulfonamide derivatives, preferably sulfathiazol or sulfadiazine, is advisable, and otherwise any symptomatic treatment that may be indicated. Probing should not be done during acute exacerbations. When the acute attack has completely subsided, usually after several weeks, the calculus may be removed or the gland excised as indicated. For probing the duct (Wharton's) or removing a calculus I prefer to immobilize the duct at its orifice in the papilla with two silk retraction sutures as suggested by me in 1934 and here illustrated in Figure 1. Immobilizing the calculus against the inner side of the jaw with the finger, and cutting down upon it directly is the most commonly employed method of removal. When the calculus is small it is not always easily palpated, in which case cutting directly down upon it is sometimes difficult. When traction is made with properly placed silk sutures the orifice is converted into a long slit into which it is extremely

easy to pass the end of almost any kind of a small instrument. They also give good immobilization.

It should be remembered that the ranine artery, lingual vein, and lingual nerve are all on the tongue side of the duct, and therefore when working in this region one should work toward the jaw side as much as possible to avoid these structures. Excision of the submaxillary gland is the indicated procedure when the gland is severely involved, with or without calculus. This is comparatively simple but one must identify vessels and nerves, most of which are in relation with its posterior and internal aspect, namely the facial vein, the facial artery and the hypoglossal nerve. Deeply also, the lingual nerve. The facial nerve should be well out of the field. If an abscess forms it should be drained, but extensive dissection for the removal of calculi should not be done until all acute inflammation has subsided.

The foregoing applies to the submaxillary gland. The problem is more complicated in the case of the parotid gland because of anatomical location and relationships. The drainage incision for parotid abscess should never be made vertically because it will cut across the branches of the facial nerve. A horizontal incision parallels the nerve branches and avoids this. Stenson's duct perforates the buccinator muscle not far from its orifice in the mouth, and beyond this point lies between the muscle and the skin of the face. Any incision of the duct within the mouth farther back than about 2 centimeters from its orifice must involve this muscle and from the mouth aspect is deeply placed. Incision into the duct should never be made externally through the skin for fear of producing a salivary fistula, and this is to be avoided at all costs. Excision of the parotid gland is a formidable procedure and is practically never done except for malignant growths. Drainage of gland abscess should be done promptly when the indications arise. Usually small incisions that penetrate the capsule, parallel with the branches of the facial nerve suffice. The skin incision may be a single larger one. Injury to Stenson's duct must also be avoided. I have seen salivary fistula develop from a pocket knife stab wound in the sulcus between the tip of the mastoid process and the angle of the jaw. It was not in the vicinity of Stenson's duct nor did it involve the facial nerve. A wound in the gland does not always cause fistula. In that case it was decided to produce glandular atrophy by means of roentgen therapy but to date this has failed. At the time of the injury it was necessary to ligate the carotid.

The last case of acute symptomatic parotitis in our wards developed on the fourth postoperative

day. Four days later the otolaryngologist saw the patient in consultation and immediately prescribed sulfadiazine in full dosage attaining a concentration of 8.2 milligrams per cent. The swelling subsided in 48 hours without recurrence and the patient convalesced from the pelvic operations uninterruptedly. This is a striking example of the effect of the new weapon we now possess in the sulfonamide derivatives. Without their help such a case might have gone on to a disastrous septic termination or at the least a stormy septic bout. From observations made over the years before these drugs were available I have been convinced that the patient is never again the same healthy individual he was previous to the infection. It may be true that he will have acquired a more or less temporary strong immunity to the particular type of infection, but at the expense of irremediable damage to such vital organs as the heart, liver and kidneys which in time will make itself manifest. Therefore the long range effect of these drugs in cutting short these severe infections is incalculable.

After reviewing the history I had the desire to know whether or not any of the drug is excreted in the saliva, and if present the approximate quantity. With that in mind specimens of saliva were collected at intervals after the administration of the drug by mouth. The drug was given in capsules to minimize or avoid any retention of it in the mouth. We were considerably handicapped by the shortness of time at our disposal, and the following meager results are submitted in the hope that others, better equipped than we will make more comprehensive and conclusive investigations.

Our resident house officer, Dr. P. E. Noonan, made a survey of the house and from each of the patients who was receiving a sulfonamide derivative regardless of the kind of illness, collected saliva specimens of as large a quantity as the patient could produce at the following intervals of time. The first specimen was taken 15 minutes after administration, the second, 30 minutes after the third, 45 minutes after and the fourth, 1 hour after. The doses were spaced 4 hours apart. As there were too few who were being started on the drug those who had been taking it for varying periods of time were included. As you know the quantitative estimations are done by colorimetry and in the saliva these color reactions can be seen but are too small to be measured. In other words the concentration is far less than even a low blood concentration and it is not possible to designate it in figures. It is therefore approximate in the extreme. However it was unmistakably seen that

BECK INFLAMMATION OF THE SALIVARY GLANDS

615

the deepest coloration in the saliva almost invariably appeared in the first, the 15 minute specimen, but once in the 30 minute one, probably because of a slower rate of absorption of the drug in that patient. In those cases which had been receiving the drug the saliva concentration was again at the level existing prior to the administration of the dose at the end of one hour. In those receiving first dose it had completely disappeared in one hour. Nine tests were made with no variations in results.

is a very small amount of the drug in the saliva while it is being taken by the patient. In other words the secretory cells of the glands do pass some of it through.

Two conclusions may be definitely arrived at. First, there is at no time a high concentration in the saliva, in fact it is very low. Second, the highest concentration appears in from 15 to 30 minutes after administration of the dose, and quickly diminishes. From all this it may therefore be concluded that any influence of the drug on infection in the salivary glands comes from the concentration in its circulating blood, and that any influence from that in the salivary secretion is practically negligible. How much, if any, may accumulate in the gland secretion when there is obstruction to its outflow is not known. On the other hand it may be definitely stated that there

REFINEMENTS OF GENERAL SURGICAL TECHNIQUE AS APPLIED TO OPHTHALMIC OPERATIONS

CONRAD BERENS M.D. F.A.C.S. New York, New York

In a consideration of the evolution of modern ophthalmic surgery in relation to general surgical technique, it is often merely inferential to associate certain ocular surgical techniques with the practices of the general surgeon. However, most ophthalmic surgeons obtained their early training in general surgery and undoubtedly received their first inspiration from the masters of general surgical technique.

The practice of eye surgery is based upon the same 3 fundamentals governing general surgery (1) the control of hemorrhage, (2) the proper anesthesia and (3) the prevention of infection. Improved methods of controlling hemorrhage and better anesthesia have made the rapid skillful eye surgeon whose surgical judgment may not have been too good, less important than the thoughtful, careful but possibly less brilliant technician. Better methods of preventing infection have greatly lessened deformity and blindness from this source. That modern ophthalmic surgery owes a great debt to the pioneers who dared to break away from the routine, conservative and often antiquated practices to undertake new methods and new techniques in surgery is evident. We know that Harvey who discovered the circulation of the blood, received the ridicule of his colleagues; he and his followers were called "circulators" which meant quacks and charlatans. The men associated with the development of ether anesthesia had tragic fates with the exception of Long.

Pasteur who destroyed the theory of spontaneous generation and laid the foundation for the prevention of operative and postoperative infection, worked for years without recognition. Unless Lister had been prepared to receive the message of Pasteur and carry on his work of preventing wound infection in spite of the active opposition of his colleagues, he would never have introduced the Listerian principle of antiseptic surgery upon which modern ophthalmic surgery is founded.

To determine exactly where credit is due for present day ophthalmic practice is difficult, for many surgical procedures are of ancient origin.

For example ligature for the control of bleeding in wounds was used by the Greek and Roman surgeons. Therefore one is inclined to agree with Ambrose Paré, who said "you will have to render an account not to the ancients but to God for your humanity and skill."

ANESTHESIA

General anesthesia has been and still is of great importance in the development of ophthalmic surgery but for most operations local anesthesia is preferred. Before a general anesthetic is administered it is advisable to quiet the patient by the use of chloral and bromide by rectum or by the administration of morphine and hyoscyne.

Flagg's intratracheal inhalation anesthesia is a valuable improvement in administering ether. It has facilitated the performance of delicate eye operations, as recession and cataract, as it eliminates disturbing head movements and congestion of the eyes, and lessens the danger of lung infection.

Rectal anesthesia with avertin (19, 77) is especially useful in ophthalmic surgery in preventing fear of operation in young children.

Intravenous anesthesia with evipan (sodium evipan) has been used in paracentesis, enucleation, excision, cataract, trephine, iridectomy for acute glaucoma, exenteration of orbital growths and squint (56). However cases in which vomiting (5) sneezing, sobbing, and postoperative restlessness occurred have been reported. When intravenous injections can be made, this anesthetic is satisfactory for short operations (72).

Local anesthesia with cocaine applied to eye surgery through the brilliant research of Koller was undoubtedly even more important for ophthalmology than general anesthesia. Cocaine is still used in ophthalmic operations when vasoconstriction and dilatation of the pupil are desired. Because procaine is less irritating than cocaine and produces less drying of the epithelium, a one per cent solution of this drug (78) is gaining popularity as a local anesthetic for eye surgery.

The development of procaine (novocain) which is much less toxic than cocaine (16) led to the more constant use of deep injections about the eye for anesthesia and akinesia. A solution of procaine and adrenalin is employed in Grädle's application

Aided by grant from The Ophthalmological Foundation, Inc. Presented at the symposium, Principles of Ophthalmic Surgery before the Clinical Congress of the American College of Surgeons, Boston, November 2-7 '34

Fig 1, left Tarsal anesthesia (Gradle) *a*, The point of the needle is introduced through the conjunctiva at the temporal edge of the tarsus and passed parallel to the upper edge of the tarsus, thus ballooning out the retrotarsal fold *b*, The needle is pushed slightly toward the skin side, thus thoroughly anesthetizing the entire eyelid including the skin and conjunctiva

Fig 2 Modification of the Van Lint method of producing akinesia

of the method of nerve block anesthesia (31) to surgery of the eyelids (Fig 1) In this procedure, the point of a 25 gauge hypodermic needle is introduced through the conjunctiva at the upper temporal border of the tarsus One or 2 minims of a solution of procaine and adrenalin is injected at this site and the needle is passed forward parallel to the edge of the tarsus, thus ballooning out the retrotarsal fold

In spite of the numerous advances in anesthesia, the ophthalmic surgeon still awaits the development of a pill or capsule which will cause rapid, prolonged anesthesia without complications

AKINESIA

Modification of Van Lint's method of producing akinesia Because Van Lint's splendid method of akinesia sometimes produces too great and prolonged relaxation of the eyelids, the following technique has been developed A 26 gauge needle, 25 millimeters in length, is inserted subcutaneously 8 millimeters temporal to the external canthus The needle is pushed forward as the plunger forces the procaine (2 per cent, 2 drams) and adrenalin (3 minims, 1 1000 solution) under the skin of the upper eyelid as shown in Figure 2 The needle is then partially withdrawn and inserted in the lower eyelid, ballooning the tissues over the outer third of the lower eyelid A second puncture is made at the center of the eyelid, 3 millimeters above the orbital margin, and the needle directed toward the inner canthus, thus the solution balloons the skin

In the O'Brien method of akinesia (49) the point of injection is just anterior to the tragus of the

ear, below the posterior portion of the zygomatic process and directly over the condyloid process of the mandible From 1 to 2 cubic centimeters of a 2 per cent solution is injected at a point directly over the exit of the branch supplying the orbicularis, while the remainder is injected superficially under the skin and spreads fanlike, in a forward direction, above and below the eyeball (Fig 3) When a patient has an extremely broad face, complete akinesia may not be produced by the O'Brien method, even with a second or third injection In this event, the modification of Van Lint's method of producing akinesia is indicated However, the more remote the site of the injection from the field

of operation, the less the danger of complication therefore the O'Brien akinesia is preferable to the injection of the eyelids, especially for plastic operations.

INCISIONS

Knowledge of the healing of skin incisions dates from the time of Hippocrates, who operated for calculi in the kidney by incision. Diocles Cynastus (circa 350 B. C.) bandaged the head for wounds caused by darts. Theodorici (250) of the order of the Preaching Friars taught that wounds should heal by first intention and that suppuration was unnecessary. As it is so well established today it seems impossible that Paracelsus had to fight for this principle as late as the sixteenth century.

Wounds were closed by adhesive strips and by rollers and compressors until animal gut sutures were employed by Rhazes (A. D. 852). Physick (1768) experimented with bookstring. French had and animal gut as ligatures. In 1848 W. T. Wright wrote on the use of sutures in surgery and their advantages over adhesive strips and other modes of coaptation of the edges of wounds. Adhesive tape and Scotch tape still have their uses. Because

there is little danger of death from the separation of eye wounds, the use of adhesives as advised by general surgeons (23) is valuable in primary and secondary wound closure when fear or shock is to be avoided. It is usually advisable to cut a notch in each side so that the strip will be narrow where it crosses the wound. If the tape is flamed, it usually holds better.

Postoperative scars. Ophthalmic surgeons have learned much concerning the prevention of scarring from the teachings of general and plastic surgeons. For example (1) The incision must be made with a sharp knife and part of a safety razor blade is advised by the plastic surgeons. (2) Make a sharp edge. However, since cataract knives may be sharpened so well, many ophthalmic surgeons use these knives for other than cataract incision. (3) The incision should not cut across the skin lines and must not be beveled because epidermal

Fig 5 The halving operation (Wheeler) a inserting fascia lata in depressed wound in malar region, b and insert method of suturing skin which has been halved

after the layers of the corium have been accurately approximated, excellent results are obtained. However, there is usually some uncertainty about suturing the different levels of the skin accurately, and halving the skin, as suggested by the general surgeons, permits accurate approximation of the epidermal layers. On one side of the incision the outer half of the skin is excised and on the other side the inner half of the skin is removed. These incisions of the skin need be only a few millimeters in width, the wound edge on which the deeper tissue has been removed is drawn over the surface of the wound edge, the outer surface of which has been removed (Fig 4).

Wheeler used the halving operation for lower eyelid and malar bone deformities (Fig 5). After proper coaptation has been obtained, infection is the most serious danger to healing and each stitch should be observed daily. Keloid is particularly disfiguring and the general surgeons have pointed the way here by suggesting excision and radium treatment (61).

SUTURES AND SUTURING

Largely because of the delicacy of ophthalmic surgery, needles and suture material have been constantly improved. Most ophthalmic hospitals now have atraumatic needles available in various sizes, threaded with fine catgut and No 000,000 to No 00,000,000 white and black silk. Mersutures on curved eye needles, No 000,000 black gossamer silk worm, have been useful in plastic surgery of the eye. I have found nylon sutures of value in transplanting Tenon's capsule (7) and in resection (4) and retroplacement operations (9) for strabismus, nylon sutures have also been found of value for closing skin incisions.

Much of what ophthalmologists have learned concerning the use of new suture material has been derived from their general surgical application, for example, the dangers of catgut. In the time of Lister, catgut had been tried often and as often abandoned. The factors governing the loss of strength of catgut when embedded in tissue were pointed out by Howes. He found that (1) in the presence of fluids such as physiologic sodium chloride solution or of blood serum, the tensile strength is moderately diminished, (2) in an inflammatory exudate composed in large part of phagocytic cells, plain or chromicized catgut, practically irrespective of size, loses tensile strength with great rapidity, (3) when infection is foreseen or when the premature loss of tensile strength in the catgut would be disastrous, removable nonabsorbable tension sutures are indicated as an adjunct to the closure of the wound.

When enucleation was performed the fact that suppuration often followed and that difficulty arose in obtaining complete closure of Tenon's capsule led to the conclusion that the catgut was often unsterile and that its use did not permit complete closure of Tenon's capsule.

The idea of not burying catgut was first brought to my attention when I observed gynecologists (30a) closing abdominal wounds. This principle has been applied to the enucleation operation (6). One needle of the double-armed suture of No 5 parafinized black silk is then passed through the conjunctiva. The needle is then passed through Tenon's capsule into Tenon's space. A purse-string suture is placed within Tenon's capsule and includes the tendons of the recti, care is used not to overlap the edge of the capsule. The ends of the sutures are then knotted over a rubber tubing and the

of operation the less the danger of complication therefore the O'Brien technique is preferable to the injection of the eyelids, especially for plastic operations.

EXCISIONS

Knowledge of the healing of skin incisions dates from the time of Hippocrates, who operated for calculi in the kidney by incision. Diodorus Cynic (c. 350 B. C.) bandaged the head for wounds caused by darts. Theodoric (c. 150) of the order of the Preaching Friars taught that wounds should heal by first intention and that suppuration was unnecessary. As it is so well established today it seems impossible that Paracelsus had to fight for this principle as late as the sixteenth century.

Wounds were closed by adhesive strips and by rollers and compressions until animal gut sutures were employed by Rhazes (A. D. 852). Phrynik (c. 768) experimented with buckstring. French kld, and animal gut as ligatures. In 1848 W. T. Wrigg wrote on the use of sutures in surgery and their advantages over adhesive strips and other modes of coaptation of the edges of wounds. Adhesive tape and Scotch tape still have their uses. Because

there is little danger of death from the separation of eye wounds, the use of adhesives as advised by general surgeons (23) is valuable in primary and secondary wound closure when fear or shock is to be avoided. It is usually advisable to cut a notch in each side so that the strip will be narrow where it crosses the wound. If the tape is flamed, it will usually hold better.

Postoperative scars. Ophthalmic surgeons have learned much concerning the prevention of scarring from the teachings of general and plastic surgeons. For example () The incision must be made with a sharp knife and part of a safety razor blade is desired by the plastic surgeons to leave a sharp edge. However since cataract knives may be sharpened so well, many ophthalmic surgeons use these knives for other than cataract incision. () The incision should not cut across the skin lines and must not be beveled because epidermis cannot be approximated with epidermis and corium with corium if the skin is beveled. (3) Effort should be made to a "jagged" edge. (4) If the surface sutures are the finest obtainable include only epidermis, and are placed without tension.

Fig. 5 The halving operation (Wheeler) a, inserting fascia lata in depressed wound in malar region, b, and insert, method of suturing skin which has been halved

after the layers of the corium have been accurately approximated, excellent results are obtained. However, there is usually some uncertainty about suturing the different levels of the skin accurately, and halving the skin, as suggested by the general surgeons, permits accurate approximation of the epidermal layers. On one side of the incision the outer half of the skin is excised and on the other side the inner half of the skin is removed. These incisions of the skin need be only a few millimeters in width, the wound edge on which the deeper tissue has been removed is drawn over the surface of the wound edge, the outer surface of which has been removed (Fig. 4).

Wheeler used the halving operation for lower eyelid and malar bone deformities (Fig. 5).

After proper coaptation has been obtained, infection is the most serious danger to healing and each stitch should be observed daily. Keloid is particularly disfiguring and the general surgeons have pointed the way here by suggesting excision and radium treatment (61).

SUTURES AND SUTURING

Largely because of the delicacy of ophthalmic surgery, needles and suture material have been constantly improved. Most ophthalmic hospitals now have atraumatic needles available in various sizes, threaded with fine catgut and No. 000,000 to No. 00,000,000 white and black silk. Mersutures on curved eye needles, No. 000,000 black gossamer silk worm, have been useful in plastic surgery of the eye. I have found nylon sutures of value in transplanting Tenon's capsule (7) and in resection (4) and retroplacement operations (9) for strabismus, nylon sutures have also been found of value for closing skin incisions.

Much of what ophthalmologists have learned concerning the use of new suture material has been derived from their general surgical application, for example, the dangers of catgut. In the time of Lister, catgut had been tried often and as often abandoned. The factors governing the loss of strength of catgut when embedded in tissue were pointed out by Howes. He found that (1) in the presence of fluids such as physiologic sodium chloride solution or of blood serum, the tensile strength is moderately diminished, (2) in an inflammatory exudate composed in large part of phagocytic cells, plain or chromicized catgut, practically irrespective of size, loses tensile strength with great rapidity, (3) when infection is foreseen or when the premature loss of tensile strength in the catgut would be disastrous, removable nonabsorbable tension sutures are indicated as an adjunct to the closure of the wound.

When enucleation was performed the fact that suppuration often followed and that difficulty arose in obtaining complete closure of Tenon's capsule led to the conclusion that the catgut was often unsterile and that its use did not permit complete closure of Tenon's capsule.

The idea of not burying catgut was first brought to my attention when I observed gynecologists (30a) closing abdominal wounds. This principle has been applied to the enucleation operation (6). One finized black silk is passed through the conjunctiva. The needle is then passed through Tenon's capsule into Tenon's space. A purse-string suture is placed within Tenon's capsule and includes the tendons of the recti, care is used not to overlap the edge of the capsule. The ends of the sutures are then knotted over a rubber tubing and the

Fig 6 Methods of closing cataract wounds. a, Williams conjunctival suture (867) b, Kalt corneoscleral suture (894) c, Van Lint conjunctival flap d, Barraquer (923) and Green (931) conjunctival apron e, Berens remaining conjunctival and episcleral suture (923) f, McLean corneoscleral suture (940)

conjunctiva is closed by means of interrupted plain silk or catgut sutures. Only the deep sutures are removed. This technique has been used in more than 60 enucleation operations and post-operative loss of the implanted foreign substances has been less frequent than when catgut sutures were buried. The plastic implant (10) has been expelled in only 2 cases.

Although surgical wounds have been closed with sutures for years ophthalmic surgeons have been slow in suturing cataract wounds. However the use of sutures in this operation has been almost universally adopted in the United States of America since the discussion of this subject before the American College of Surgeons in 1925 by Zentmayer Posey Eliott, and the author at that time there was great difference of opinion in regard to the value of suturing. Eliott championed the K

suture the author the conjunctival episcleral suture whereas Zentmayer and Posey opposed the use of sutures. At that time none of the surgeons at the New York Eye and Ear Infirmary was employing sutures, except occasionally in complicated cases. Now in the majority of eye hospitals in the United States, sutures are used routinely for cataract extraction and several refinements have been suggested (Fig 6)

The principle of not using tension in suturing has been applied to cataract wounds for too much tension causes overlapping of the scleral and corneal wound edges.

STERILIZATION OF INSTRUMENTS AND DRUGS

By 1895, chemical sterilization had been replaced by dry heat and steam sterilization, except in the preparation of the skin and of the operating field.

Moist dry heat method This method is satisfactory for the sterilization of eye instruments. Thoroughly cleansed dry instruments are placed in open boxes in an electric sterilizer (Moria) and the door is left partly open until a temperature of 180 degrees F (80 degrees C.) is reached, to be sure the instruments are dry. The boxes are closed and wrapped in paper and the door is shut when the danger of retained moisture with resulting oxidation is past. When 335 to 345 degrees F (155 to 160 degrees C.) is reached, this temperature is maintained for 30 min. Sets of instruments may be kept sterile for 1 week. If wrapped boxes are dated, the differentiation of sterile from non-sterile instruments is facilitated. Single instruments and syringes may be sterilized in large glass test tubes closed with cotton. The principal objection to the dry heat method is that several sets of instruments are required.

Chemical sterilization For the chemical sterilization of instruments M. H. Post has used solution of alcohol 95 per cent with liquid cresols compound 2 per cent ounces, commercial chloroform 2 ounces liquid boric acid 1 dram. With these chemicals no rust or tarnish appears on the blades after many days.

Buffering eye solutions for surgical use and their sterilization. To lessen congestion of the eyes in operating it is well to use solutions which are nonirritating. A refinement of general surgical technique is Gifford's method of buffering eye solutions (20). The composition of the acid buffer solution No. 1

Boric acid (anhydrous)
Potassium chlorate
Distilled water

100 ml
100 ml
100 ml

100 ml
100 ml
100 ml

Fig 7 Transplantation of Tenon's capsule a, A vertical incision is made along the semilunar fold in order to expose the medial rectus, Tenon's capsule is not disturbed, and a muscle forceps without teeth or pins is passed beneath the muscle, b, the muscle is severed from its insertion, and the fibers lying between the forceps and the insertion are excised if a resection is desired. Two double armed sutures are passed through the muscle from the scleral surface and then through the holes in the forceps. Tenon's capsule is undermined on one side of the muscle and two double armed sutures are passed through the border of the capsule

Incisions are made on each side of the sutures c, Two additional sutures are passed through Tenon's capsule and the graft is freed, d, Tenon's capsule is reversed and sutured with episcleral sutures over the rough scleral area where the medial rectus was formerly adherent e, the medial rectus is drawn over the graft by means of traction with fixation forceps after the sutures have been passed through the muscle stump, f, the conjunctival wound is closed with a running suture. It is possible at this point to see the muscle and the graft in outline through the conjunctiva

The composition of the stock sodium carbonate solution is
Sodium carbonate (anhydrous)
Distilled water

Gifford's acid buffer solution No 2, which is suitable for cocaine and epinephrine, is made by adding 0.05 cubic centimeter of the stock sodium carbonate solution to 30 cubic centimeters of acid buffer solution No 1. His alkaline buffer solution No 1 is made by adding 1.5 cubic centimeters of the stock sodium carbonate solution to 30 cubic centimeters of acid buffer solution No 1. It is suitable for atropine, homatropine, pilocarpine and physostigmine. Alkaline buffer solution No 2

21.2 gm
1000 c c

is made by adding 4 cubic centimeters of the stock sodium carbonate solution to 30 cubic centimeters of the acid buffer solution. It is useful in cases of vernal and chronic conjunctivitis.

Preoperative preparation of the conjunctiva To sterilize the conjunctiva the antiseptics used should be selected according to the organisms found on smear and culture but a 0.25 per cent solution of zinc sulphate is useful as a routine procedure. In certain cases 1:2500 metaphen instilled several times a day has been helpful. Silver as suggested by Bell has been used with apparent success in lessening postoperative infection in catarract operations. Excellent results are likewise claimed by certain surgeons (11), who use no anti-

Fig. 6 Methods of closing cataract wounds. a, Williams' conjunctival suture (807) b, Kalt corneoscleral suture (804) c, Van Lint conjunctival flap d, Barraquer (923) and Green (93) conjunctival apron e, Berens running conjunctival and episcleral suture (925) f, McLean corneoscleral suture (940)

conjunctiva is closed by means of interrupted plain silk or catgut sutures. Only the deep sutures are removed. This technique has been used in more than 60 enucleation operations and post-operative loss of the implanted foreign substances has been less frequent than when catgut sutures were buried. The plastic implant (10) has been expelled in only 2 cases.

Although surgical wounds have been closed with sutures for years, ophthalmic surgeons have been slow in suturing cataract wounds. However the use of sutures in this operation has been almost universally adopted in the United States of America since the discussion of this subject before the American College of Surgeons in 1925 by Zentmayer Posey Ellett, and the author at that time there was great difference of opinion in regard to the value of suturing. Ellett championed the Kalt

suture the author the conjunctival episcleral suture whereas Zentmayer and Posey opposed the use of sutures. The principle of not using tension in suturing has been applied to cataract wounds for too much tension causes overlapping of the scleral and corneal wound edges.

STERILIZATION OF INSTRUMENTS AND DRUGS

By 1805 chemical sterilization had been replaced by dry heat and steam sterilization except in the preparation of the skin and of the operating field.

Morax dry heat method This method is satisfactory for the sterilization of eye instruments. Thoroughly cleansed dry instruments are placed in open boxes in an electric sterilizer (Morax) and the door is left partly open until a temperature of 180 degrees F (80 degrees C) is reached, to be sure the instruments are dry. The boxes are closed and wrapped in paper and the door is shut when the danger of retained moisture with resulting oxidation is past. When 335 to 345 degrees F (155 to 160 degrees C) is reached, this temperature is maintained for 30 minutes. Sets of instruments may be kept sterile for 1 week. If wrapped boxes are dated, the differentiation of sterile from non-sterile instruments is facilitated. Single instruments and syringes may be sterilized in large glass test tubes closed with cotton. The principal objection to the dry heat method is that several sets of instruments are required.

Chemical sterilization. For the chemical sterilization of instruments M. H. Post has used a solution of alcohol 95 per cent with liquid cresols composed 2 per cent ounces, commercial chloroform ounces, liquid abalone 2 drams. With these chemicals no rust or tarnish appears on the blades after many days.

B. Ferri's eye solutions for surgical use and their sterilization To lessen congestion of the eyes in operating it is well to use solutions which are nonirritating. A refinement of general surgical technique is Gifford's method of buffering eye solutions (29). The composition of the acid buffer solution No. 1 is

Boric acid (anhydrous) 4 grs
Potassium chloride (anhydrous) 7 1/2 grs
Distilled water q.s.

4 grs
7 1/2 grs
q.s.

This is suitable for phenacaine and betyn.

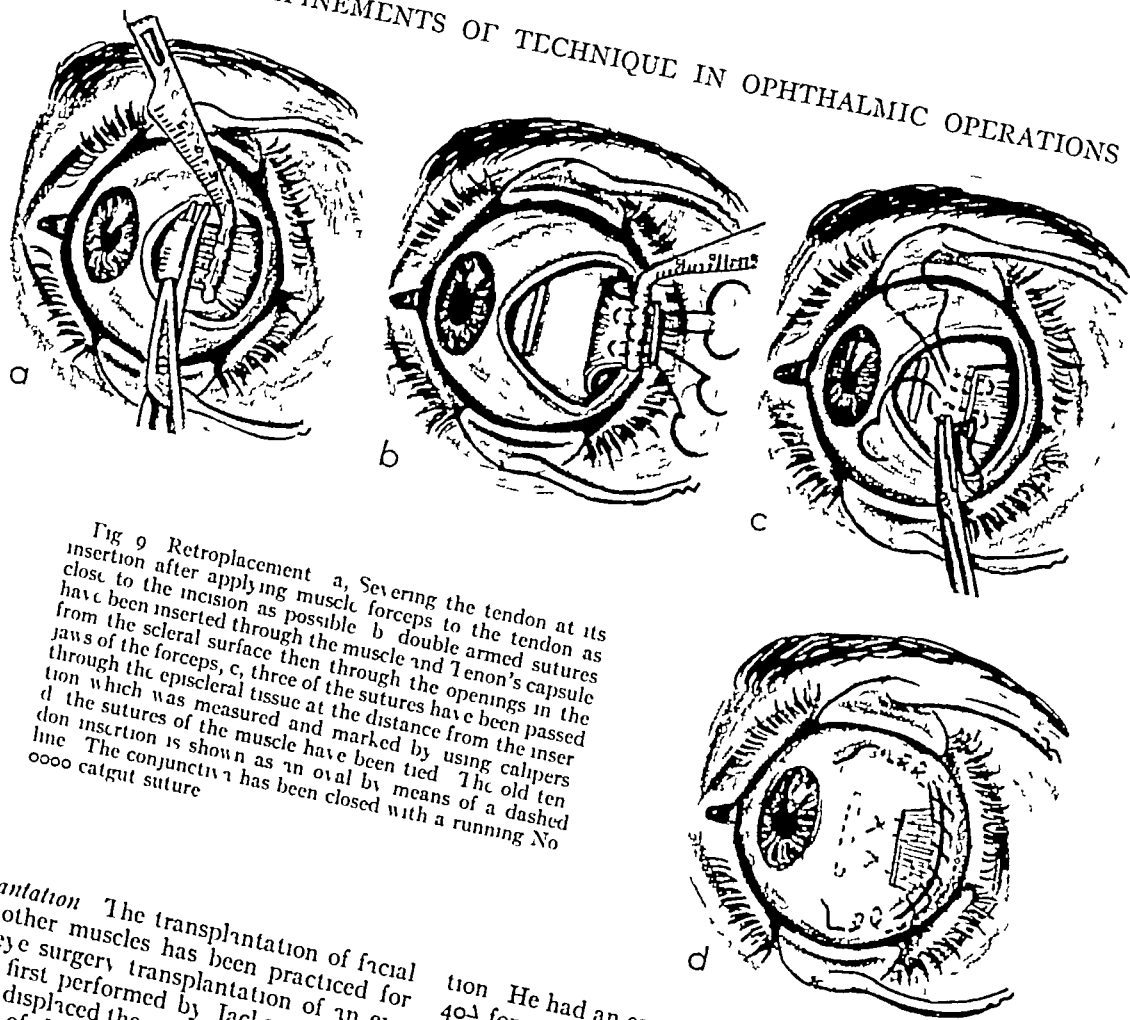

Fig 9 Retroplacement a, Severing the tendon at its insertion after applying muscle forceps to the tendon as close to the incision as possible b double armed sutures have been inserted through the muscle and Tenon's capsule from the scleral surface then through the openings in the jaws of the forceps, c, three of the sutures have been passed through the episcleral tissue at the distance from the insertion which was measured and marked by using calipers d the sutures of the muscle have been tied The old tendon insertion is shown as an oval by means of a dashed line The conjunctiva has been closed with a running No 0000 catgut suture

Transplantation The transplantation of facial muscle or other muscles has been practiced for years In eye surgery transplantation of an eye muscle was first performed by Jackson when he receded and displaced the superior rectus laterally for paralysis of the superior oblique Gifford (30) believes that transplantation of living tendon slips from the superior and inferior rectus muscles offers the best chance of a cosmetic and functional result in paralysis of the lateral rectus muscle

A brilliant result was obtained by me in one patient (Major I L), who had a paralysis of the sixth nerve, and was referred by Dr Daniel B Kirby Transplantation of the lateral half of the superior and inferior recti with Tenon's capsule to the attachment of the lateral rectus, combined with a 6 millimeter resection of the medial rectus, was performed Binocular single vision was obtained and he was admitted to the Civilian and American Air Forces Before operation his vision was 20-15 in each eye without correc-

tion He had an esotropia of 45Δ for distance and 40Δ for near At the last examination he measured an esophoria of 10Δ for distance and 5Δ for near His vision was normal in each eye and no lenses were prescribed At the time of the patient's first visit, he complained of diplopia and at the last visit he could hold binocular vision a little beyond the midline in the field of action of the paralyzed lateral rectus

PLASTIC OPERATIONS

With the advent of Listerian antiseptic procedures, it became possible to repair hitherto permanent disfigurements of the body Some surgeons began to treat these cases by utilizing living bone, cartilage, and flesh It was World War I that made a specialty of plastic surgery

Cartilage transplantation Von Mangold in 1897 first advocated the use of a section of cartilage to support the interior prominence of the nose Bone and cartilage are used for the purpose of reconstructing mesodermal structures Cartilage possesses the lower metabolic rate (66) and unpre-

Fig. 8. Tendon lengthening by division of tendon. Stephenson method: a, b, d, division and lateral displacement of tendon; c, step division, suturing of upper and lower cut edges. Landolt amelia method: a, step-like division; b, reattachment of muscle. 3. Grimsdale method: a, tongue flap division; b, sutures introduced through extreme cut edges. 4. Verheeff method: a, a pair of vertical incisions through one fifth the breadth of the tendon at the upper and lower borders, and a vertical incision midway between the incisions through the middle quarters

of the tendon. 5. Todd method: a, tendon is stretched between two strabismus hooks, and incisions are made through one third of the tendon; b, the upper border and one incision made through one third of the tendon at the lower border. 6. O'Connor 1. o-stage tenotomy: a, central tenotomy is performed leaving incut margin of millimeters; b, the upper and lower borders of the muscle; c, after 4 weeks tenotomy of the millimeter bands; d, the ends are left attached at the upper and lower borders is performed.

septica on the conjunctiva before operation because they assert that asepsis of the conjunctiva is probably maintained by the lysozyme of Fleming when it is contained in the tears in normal concentration. Antiseptics possibly decrease the concentration of lysozyme by increasing lacrimation. Atropine by producing paralysis of the parasympathetic nerves, diminishes lacrimation and increases the concentration of lysozyme.

MUSCLES

The prevention of adhesions following muscle operations probably originates from the covering of intestinal wounds to prevent adhesions. In eye surgery this principle has been recently applied (7) to the prevention or treatment of adhesions be-

tween the muscles of the eyeball and the sclera (Fig. 7). The results in 9 cases have been most encouraging, although in one case the first operation made the condition worse and this has not been rectified. In another patient the first operation also made the condition worse, but a second Tenon's capsule transplant which was performed at the insistence of James W. White and Daniel B. Kirby resulted in improvement in motility and appearance.

Tendon lengthening has been used for weakening eye muscles for years; the first attempts following the principles used in general surgery (Fig. 8). However, this procedure has been almost completely discarded in recent years for recession (17, 38) and retroplacement (9) (Fig. 9).

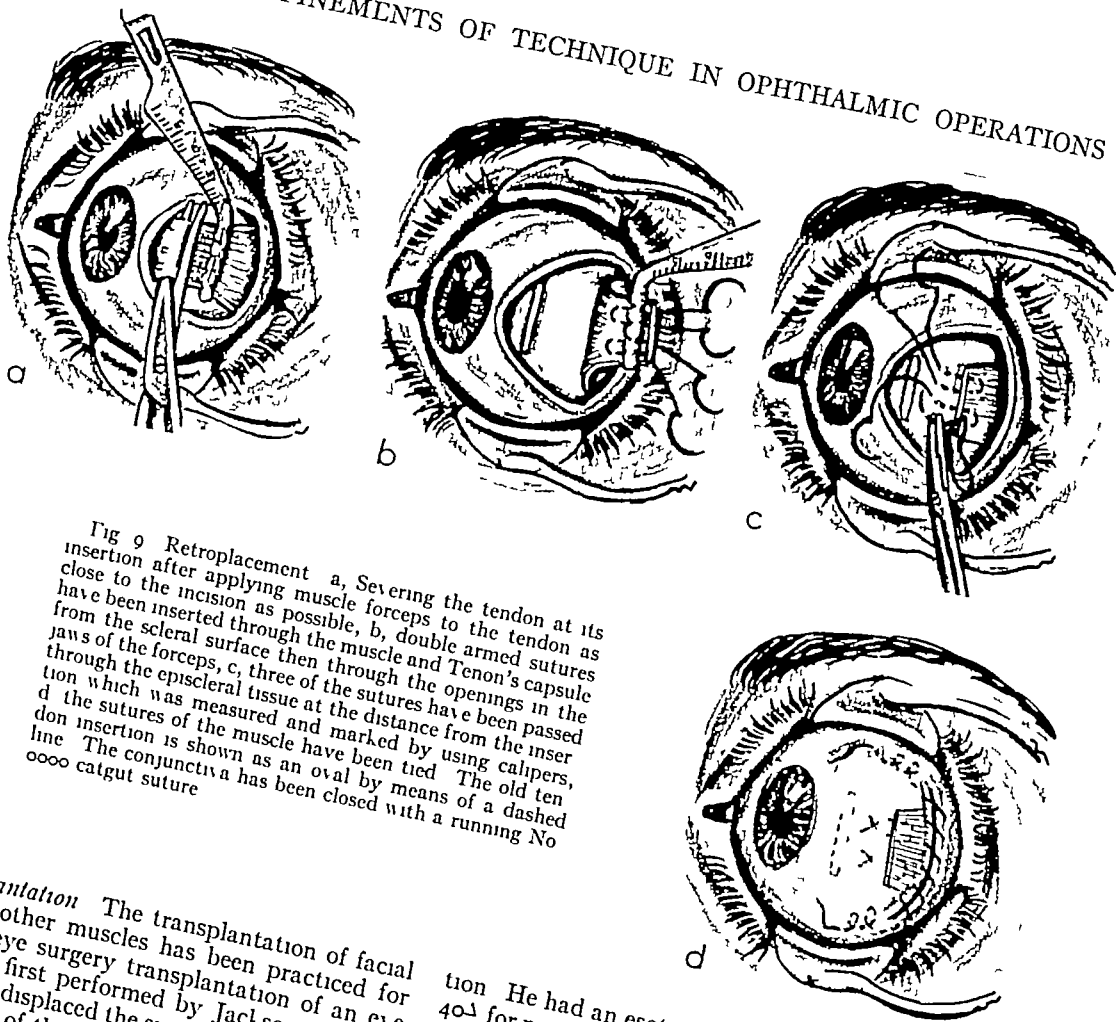

Fig 9 Retroplacement a, Severing the tendon at its insertion after applying muscle forceps to the tendon as close to the incision as possible, b, double armed sutures have been inserted through the muscle and Tenon's capsule from the scleral surface then through the openings in the jaws of the forceps, c, three of the sutures have been passed through the episcleral tissue at the distance from the insertion which was measured and marked by using calipers, d the sutures of the muscle have been tied The old tendon insertion is shown as an oval by means of a dashed line The conjunctiva has been closed with a running No 0000 catgut suture

Transplantation The transplantation of facial muscle or other muscles has been practiced for years In eye surgery transplantation of an eye muscle was first performed by Jackson when he receded and displaced the superior rectus laterally for paralysis of the superior oblique

Gifford (30) believes that transplantation of living tendon slips from the superior and inferior rectus muscles offers the best chance of a cosmetic and functional result in paralysis of the lateral rectus muscle

A brilliant result was obtained by me in one patient (Major F L), who had a paralysis of the sixth nerve, and was referred by Dr Daniel B Kirby Transplantation of the lateral half of the superior and inferior recti with Tenon's capsule to the attachment of the lateral rectus, combined with a 6 millimeter resection of the medial rectus, was performed Binocular single vision was obtained and he was admitted to the Canadian and American air forces Before operation his vision was 20-15 in each eye without correc-

tion He had an esotropia of 45Δ for distance and 40Δ for near At the last examination he measured an esophoria of 10Δ for distance and 5Δ for near His vision was normal in each eye and no lenses were prescribed At the time of the patient's first visit, he complained of diplopia and at the last visit he could hold binocular vision a little beyond the midline in the field of action of the paralyzed lateral rectus

PLASTIC OPERATIONS

With the advent of Listerian antiseptic procedures, it became possible to repair hitherto permanent disfigurements of the body Some surgeons began to treat these cases by utilizing living bone, cartilage, and flesh It was World War I that made a specialty of plastic surgery

Cartilage transplantation Von Mangold in 1897 first advocated the use of a section of cartilage to support the anterior prominence of the nose Bone and cartilage are used for the purpose of reconstructing mesodermal structures Cartilage possesses the lower metabolic rate (66) and unpre-

Fig. Epidermal proliferation through electrolysis puncture made in the eye of rabbit. Note firm localized matrix present after 8 days.

served autogenous cartilage may return to a normal state (Loeb). Autogenous costal cartilage transplantation so far has been used by ophthalmologists mainly for filling in depressions about the orbit, and as an implant after enucleation. Cartilage ("pickled" in 99 per cent alcohol) remains as tolerated dead foreign bodies (homografts) for about 9½ months (51).

Autogenous cartilage from the ribs, survives after transplantation, as living cartilage up to periods as long as 6 years, neither increasing nor decreasing in size. Obtaining the cartilage, however, is not without risk. Therefore costal cartilage obtained during autopsy has been advocated by Strauth and Slaughter in cases in which the cause of death is known and in which the deceased person's blood is serologically normal. Middle aged persons are preferred because their cartilage does not present too much fibrous tissue or too much calcification.

Cartilage from the ear is most suitable for reforming the upper eyelid.

Transplantation of fat has been used after enucleation () for filling the orbit, for preventing depression around the eye, and in cases of scar adherence to the bone.

Fascia. Fascia has been shown by general surgeons to be a living tissue, and has been used for the correction of paralytic mouth deformity and for filling depressions. Fascia is used in ophthal-

mology for filling in depressions which need not be too resistant to pressure as those in the malar region, not involving the orbital margin. Fascia is used for correcting ptosis (41) for the correction of strabismus (28) to line scleroplastics and keratoplastic conjunctival flaps (57) for paralytic lagophthalmos (73) as subconjunctival grafts (74), and for replacing the tarsus.

Preserved fascia lata is claimed to be as useful as fresh tissue and Ellett (20) has used it for the correction of ptosis with varying results.

Grafts. Plastic surgeons have taught ophthalmologists many ways of using different types of grafts. Although Szymonowski in 1867 wrote the first thorough book on restorative surgery it was not until 1871 that Reverdin introduced the circular epidermal skin grafts.

The Thiersch graft was introduced in 1886 and proved that comparatively large pieces of skin could be transplanted. These grafts consist of very thin strips of epidermal skin taken from the extensor surface of the arm or the anterior region of the thigh. The Thiersch razor an ordinary razor or grafting knife may be used to remove the strips but I have found that more uniform and thinner grafts may be obtained with the Padgett (52) dermatome. The technique I have found useful in restoring the socket is as follows: The socket is prepared as advised by Weeks (71) and Wheeler. The eyelids are undermined to the orbital margins. Kerr's dental compound wrapped in a Thiersch graft is inserted after the canthotomy.

Gillies has used the *Esmer epithelial inlay* (72) for contraction of the outer canthi.

Wolfe of Glasgow 1876 also utilized fairly large free skin grafts. The piece of skin was cut from selected parts of the body preferably the outer side of the arm. Its size was about one-third larger than the size and shape of the area to be covered. Weeks (71) used the Wolfe graft for restoring the lower eyelid, obtaining the graft from the inner surface of the upper arm. When possible it seems preferable to obtain the skin from the upper eyelid as the color is better.

Pedicle grafts were used by Kaspar Tagliacozzi and described in his book entitled *De Chirurgia per iustitiam* (597). He restored the entire nose by means of a double pedicle flap taken from the arm. Pedicle flaps have been used for coloboma, and the correction of permanent fistula of the eyelids.

Blair and Brown prefer a skin graft of intermediate thickness for certain plastic procedures, for example the back of the hand not over the knuckles and on the subcutaneous muscles of the face and orbicularis oris and palpebrum.

Blanket grafts A method of skin grafting which is termed "blanket graft" by which a graft with a total area of 176 square inches is prepared, has been described by McPheeters and Nelson. In their technique a pattern of the area to be covered is made by tailoring a sheet of gutta percha to fit it exactly, and this sheet in turn is covered with the thinnest grafts obtainable with the Padgett dermatome. The individual grafts are then sutured.

There can be little doubt that the use of free grafts by general surgeons inspired the attempts at total (58) and partial (35) corneal transplantation. Usually the grafts have been obtained from enucleated eye and transferred immediately but grafts from cadavers have been advocated by Ilatov. A transplant was taken from the eye of a cadaver 41 hours after its enucleation. In his case the tissue remained transparent during 41 months of observation. Eyes for this purpose are enucleated 2 hours after death and kept in a refrigerator at 5 to 6 degrees centigrade.

GLAUCOMA

There are some points of similarity between intracranial hypertension and glaucoma and the surgical treatment used by neurosurgeons and ophthalmologists. In 1665 D. Julio Sala employed a trephine to drain a penetrating head wound. Who can doubt that the trephine operation for glaucoma really had its inspiration in the work of Sala. Elliott and Iergue were the first to use a trephine for the removal of a segment of the corneosclera in operations for glaucoma.

There is a marked similarity between the La grange iridosclerectomy (39) and iridosclerectomy (5) and subtemporal decompression (18). However, according to Hirtmann (34), Lagrange developed his technique without knowledge of Cushing's work, although one might surmise that there was a relationship.

Formerly in the treatment of brain abscess, trephination and drainage by means of wicks were employed. Mosher's drain (1910), was a real and since. This operation may be compared with iridotomy (12) and with the drain operation of Troncoso as well as the ecton operation (80) and the Wiener drainage operation. Wiener put a thread between the choroid and the sclera (70).

ALCOHOL INJECTIONS

In 1902, Schlosser used alcohol injections for trigeminal neuralgia. In 1915 Sicard (62) injected alcohol into the nerve trunk of the median nerve in cases of painful lesions of the nerve plexus. In 1908 Weckers called attention to the sedative

action of the intraorbital injections of alcohol. He referred to the work of N. Bruce in 1913, Brady in 1915 and others who showed the value of anesthetics in inflammations.

Ciliary ganglion Magitot injects 1 to 1.5 cubic centimeters of 20 to 50 per cent alcohol into the ciliary ganglion in cases of iritis, iridocyclitis, glaucoma secondary to iridocyclitis, interstitial keratitis (syphilitic), phlyctenular keratitis in children, and acute glaucoma even with good vision. I have used 1 cubic centimeter of 80 per cent alcohol in absolute glaucoma with high tension and pain. The pain and tension have been relieved in several cases. I inject 1 cubic centimeter of novocain, 4 per cent, with 3 minims of 1:1000 adrenalin in the region of the ciliary ganglion. The needle is left in place, after 5 minutes the alcohol is injected.

For pain and glaucoma, Alexander rejected the resection of the ciliary ganglion and Grueter's injection of alcohol into the orbit around the ciliary ganglion on account of their risk and adverse complications, i.e., paralysis of ocular muscles, perforation of sclera, possible necessity for enucleation, gasserian ganglion gave great satisfaction in the relief of the trigeminal, as there were no ill effects. **Fifth nerve and gasserian ganglion** Schlosser, Ostwald, Levy and Boudouin and Sicard (62) were among the first to inject the nerve-trunk in trigeminal neuralgia. Groves has recommended the injection of the branches of the trigeminal nerve with 80 per cent alcohol. This is done through a long needle thrust into the cheek so as to lie above the sigmoid curve of the jaw, and an ender or is made to enter the foramen ovale or the sphenomaxillary fossa, in order to inject the actual nerve trunks near the ganglion.

Supraorbital neuralgia Three cases of severe headaches were treated by Swetlow with relief for 10 to 12 weeks, by alcohol injections of the great occipital or supraorbital nerve.

Sphenopalatine ganglion Pain produced by keratitis, iritis, glaucoma, and other ocular conditions may be controlled by anesthetizing Meckel's ganglion or by intraorbital injections. In addition to the relief of pain there may also be a decrease in photophobia, blepharospasm, and lacrimation. Magitot's methods of anesthetizing the sphenopalatine ganglion are as follows:

A. Local application—Boric acid solution (2 per cent) is applied with a cotton pledget to the cornea after occlusion of the eye. The procedure may be repeated every 4 or 5 days. The procedure is continued between 4 and 7 days. The procedure is continued between 4 and 7 days. The procedure is continued between 4 and 7 days.

Fig. Fascial proliferation through electrolysis puncture caused in the eye of rabbit. Note firm localized contract present after 8 days.

served autogenous cartilage may return to a normal state (Loeb). Autogenous costal cartilage transplantation so far has been used by ophthalmologists mainly for filling in depressions about the orbit and as an implant after enucleation. Cartilage ('pickled' in 50 per cent alcohol) remains as tolerated dead foreign bodies (homografts) for about 9½ months (53).

Autogenous cartilage from the ribs, survives after transplantation as living cartilage up to periods as long as 6 years, neither increasing nor decreasing in size. Obtaining the cartilage however is not without risk. Therefore costal cartilage obtained during autopsy has been advocated by Straith and Slaughter in cases in which the cause of death is known and in which the deceased person's blood is serologically normal. Middle-aged persons are preferred because their cartilage does not present too much fibrous tissue or too much calcification.

Cartilage from the ear is most suitable for re-forming the upper eyelid.

Transplantation of fat has been used after enucleation (2) for filling the orbit, for preventing depression around the eye and in cases of scar adherence to the bone.

Fascia. Fascia has been shown by general surgeons to be a living tissue, and has been used for the correction of paralytic mouth deformity and for filling depressions. Fascia is used in ophthal-

mology for filling in depressions which need not be too resistant to pressure as those in the malar region not involving the orbital margin. Fascia is used for correcting ptosis (43) for the correction of strabismus (8) to line scleroplastic and keratoplastic conjunctival flaps (57) for paralytic lagophthalmos (75), as subconjunctival grafts (74), and for replacing the tarsus.

Preserved fascia lata is claimed to be as useful as fresh tissue and Ellett (50) has used it for the correction of ptosis with varying results.

Grafts. Plastic surgeons have taught ophthalmologists many ways of using different types of grafts. Although Strymanowski in 1867 wrote the first thorough book on restorative surgery it was not until 1871 that Reverdin introduced the circular epidermal skin grafts.

The Thiersch graft was introduced in 1886 and proved that comparatively large pieces of skin could be transplanted. The Thiersch razor or ordinary razor or grafting knife may be used to remove the strips but I have found that more uniform and thinner grafts may be obtained with the Padgett (5) dermatome. The technique I have found useful in restoring the socket is as follows. The socket is prepared as advised by Weeks (71) and Wheeler. The eyelids are undermined to the orbital margins. Kerr a dental compound wrapped in a Thiersch graft is inserted after the canthotomy.

Gillies has used the Esser epithelial inlay (22) for contraction of the outer canthus.

Wolfe of Glasgow 1876 also utilized fairly large free skin grafts. The piece of skin was cut from selected parts of the body preferably the outer side of the arm. Its size was about one-third larger than the size and shape of the area to be covered. Weeks (72) used the Wolf graft for restoring the lower eyelid, obtaining the graft from the inner surface of the upper arm. When possible it seems preferable to obtain the skin from the upper eyelid as the color is better.

Pedicle grafts were used by Kaspar Tagliacozzi and described in his book entitled *De Chirurgia per insulionem* (1597). He restored the entire nose by means of a double pedicle flap taken from the arm. Pedicle flaps have been used for coloboma, and the correction of permanent fistula of the eyelids.

Blair and Brown prefer a skin graft of intermediate thickness for certain plastic procedures, for example the back of the hand not over the knuckles and on the subcutaneous muscles of the face and orbicularis oris and palpebrum.

BERENS REFINEMENTS OF TECHNIQUE IN OPHTHALMIC OPERATIONS 625

Blanket grafts A method of skin grafting which is termed "blanket graft" by which a graft with a total area of 176 square inches is prepared, has been described by McPheeters and Nelson. In their technique a pattern of the area to be covered is made by tailoring a sheet of gutta percha to fit it exactly, and this sheet in turn is covered with the thinnest grafts obtainable with the Padgett dermatome. The individual grafts are then sutured.

There can be little doubt that the use of free grafts by general surgeons inspired the attempts at total (58) and partial (35) corneal transplantation. Usually the grafts have been obtained from an enucleated eye and transferred immediately but grafts from cadavers have been advocated by Filatov. A transplant was taken from the eye of a cadaver 41 hours after its enucleation. In his case the tissue remained transparent during 41 months of observation. Eyes for this purpose are enucleated 2 hours after death and kept in a refrigerator at 5 to 6 degrees centigrade.

GLAUCOMA

There are some points of similarity between intracranial hypertension and glaucoma and the surgical treatment used by neurosurgeons and ophthalmologists. In 1665 D. Julio Sala employed a trephine to drain a penetrating head wound. Who can doubt that the trephine operation for glaucoma really had its inspiration in the work of Sala. Eliott and Fergus were the first to use a trephine for the removal of a segment of the corneosclera in operations for glaucoma.

There is a marked similarity between the Langer iridoclerectomy (39) and iridocorneosclerectomy (5) and subtemporal decompression (18). However, according to Hartmann (34), Lagrange developed his technique without knowledge of Cushing's work, although one might surmise that there was a relationship.

Formerly in the treatment of brain abscess, trephination and drainage by means of wicks were employed. Mosher's drain, 1916, was a real advance. This operation may be compared with iridotaxis (13) and with the drain operation of Troncoso as well as the seton operation (80) and the Wiener drainage operation. Wiener put a thread between the choroid and the sclera (76).

ALCOHOL INJECTIONS

In 1903, Schloesser used alcohol injections for trigeminal neuralgia. In 1915, Sicard (62) injected alcohol into the nerve-trunk of the median nerve in cases of painful lesions of the nerve plexus. In 1930, Weckers called attention to the sedative

action of the intraorbital injections of alcohol. He referred to the work of N. Bruce in 1913, Brachet in 1915 and others who showed the value of anethetics in inflammations.

Ciliary ganglion Magitot injects 1 to 1.5 cubic centimeters of 20 to 50 per cent alcohol into the ciliary ganglion in cases of iritis, iridocyclitis, glaucoma secondary to iridocyclitis, interstitial keratitis (syphilitic), phlyctenular keratitis in children, and acute glaucoma even with good vision. I have used 1 cubic centimeter of 80 per cent alcohol in absolute glaucoma with high tension and pain. The pain and tension have been relieved in several cases. I inject 1 cubic centimeter of novocain, 4 per cent, with 3 minims of 1:1000 adrenalin in the region of the ciliary ganglion. The needle is left in place, after 5 minutes the alcohol is injected.

For pain and glaucoma, Alexander rejected the resection of the ciliary ganglion and Grucers in resection of alcohol into the orbit around the ciliary ganglion on account of their risk and adverse complications, i.e., paralysis of ocular muscles, perforation of sclera, possible necessity for enucleation. He found that injections of alcohol into the gasserian ganglion gave great satisfaction in neuralgia of the trigeminus, as there were no ill-effects.

Fifth nerve and gasserian ganglion Schloesser, Ostwalt, Levy and Baudouin and Sicard (62) were among the first to inject the nerve trunk in trigeminal neuralgia. Groves has recommended the injection of the branches of the trigeminal nerve with 80 per cent alcohol. This is done through a long needle thrust into the cheek so as to be in the sigmoid curve of the jaw, and an endeavor made to enter the foramen ovale or the maxillary fossa, in order to inject the active trunks near the ganglion.

Supraorbital neuralgia Three cases of supraorbital headaches were treated by Swetlow with 10 to 12 weeks, by alcohol injections of the occipital or supraorbital nerve.

Sphenopalatine ganglion Pain produced by iritis, glaucoma, and other ocular affections may be controlled by anesthetizing the ganglion or by intraorbital injections. In a case of photophobia, blepharospasm, and hyperemia, Magitot's methods of anesthetizing the sphenopalatine ganglion are as follows:

A Local application—Bonain's solution (alcohol, carbolic acid) is applied with a cotton applicator directly or after cocaine 4 to 5 per cent. The applicator, slightly bent, is introduced between the middle turbinates, following the lower edge of the turbinate until its posterior end is reached.

applicator is rotated slightly outward and is pushed little further allowing it to rest on the fossa containing the sphenopalatine ganglion for a minutes.

B. Injection of the sphenopalatine ganglion—with novocain injected directly in the sphenopalatine ganglion, through the greater palatine canal, injection should be made in the mouth at the level between the second and third molar here the canal merges into the gum. Auhin angulated syringe is used with 35 millimeter rather blunt needle. Some novocain is injected under the mucous membrane of the mouth, the needle is then pushed into the greater palatine canal (35 mm. deep) and .5 cubic centimeter of 1 per cent solution of novocain is injected. It is inadvisable to inject alcohol because some cases of necrosis of the maxilla have been reported, probably because the palatine artery was injured.

Spastic entropion. The injection of alcohol for the correction of spastic entropion has been advocated by several ophthalmic surgeons. The skin about the external canthus is painted with 3 per cent iodine and .5 cubic centimeter of a 4 per cent solution of novocain, is injected into the outer fibers of the orbicularis muscle extending a distance of about 4 or 5 millimeters into the lower eyelid near the margin. The needle is left in place and .5 to .3 cubic centimeter of an 80 per cent solution of alcohol is usually injected into the muscle. (I prefer .5 c.c. of 60 per cent ethyl alcohol.)

INJECTIONS FOR PAIN IN HERPES ZOSTER

According to Secunda, Wolf and Price in 13 of 15 patients with acute herpes zoster relief from pain was obtained by injections of .5 per cent to 2.0 per cent novocain followed as necessary by nupercaine. Hollander's formula or a modification of it, thus

Benzocaine
Benzyl alcohol
Phenol
Oil of sweet almond q. ad

While pain disappeared promptly it recurred in some patients from 1 to 30 hours later. Injections of novocain and the anesthetic in oil permanently abolished the pain in 7 of 9 patients. The areas of herpetic hyperesthesia are mapped out by pin prick, brush or pinching, cleaned with 95 per cent alcohol and subcutaneously infiltrated with the therapeutic agent until there is total anesthesia.

SCLEROSING INJECTIONS FOR ANGIOMAS

There can be little doubt that the injection of sclerosing solutions for varicose veins (27) and hemorrhoids led to the use of these solutions by ophthalmologists. Forester who made the first injections recommended sodium salicylate, quinine, and red mercuric iodide. The reaction (venitis) which leads to obliteration and secondary

atrophy of the superficial vessels is now usually produced by sodium chloride, sodium morthate, monoethanolamine oleate, 66 per cent solution of dextrose.

Malkin has successfully injected hemangioma of the eyelid with sclerosing solutions (e. g. quinine and ethyl carbamate, quinine dihydrochloride, sodium chloride)

ELECTROSURGERY IN THE EXCISION OF TUMORS EXENTERATION AND DETACHMENT OF THE RETINA

The experiments of d'Arsonval and Oudin led to the use of electrosurgery in 1907 and diathermy was first employed in eye operations in 1911. In 1929, Moers described the use of the diathermy knife for orbital phlegmon. He believes that the advantages of this method are (1) pus is evacuated without opening blood vessels or lymphatics and (2) the diathermy incision produces sterilization along the line of incision and of the tissues a certain distance from the point of application. Monbrum has given the following indications for coagulation: exenteration of the orbit for a large invading tumor as well as destruction of tumors or other chronic proliferations of the eyelids and the bulbar conjunctiva.

In performing exenteration of the orbit, Mc Reynolds also prefers the electrocautery knife which reduces to a minimum the hazard of spreading the cancer cells.

Diathermy has been most successfully applied to operations for retinal detachment, and the majority of surgeons in the United States of America (8) prefer it. Safar used a diathermy current of about 30 milliamperes, small needles about 1.5 millimeters in length placed over the retinal tear then over the entire area of the detachment. After all the needles are placed and the current is applied, he removes them, thus allowing free escape of subretinal fluid. Some surgeons prefer the Lacarrere needle, Walker pins, or the Graefe curved needle applicator and about 40 milliamperes of current.

ELECTROLYSIS

Electrolysis, so long used by dermatologists for the removal of superfluous hair is especially useful to remove cilia. I prefer to use 0.5 milliamperes for 1 minute. Electrolysis was first used in operations for retinal detachment by Verboef in 1911. In my experience (8) and from animal experiments (Fig. 10) electrolysis makes a more firm union between the retina, choroid and sclera than does diathermy. In applying electrolysis in the macular region I have found that the delicate photore-

needles of Walker, 15 milliamperes for 3 seconds, are useful. I prefer to use the Grieshaber steel needles, 5 milliamperes for 5 seconds, in the peripheral parts of the retina.

SUMMARY AND CONCLUSIONS

Although some surgical practices seem to have originated with ophthalmic surgeons, most of their procedures seem to be adaptations or refinements of general surgical technique. Special consideration is given to the following: anesthesia, incisions, sutures and suturing, sterilization of instruments and drugs, muscles, plastic operations, glaucoma, alcohol injections, injections for pain in herpes zoster, akinesia, sclerosing injections for angiomas, electrosurgery in the excision of tumors, exenteration, detachment of the retina, and electrolysis.

Although Ambrose Paré said we will have to give thanks to God for our humanity and skill, the ophthalmic surgeons should also thank the general, neurologic, and plastic surgeons for much of their success in attaining the hippocratic ideals of ability, grace, speed, and painlessness.

RECENT TRENDS IN THE SURGERY OF HETEROTROPIA

MOACYR E. ALVARO M.D. São Paulo, Brazil

THE operative treatment of heterotropia has recently completed its one hundred and second year. On October 26 1830, Dieffenbach, inspired by Strohmeier's ideas and following Delpsch a technique for tenotomies, performed the first squint operation by cutting the internal rectus of the right eye in a boy of seven. Since then much has been written on the subject. At first there was an almost unbelievable mania for operating on cross-eyed individuals, and tenotomies and myotomies were done by the thousands in all parts of the world with the inevitable bad results. There followed the usual reaction of skepticism. The improvements in surgical technique by von Graef and others throughout the nineteenth and at the beginning of the twentieth century did not seem able to overcome that reaction, and in 1905 Haab is quoted as having stated that the operation for the correction of strabismus is the least satisfactory of all operative procedures on the eyes (83). Landolt mentioned the fact that an old practitioner and professor of ophthalmology had given the surgical treatment of strabismus up completely on account of its unsatisfactory results. But Landolt himself did not agree with that attitude toward the operative treatment of heterotropia and emphasized that bad results were a consequence of not adhering to the fundamental surgical principle "Understand the nature of the disease we attack. Understand the way operations work. Much good clinical and surgical work has been done since in the field of surgical treatment of strabismus, chiefly in Anglo-Saxon countries, and Landolt's advice seems to have been followed as much as possible. Consequently the results of that treatment have improved continuously.

Strabismus, according to William Thornwall Davis, is really a complex of diseases having one common symptom, namely the deviation of the eyes from their parallelism. Better understanding of this complex of diseases is responsible for the establishment of general rules for treatment to be applied intelligently in each individual case. Surgery is a very important part of that treatment although one should always bear in mind that "to

employ the highest type of surgery is but to take a small step toward the production of a physiological result (Nugent). This small step, however is in many instances absolutely necessary and it seems to be an accepted rule that when strabismus does not show any improvement after a reasonable trial period of 6 months (Wilkinson) with medical and orthoptical treatment or if such improvements come to a standstill, there is no other alternative but to operate. Duane's statement that "temporizing treatment with prisms and exercises has very decided limitations should never be forgotten. Worth-Chavasse added to Duane's caution "temporizing treatment must now be recognized for what it is—fiddling while Rome burns."

There does not any longer seem to be serious controversy regarding the necessity for early treatment of strabismus nor regarding the aim of the treatment—namely to establish simultaneous binocular stereoscopic vision. It is true too that when operations have to be resorted to, they are but one phase of the treatment, preoperative and postoperative orthoptic medical treatment being equally essential in order to get good physiological results. It is an equally accepted truth that the medical treatment of heterotropia succeeds in greatly reducing the proportion of surgical cases.

As Lancaster has recently emphasized accurate knowledge of the nature of the extraocular muscles, of their form and functions is of great importance for the complete understanding of the surgical treatment of heterotropia. As he has pointed out, it is essential to know that weakening or strengthening one given muscle is not the purpose of an operation for the correction of strabismus. The real aim of such procedure is to place the eye in a more favorable position for synergic movements with the fellow eye to enable simultaneous macular perception fusion, and stereoscopic vision. One should never forget that there is a great disproportion between the power of each muscle and the energy actually needed for the movement of the eyeball consequently the idea of strengthening or weakening simply one muscle cannot prevail.

In order to be able to choose the best surgical procedure it is of great importance to investigate the nature of each case of heterotropia and never to neglect consideration of convergence and di-

From the Department of Ophthalmology Escola Paulista de Medicina

Presented at the symposium, Surgery of Heterotropia and Heterotropia, before the Clinical Congress of the American College of Surgeons, Boston, November 3-7 1941

Recently Harms, Herlyn and Renner made a survey of a series of strabismus patients in central Europe who had already been operated on, and found that very few patients indeed could be spoken of as physiologically cured. In an overwhelming majority of cases there was a more or less perfect anatomic cure. As Harms pointed out, this was due to the fact that the approach to the significance and essence of concomitant strabismus is not sound and many ophthalmologists still abide by Wiesel's ideas expressed as follows: "The surgeon performing an operation for strabismus does away with the pathological alterations found in the eye and thus serves cosmetic purposes which are so generally welcomed nowadays."

Experimental pathological investigation in order to verify histologically the result of surgical methods has been done to a small extent. It can be readily understood why such investigation cannot be easily carried further with human eyes. Consequently the source of our knowledge must of necessity remain in the clinical field. Thus it would be of great advantage to the progress of our knowledge if ophthalmologists could be induced to give the subject of strabismus more care, so that so much of their efforts would not be completely lost. Only analysis of the end results of many well observed cases will enable us to judge the advantages of a particular method and for that purpose a fixed criterion for gathering the data for such papers should exist. A comparatively large number of instructive papers dealing with the treatment of strabismus and meant for doctors who are not ophthalmologists, and even for the lay public, have been successful in increasing the number of cross-eyed children being given proper care. In the same way possibly something could be achieved to educate ophthalmologists.

In spite of the great difference in standards, by and large considerable progress in the surgical treatment of concomitant strabismus may be noted, and it is to be hoped that with an increasing number of cases coming for early treatment, as a result of the enlightenment of the general practitioner and the lay public, more will be achieved in the near future.

Regarding the surgical treatment of paralytic strabismus, in comparison there has been more progress in the last few years, as can be readily inferred from the increasing number of papers (the majority of them very good) dealing with this subject, which are found in the literature. This growing interest in the surgical treatment of paralytic strabismus is most desirable because as it has been pointed out by Gifford (28) there are still many ophthalmologists who give the matter

little or no attention, and moreover our approach to the subject will undoubtedly benefit from the gathering of new data.

Differences of opinion still prevail to a large extent regarding the choice of the operation for each type of case. This seems to be due more to a lack of proper diagnosis, quite difficult in many instances, than to actual individual disagreement. The paralysis of an external muscle can easily cause a contraction of its opponent or an overaction of its synergical associate muscle in the contralateral eye and the predominance of the latter or of the former action can give a rather confusing picture. If the real cause of the deviation is not discovered, improper treatment will follow with all of its evil consequences, including the discrediting of a good method.

The exact diagnosis is sometimes really difficult to establish. Sound knowledge of all the muscular functions, more especially in the several directions of ocular gaze as it was emphasized by Vander Hoeve and Rockers is a condition *sine qua non* of success.

Generally speaking there are already some accepted rules for the choice of the operative method, as Peter has pointed out, and these rules are the result of constant observation. But regarding what can be expected from each type of surgical treatment there is still some controversy (Gifford, Bielchowsky et al.) The same controversy prevails in relation to the possibility of transplanting the tendon of a lateral rectus to a spot a few millimeters above or below its former attachment for the purpose of correcting vertical deviations (Casten, Mikuni). There is also a difference of opinion regarding the action of transplanted tendons of abducting muscles. Experiments in *anima vili* (Olmstead, Marguti and Yamagawa, 72) seem to prove that such transplanted muscles can thereafter have an adducting action, while others (Beard) deny that possibility. Equally controversial is the matter of priority in the surgical treatment of combined vertical and lateral deviations. White (79) is in favor of correcting the vertical deviation first whereas others prefer to correct both lateral and vertical defects simultaneously. The importance of vertical deviations has been emphasized too (Harms, 33) especially in children in whom its early correction has been advocated (Kroeckmann) in order to prevent torticollis with its injurious results in the development of the skeleton. Anatomical findings of absent muscles (Casten) and of muscular bands under the contracted rectus internus (Apple) which cannot be suspected before the operation also have been reported.

I shall now proceed to review the several advances in the surgical treatment of heterotropia reported in the literature on the subject from 1937 up to 1940. The year of 1937 has been chosen because a very complete review of the literature up to that date was published by C. Maynard Wheeler in that year.

The prevailing views on the several aspects of the surgical treatment of heterotropia according to the literature in the last few years follow.

Age at which to operate. It appears that in the United States there is an almost unanimous view regarding the question of age as a limitation for the operation of strabismus. Operative treatment should be resorted to whenever found necessary, if the medical orthoptic treatment did not bring about any improvement after a trial period of 6 months, irrespective of the patient's age.

The principal reasons given in favor of an early operation are (a) greater response to postoperative orthoptic treatment in younger patients, and (b) the disadvantage of having a physically handicapped child mentally influenced by that handicap (Dunnington).

There are still quite a number of opinions in favor of a late operation, chiefly in Europe. The explanation for those opinions are chiefly (a) the advantage of operating with local anesthetic, this being only possible after adolescence, (b) the possibility of spontaneous cure before adolescence, (c) the difficulty in securing the parents' permission to operate early. Spontaneous cure appears to be very rare indeed, the straightening of the deviated eye at adolescence proving with hardly any exception only an anatomic cure with binocular vision practically always absent.

Regarding the parents' unwillingness to grant permission for the operative treatment, it is a matter of education, and according to the suggestion of Martin and Nugent, both the medical profession and the laymen should be instructed about the advantages of early treatment, operative or otherwise. Regarding the anesthetic, general anesthesia is finding greater favor in strabismus operations at all ages.

Choice of cases for operation. All cases of divergent concomitant strabismus, not responding in a short time to medical orthoptic treatment, are surgical cases. In convergent heterotropia, opinions vary as to the maximum degree of deviation justifying conservative treatment. Some go as far as to advise surgical treatment for all cases above 8 degrees (Sternberg), others to state that under 15 orthoptic treatment alone is adequate. Here again it is rather hard to establish a fixed limit based on the degree of deviation for operative and

nonoperative cases. As long as there is marked and continuous improvement with orthoptic treatment, operative treatment should be postponed. Whenever there is a high degree of hypermetropia great caution is advisable even if full correction of the existing ametropia fails to correct the tropia immediately, a belated improvement may still be expected and consequently surgical treatment should wait (Dunnington).

OPERATIVE PROCEDURES

There are several types of operations for heterotropia. Some aim at increasing the effect of the muscles, and others at decreasing it. Among the operations of the first group are the advancement of the tendon and the shortening of the muscle, or the combination of both types, as in advancement with resection. The advantages and disadvantages of each group will be discussed later.

The different types of operations should not be used indiscriminately. If individual preferences for a particular surgical procedure are put aside when the preference seems to have no special basis, there are definite reasons for the chosen methods of treatment of the several types of strabismus.

According to Gibson there are three main causes of bad results in the surgical treatment of heterotropia, namely overcorrection, undercorrection, and choice of the wrong type of operation. Hence, it is important to choose the type of operation most adequate according to the exact findings and measurements in each individual case.

Some controversy seems to prevail regarding the importance of measuring the actual strength of each individual muscle in order to choose the operation in the different cases. Lancaster does not pay much attention to the action of each individual muscle, whereas others still attach great importance to it and even go to the extent of testing the strength of the muscle at the beginning of the operation in order to decide the type of surgery ultimately to be used (Jameson).

The relative state of convergence and divergence appears to be of major importance in the choice of the operative method (Maxwell Langdon, 42, Peter, 54, Dunnington). According to Prangen (59) increased esotropia at the near point is a sign of excess of convergence and increased esotropia for distance is a sign of excess of divergence. Conversely, decreased esotropia at the near point is a sign of lack of convergence and decreased esotropia for distance is a sign of lack of divergence. Accordingly, in cases of excess of convergence the interni should be weakened, in cases of excess of divergence, the abductors should be

weakened in cases of lack of convergence in convergent strabismus, an operation strengthening the external should be preferred in cases of lack of convergence in divergent strabismus an advancement of the internal should be chosen in cases of lack of divergence strengthening of the abductors is the method of choice.

More and more the idea prevails that the action of the operative treatment should be equally divided as much as possible between the two antagonist muscles of the same eye, in order not to have too much tension in the sutures which might cause ultimate changes in the results (Curdy Berens, 12 Kilwan) Gibson was led to favor this idea too by the good results observed in cases of very great deviations in which this method of operating simultaneously on two muscles of the same eye had been used.

A careful examination of each individual patient is essential for the proper diagnosis of the actual cause of the "symptom." And this diagnosis is absolutely necessary for the choice of the proper operative method. Gulbor classified the several types of strabismus and their respective aspects in the different tests. Thus, the test for visual acuity will spot all cases of amblyopia testing the movements of the eyeball will show the difference between a pseudoparalytic strabismus and that of heterotropia due to underaction or overaction of individual muscles the use of atropine rotates the eye inward in the pseudoparalytic and decreases the deviation in the accommodative type. The correction of ametropias with proper glasses will decrease the deviation angle in both accommodative and anisometropic type measuring the angle for the near-point and for distance enables the separation of the muscular from the accommodative types the tests for fusion will show a certain degree of fusion in the accommodative type, fusion for larger images in the anisometropic, partial fusion in the amblyopic, and none at all in the fusion type.

When double hyperphoria (Verhoeff) is found simultaneously with lateral deviations it is very important to have that corrected either before or at the same time as the lateral strabismus.

Simple tenotomy Simple tenotomy nowadays had better be mentioned in the historical part of the surgical treatment of heteropia, for there is no possible difference of opinion regarding the unpredictable effects of this crude and unscientific method. Both experimental work and clinical investigation have proved without any possible doubt how unreliable the method is. A few surgeons still use simple tenotomies, but the only acceptable reason for its use is the fact that it is

very simple, lending itself to easy performance on young children. However, the possibility of hampered convergence resulting from tenotomy on the internal recti of young children is one of the principal reasons why the operation should not be used.

In the surgery of divergent strabismus, simple tenotomy of the external rectus is still advocated, but logically a recession would replace the simple tenotomy very advantageously.

Controlled tenotomies In order to avert the dangers of simple tenotomy, several methods have been devised by which a stitch is passed through the muscle or the tendon before it is severed, this stitch being tied afterward to the tendon stump on the sclera, to the conjunctiva, or both.

Von Blascovics described a technique for a controlled tenotomy and his method has found great favor in central Europe (Harms, 33 Miklos). Von Blascovics' controlled tenotomy is quite an improvement upon the more primitive procedure of simple tenotomy but neither this method nor any other presented so far can compare with Jameson's recession, the tendon of the severed muscle not being properly attached to the sclera and consequently the final attachment being somewhat uncertain and unpredictable. The favor met by controlled tenotomies can be ascribed to the possibility of subsequent improvement of the results of an operation when overcorrection or undercorrection are found to be present. This is achieved by leaving the sutures tied in a way that allows for the tightening or the loosening of the suture in the first days after the operation. More will be said about this presently.

Weakening of muscular action through other methods than tenotomies Lengthening of muscles is seldom used any more, but occasionally the method is mentioned in the literature. Samurawitz recently advocated lengthening the muscle by pulling hard at it with a strabismus hook. He associates this with advancement of the antagonist. Central tenotomies are still practiced here and there but their use does not seem justified since, as it has been proved by the experiments of Watrous and Olmstead this type of operation is effective only because the postoperative attachments to the sclera of the part of the tendon operated upon bring about reduction in the arc of contact. Peter has deliberately reduced the arc of contact by suturing the tendon to the sclera some millimeters back of the point of normal attachment. Alabaster with gold sutures pulls the muscle in the opposite direction of its action during the advancement of the antagonist, and Worth-Chavasse places a band of electrocoagulation

not exceeding 1 millimeter at the bottom of a deep groove of the same width with the purpose of converting the contractile portion of the muscle in front of the band into inert tendon, thus reducing the action of the muscle. Walker, who studied histologically the muscles after this sort of diathermocoagulation, found that both the nerves and the muscular fibers are destroyed. By and large these different methods have not met with great favor and too little is known about their real merits.

Recession Recession is undoubtedly the best type of operation for the purpose of weakening the action of a muscle. Jameson advocates a wide conjunctival incision in the plica semilunaris. Curdy severs the tendon with a knife. Peter (55) recommends great care in the handling of the muscle and thus condemns the use of forceps. With the aid of a hook with which he lifts the muscle first on one and then on the other side, he makes one whipstitch at each side of the tendon before it is cut. Even fanlike spreading of the tendon on the sclera seems to be of great importance for the avoidance of future cyclophoria, and the stitches should be made with proper care in order to ensure uniform attachment.

Recessions are limited by the distance to the equator of the point of attachment of the different muscles on the sclera. Thus 5 millimeters for the rectus internus, 4 millimeters for the rectus inferior, 3 millimeters for the rectus externus, and 2.5 millimeters for the rectus superior seem to be the maximum that can be receded. In the case of larger eyes (the diameter of the cornea according to Priestley Smith being possibly the best index to judge about the size of an eye), 1 to 1.5 millimeters more can be allowed for each muscle. It has been claimed that even with larger recessions no ill results such as lack of convergence have been found, and apparently with the rectus externus more liberties can be taken, but on the rectus internus the maximum limit of 6 millimeters should not be stepped over. According to Jameson a 5 millimeter recession of the rectus internus will correct 20 to 25 degrees, and the recession of the rectus externus corrects one-third of that. According to Peter (54) only 12 degrees' correction can be expected from a recession of 6 millimeters, whereas 25 degrees can be expected if the recession is combined with advancement. Results vary considerably according to individual variations of the muscles. As a rule about 5 degrees for every millimeter of recession can be estimated, if the antagonist is operated on simultaneously.

Advancement This type of operation meant to enlarge the arc of contact is still in great favor

(Wheeler) although its results have been questioned and some controversy has arisen regarding its action. Duverger, quite some years ago, experimenting on rabbits found that after some time the advanced tendon finds itself attached to the former stump, in which case the advancement would only act through the shortening of the muscle. Prangen and Horay are of a similar opinion regarding the results of advancements, but Jameson believed that the muscular fibers are still active and can take action even when they are embodied in the attachments to the sclera. Peter is in favor of advancements because he finds that by including the capsule and the conjunctiva in the advancement about 5 to 10 degrees more can be corrected with this type of operation.

Apparently advancements will not correct more than about 15 degrees (Wheeler) except if associated with recession of the opponent. The possibility of using advancements for the purpose of correcting simultaneously vertical and lateral deviations has been considered, but an agreement does not seem to have been reached so far. The majority of papers dealing with advancement merely add details of new techniques, chiefly in the sutures. The operation lends itself to ulterior changes in the sutures for the purpose of correcting surgical defects during the first few days after the surgical procedure.

Resection Reese's method nowadays finds great favor. The effect of the operation is that of shortening the muscle and sometimes it has been used combined with advancement in order to increase its action. Great care has been taken to make the sutures more effective and to make them safer, by attaching the muscle to the conjunctiva before it is severed. The anchorage of the suture on the tendon stump has been improved too, and several new techniques have been described to that effect. As in all operations on the external muscles, the trend now is to make a large conjunctival incision in order to be able to operate freely on the muscle.

Tucking In order to obviate the undesirable attachments above or below the previous point of insertion a tucking operation, in which the muscle is not severed at all, was devised some time ago.

An argument raised against the tucking methods, first advocated chiefly by Burch and Grant, is that they are not very exact, as considerable stretching of the muscle fibers takes place during the first days after the operation and that consequently it is very difficult to know how much should be tucked in order to have dependable results. Possible necrosis of the muscle, due to strangulation of the blood supplying vessels, has been mentioned too. But the method has gained

weakened in cases of lack of convergence in convergent strabismus, an operation strengthening the external should be preferred. In cases of lack of convergence in divergent strabismus an advancement of the internal should be chosen. In cases of lack of divergence strengthening of the abductors is the method of choice.

More and more the idea prevails that the action of the operative treatment should be equally divided as much as possible between the two antagonist muscles of the same eye, in order not to have too much tension in the sutures which might cause ultimate changes in the results (Curdy, Berens, 12; Kirwan). Giffson was led to favor this idea too by the good results observed in cases of very great deviations in which this method of operating simultaneously on two muscles of the same eye had been used.

A careful examination of each individual patient is essential for the proper diagnosis of the actual cause of the "symptom." And this diagnosis is absolutely necessary for the choice of the proper operative method. Gullhor classified the several types of strabismus and their respective aspects in the different tests. Thus, the test for visual acuity will spot all cases of amblyopia; testing the movements of the eyeball will show the difference between a pseudoparalytic strabismus and that of heterotropia due to underaction or overaction of individual muscles; the use of atropine rotates the eye inward in the pseudoparalytic and decreases the deviation in the accommodative type. The correction of ametropias with proper glasses will decrease the deviation angle in both accommodative and anisometropic type; measuring the angle for the near-point and for distance enables the separation of the muscular from the accommodative types; the tests for fusion will show a certain degree of fusion in the accommodative type; fusion for larger images in the anisometropic, partial fusion in the amblyopic, and none at all in the fusion type.

When double hyperphoria (Verboeff) is found simultaneously with lateral deviations it is very important to have that corrected either before or at the same time as the lateral strabismus.

Simple tenotomy. Simple tenotomy nowadays had better be mentioned in the historical part of the surgical treatment of heteropia, for there is no possible difference of opinion regarding the unpredictable effects of this crude and unscientific method. Both experimental work and clinical investigation have proved without any possible doubt how unreliable the method is. A few surgeons still use simple tenotomies, but the only acceptable reason for its use is the fact that it is

very simple leading itself to easy performance on young children. However the possibility of hampered convergence resulting from tenotomy on the internal recti of young children is one of the principal reasons why the operation should not be used.

In the surgery of divergent strabismus, simple tenotomy of the external rectus is still advocated, but logically a recession would replace the simple tenotomy very advantageously.

Controlled tenotomies. In order to avert the dangers of simple tenotomy, several methods have been devised by which a suture is passed through the muscle or the tendon before it is severed, the suture being tied afterward to the tendon stump on the sclera, to the conjunctiva, or both.

Von Blascovics described a technique for a controlled tenotomy and his method has found great favor in central Europe (Harms, 33; Miklos). Von Blascovics' controlled tenotomy is quite an improvement upon the more primitive procedure of simple tenotomy but neither this method nor any other presented so far can compare with Jægersen's recession, the tendon of the severed muscle not being properly attached to the sclera and consequently the final attachment being somewhat uncertain and unpredictable. The favor met by controlled tenotomies can be ascribed to the possibility of subsequent improvement of the results of an operation when overcorrection or undercorrection are found to be present. This is achieved by leaving the sutures tied in a way that allows for the tightening or the loosening of the suture in the first days after the operation. More will be said about this presently.

Restraining of muscular action through other methods than tenotomies. Lengthening of muscles is seldom used any more, but occasionally the method is mentioned in the literature. Samura has recently advocated lengthening the muscle by pulling hard at it with a strabismus hook. He associates this with advancement of the antagonist. Central tenotomies are still practiced here and there but their use does not seem justified since, as it has been proved by the experiments of Watrous and Olmstead, this type of operation is effective only because the postoperative attachments to the sclera of the part of the tendon operated upon being about a reduction in the arc of contact. Peter has deliberately reduced the arc of contact by suturing the tendon to the sclera some millimeters back of the point of normal attachment. Alabaster with gold sutures pulls the muscle in the opposite direction of its action during the advancement of the antagonist, and Worth-Chavasse places a band of electrocoagulation

Fig 3 Diagram showing technique of the Harms controlled advancement operation

which he puts in two extra sutures through conjunctiva, muscle, and sclera and again through muscle and conjunctiva, and placed in such a way (Fig 3) that by tightening them soon after the operation it will be possible to shorten the already advanced muscle still more, thus increasing its action. Baudot described a somewhat similar method for the same purpose.

Von Blascovics, as far back as 1922, in certain cases in which slight changes in the position of the eyes (up to 5°) were still desirable, had used after operation a special dressing compelling the eye to be in extreme adduction or extreme abduction. The principle of his method was to force the eyes in a certain direction, so that the new attachments would take place in that position. Strebel and Goldman have advocated the use of that method. Instead of von Blascovics' special dressing, ordinary glasses covered with simple adhesive can serve the same purpose (Fig 4).

Methods for correcting bad operative results. Patients previously operated upon and in whom there is still some heterotropia should undergo the same careful examination as any other case of strabismus, in order to determine the proper methods of treatment at the proper time. In the case of previous recessions or tenotomies a similar operation on the antagonist is not advisable in order to avoid any degree of proptosis. For certain cases in which the ill results have been caused by unwanted adhesions between the muscles and the eyeball, Berens (11) has devised a special technique: he inserts between the adherent muscle and the sclera a transplanted piece of Tenon's capsule, taking care to turn the transplant over, so that the side which was formerly turned to the sclera, will now be turned to the muscle, thus averting the danger of renewed attachments between muscle and sclera. Capsular advancement has been found very useful in cases of paralysis due to previous simple tenotomies.

Divergent strabismus. As a rule there are no special methods for the treatment of divergent strabismus, the same general principles mentioned

Fig 4 Von Blascovics' method for subsequent correction during the first 5 to 12 days after the operation

for convergent concomitant heterotropia begin equally prevalent. Thus an accurate diagnosis of the nature of the deviation in each case is absolutely essential so that one may choose the best method. Furthermore, recessions of the external recti will be justified only in cases in which there is normal convergence, as has been pointed out by White and Brown (80). Coppez goes so far as to recommend complete tenotomies of the external recti, an operation which he otherwise condemns. But even on the external recti, tenotomies are not very satisfactory, and if weakening of the external is desired a recession should be resorted to. Cass is in favor of bilateral advancement with resection of the recti interni. Dunnington too favors a generous strengthening of convergence through a proper operation on the interni.

White and Brown (80) emphasize the importance of vertical deviations in the success of the operative treatment in divergent strabismus, as well as in the convergent. Hypertropia should be corrected preferably before the management of lateral deviation, but in some cases, when it is impossible to discover the vertical deviation with the necessary accurateness, it is justifiable to correct the lateral deviation first. In some cases it is possible to correct both deviations, lateral and the vertical, simultaneously. Generally it is the inferior oblique which is responsible for the vertical deviation, and in such cases a tenotomy or recession (von Blascovics) of the inferior oblique is the method of choice.

Cass calls attention to the fact that operative results are very deceptive in divergent strabismus, and in many cases immediate good results are followed in a short time by a relapse. Early operation is advisable in all cases of alternating strabismus and in those in which there is improper adjustment.

Paralytic strabismus. The possibility of re-establishing binocular single vision, even if this is limited to a very small area in the field of fixation,

Fig. 2. Myocompact silver ring should be cut as near as possible to the conjunctiva, first, where the scissors are, and then where the forceps appear in the illustration. The two severed ends can then be easily removed.

much favor in spite of this, and in the hands of those who sponsor this type of surgery the results have been very good. If the tucking is performed simultaneously with a recession, there will not be so much pull on the sutures of the tucked muscle, and consequently less stretching. Apparently not more than 20 degrees can be corrected with tucking. The least that can be tucked to get any effect at all is 8 millimeters (von Blascovics).

Several changes in the technique of the tucking operation have been presented, some advocating the use of instruments (tuckers) and others, only stitches. Recently a method was described providing for an anchorage of the muscle on the sclera near the limbus (Bardanelli).

The tucking of the muscle jointly with the conjunctiva has been advocated too, in order to strengthen the operation and to render it bloodless. This has been achieved with ordinary stitches (Szymanski) or with a silver ring in the myocompact of Barraquer or Lacarrière. According to Bristow the myocompact is an improvement of Briggs' instrument presented to the Section of Ophthalmology of the American Medical Association back in 1909, and Otis Wolfe gives testimony to Briggs' priority by stating that during one of his visits to Barcelona, he showed Barraquer Briggs' instrument and that later Barraquer sent him his model. According to Wolfe Barraquer never claimed priority for this method.

Myocompacts met with considerable favor in the early thirties. Later Hubert and Lebas advocated exposing the muscle first, and then shortening it with the myocompact. This renders the method much more dependable. About 10 millimeters' shortening can correct up to 20 degrees, if recession is performed simultaneously. A zonis in-

vestigated the pathology of muscles after myocompacts, and found the following changes in the strangulated part of the muscle: cyanosis, hemorrhages, and some necrosis and Jacques reported a case of repeated cyst-like growths on the conjunctiva over the tucked muscle after myocompacts. Removal of the silver ring about 1 month after the operation is sometimes rather difficult, as the ring is completely buried in the conjunctiva. In such cases, after the ring is uncovered each end should be held with a simple forceps and the ring should be cut apart as is shown in Figure 2 (Alvaro,).

"Cock operation" (O'Connor) O'Connor's clock operation was devised in 1911 and only gradually did it become extensively known. From San Francisco, where it had been used for a long time it spread gradually throughout the United States and in the last years to Europe. Everywhere it has been welcomed with marked enthusiasm. Barkan's statement about this method, calling it "the most perfect mechanical means of straightening an eye at any age" is one of the many which indicate the enthusiasm so many ophthalmologists have shown for the "shortener" operation.

The advantages of the method are chiefly the absence of sutures and of severance of the tendon. It has been pointed out by some surgeons (Wecker) that during the first days after the operation there is a rather strong reaction in the eye operated upon, but this has been denied by others (Appelman). About 10 millimeters is the maximum that can be shortened.

Smukler described a needle, $1\frac{3}{4}$ inches long, made of 14 gauge wire which he uses for winding the dermal suture round the strips of the muscle. He uses special grooved books to keep the strips separated for the insertion of the suture. The muscle is dissected as far as the equator and the dermal sutures should be placed at a certain distance from the point of attachment in order to prevent too much pull on the muscle fibers. Not more than 8 dermal sutures should be used. Cementing both ends of the dermal suture bundle with a special metallic cement is a method advocated by both O'Connor and by Smukler. The sutures should be left for about 3 weeks.

Methods for correcting after effects Apart from the controlled tenotomies, which lend themselves to further changes in the position of the eye a few days after the operation by tightening or loosening the suture, some methods have been devised of late to enable the surgeon to perform an after correction, if the results do not seem to be satisfactory in the first few days after operation. Harms (13) describes a new method of advancement in

upper part of the field of fixation—where there had been only a small vertical deviation, or none at all before the operation—there will be an overcorrection in the sense of a contrary vertical deviation. In the lateral movements results are still worse as the vertical position of the paralyzed eye is dependent upon the oblique muscles, when the patient looks toward the healthy side, the vertical deviation increases in proportion to the increased turning of the paralyzed eye, and conversely decreases when the patient looks away because the vertical position of the averted eyes is influenced by the vertical recti. After recession of the superior rectus there would be an increased deviation both in adduction and in abduction. Still more unsatisfactory is the effect of the recession of the superior rectus on the rotation of the eyes. Both the superior oblique and the superior rectus rotate inward, and consequently weakening of the superior rectus will increase the disclination. Advancing the inferior oblique (advocated by Landolt) would likewise cause a more pronounced disclination, and would improve parallelism only in the lower part of the field, but not in the center, as this muscle is inadequate in the nasal quadrant of the lower half of the field of fixation.

Best results show recession of the inferior rectus of the contralateral eye. This equalizes the function of the associated depressor muscles in the two eyes. If a tenotomy is performed there may be an overcorrection in looking down, but a recession can graduate the weakening of the inferior rectus so that no such results will ensue. It should be remembered that the left superior oblique and the right inferior rectus are associated in depressing and turning the eyes to the right. The left superior rectus turns the upper part of the cornea toward the right of the patient (internal rotation) and the right inferior rectus turns the upper part of the cornea to the right too (external rotation). If the left superior oblique is paretic the upper part of the cornea in the left eye will move to the left (outward). By receding the inferior rectus of the right eye the muscle is weakened and consequently the upper part of the cornea will be turned to the left (inward). Thus the vertical lateral and rotating elements will have been corrected.

Paralysis of the rectus internus. References to surgical treatment of paralysis of the adducting rectus are rather scanty in the literature. Shortening of the rectus internus and simultaneous recession of the rectus externus are generally advocated. Both Jackson and Peter (54) dissect the internal halves of the superior and inferior recti and transplant them to the point of insertion of

the rectus internus. Several cases have been reported, mentioning good results, of the transplantation of the superior oblique to the point of attachment of the rectus internus (Wegener), shortening of the rectus internus and recession of the antagonist being performed at the same time.

Paralysis of the rectus superior. An advancement or shortening of the superior rectus has been advocated. O'Connor's cinch operation after tenotomy of contralateral inferior oblique, if this proves insufficient, has been used for that purpose. Peter advances the rectus superior and transplants the upper halves of the tendons of the rectus externus and rectus internus to the new point of attachment of the superior rectus. An advancement attaching the tendon a few millimeters temporal to its previous attachment has been mentioned by Peter too (54). When there is an overaction of the inferior oblique of the contralateral eye, this muscle should be operated on, either by receding it, according to Rugg Gunn's method, whereby it is reattached to the periosteum about 6 millimeters from its normal insertion, or by a simple tenotomy.

White (77) favors a careful myotomy of the inferior oblique of the contralateral eye and, if this proves insufficient (Gifford, 27), an advancement and resection of the paralyzed muscle. In cases in which even the combination of these two methods is not able to correct the deviation, a recession of the rectus inferior on the paralytic eye should be resorted to. Both Dunnington and White (79) agree about the choice method being either the advancement of the rectus superior or a tenotomy of the inferior oblique of the contralateral eye. When the paralytic eye is used for fixation, there is an overaction of the synergical muscle of the other eye, and tenotomy of the contralateral inferior oblique is to be favored, and, conversely, when the good eye is used for fixation and no such overaction exists, an advancement of the paralyzed superior rectus should be performed. Operations on the superior rectus have the disadvantage of causing a disturbance of the movements of the upper lid and diplopia in the lower field of fixation.

Paralysis of the rectus inferior. An advancement with resection of the paralyzed muscle seems to be the method of choice. If there is an overaction of the superior oblique, a recession of the trochlear of the contralateral eye has been suggested (Berens), and if there is a spasm of the direct antagonist, a recession of the superior rectus. Wiener suggested severing the inferior oblique close to the sclera, reattaching it nasalward from the attachment of the inferior rectus. Casten

Fig. 5. Gussen's muscle speculum.

is welcomed as a blessing by the majority of patients. This fact, recently emphasized by Gifford (27) shows the importance of the surgical treatment of paralytic strabismus. The knowledge of conditions of binocular vision before the onset of paralysis is essential for the choice of the surgical method in each case, and the use of prisms after the operation in order to correct small defects and enable simultaneous macular perception is of equal importance.

An accurate diagnosis of the nature of each paralysis, including a minute investigation of the functional condition of each muscle and of the synergic action of all muscles involved in the movement of the eyes in the several directions in the field of fixation, is of paramount importance for the choice of the surgical method in each case. According to Bielschowsky especially in the case of vertical deviations, the following questions must be answered before a decision is made as to if and how any kind of paralytic strabismus may be surgically corrected: (1) Does the vertical deviation increase in looking up, or in looking down? (2) Is it different in the right and left halves of the field of fixation? (3) Are the double images of contours parallel in the whole field of fixation, or only in a certain part, being inclined toward each other in the other part? (4) Does the tilting of the head around the sagittal axis without changing the direction of the visual lines influence the magnitude of the vertical and the meridional deviation, and, if so, in what manner? The answers to these questions will enable one not only to differentiate between a true paralytic strabismus and a nonparalytic heterophoria but also to discover which muscles are involved—whether those which are paralyzed or those which have developed an overaction due to secondary contracture.

The surgical treatment of paralytic strabismus should be resorted to only after 6 months have elapsed after the inception of the paralysis with-

out any signs of recovery (Bielschowsky), but afterward early treatment is advisable in order to avoid contractures of the antagonist.

The operative treatment should be directed, whenever possible toward increasing the efficiency of the paralyzed muscle as it should be remembered that, according to Serrington's demonstration in 1893, the lengthening of an antagonistic muscle under normal conditions should not be regarded as a passive stretching produced by the contraction of the agonist, but is really due to an active relaxation that takes place even if the agonist does not function at all. It is now recognized therefore, that it is not possible to improve the function of a paralyzed ocular muscle by means of weakening its antagonist alone. On the other hand, Landolt's assumption that when shortening of the paralyzed muscle proved inefficient the contralateral homonymous status of the shortened muscle in one eye should be strengthened too, does not stand good any more in cases of long standing paralytic deviation with secondary contractures. Landolt very rightly opposed tenotomies and that is possibly the explanation for his policy. Recessions, however not bringing about the poor results of simple tenotomies, enable us to increase the effect of the shortening operation on the paralytic muscle by relaxation of the pull of the antagonist. In some types of paralytic strabismus strengthening of the paralyzed muscle is technically difficult and weakening of the direct antagonist is not enough or may even have a somewhat unexpected result, due to an overaction of contralateral muscles of synergical action to the paralyzed muscle.

Especially in cases of paretic vertical muscles there are other factors to be taken into consideration whenever parallelism of the eyes is to be re-established in the largest possible area of the field of fixation by means of an operation. Thus not only the overaction of the contralateral associate has to be considered as moving the eye vertically but its adduction or abduction and especially its convergence or declination are of great importance.

As an example of the complexity of matters regarding paretic vertical muscles Bielschowsky discusses the subject of inveterate trochlear palsy. As the strengthening of the paretic muscle is difficult, there might be a possibility of improvement of the vertical deviation by the weakening of the rectus superior of the paretic eye. But this would be only in a very limited area of the field of fixation, the effect of this operation being less in the lower part of the field—where the vertical defect had been greater before—whereas in the

The method advocated by Landolt, of advancing the inferior rectus, has been equally abandoned. Wheeler devised an operation to shorten the paralyzed superior oblique, but its technique seems rather difficult and its use has been discouraged (Peter, 54). Aurand dissected strips of the external and inferior recti and attached them to the sclera at a distance of 3 millimeters from the limbus at the 7 30 meridian.

Paralysis of the inferior oblique An advancement operation for the inferior oblique has been described by Wheeler. The muscle is detached from the orbit, pulled out, and sutured to the cheek bone. Recession of the superior rectus of the contralateral eye has been advocated by White and Berens.

Bilateral paralysis of homonymous muscles Handling of bilateral paralysis of homonymous muscles is rather difficult. According to what has been published so far (White, 78), bilateral paralysis of the rectus superior, when it is predominant in one eye, calls for tenotomy of the inferior oblique on the less paretic eye, and according to the result shortening of the superior rectus of the lower eye or tenotomy of the inferior oblique of the other eye. When the patient uses constantly only one eye for fixation (generally it is the more paretic eye), the external rectus of the deviated eye should be operated on by performing an advancement or recession according to the lateral deviation in each case and a tenotomy of the inferior oblique. When one or the other eye is alternately used, bilateral tenotomy of the inferior obliques and in mild cases bilateral shortening of the superior recti should be performed. Whenever bilateral paralysis of the superior recti is almost complete, care should be taken not to touch the inferior obliques, in order not to weaken the elevators entirely.

For bilateral trochlear paralysis Jaensch prescribes recession of the inferior rectus on one eye followed by a similar recession on the other eye if necessary, the second operation depending upon the results obtained in the first.

ANESTHESIA

As in other branches of surgery, the latest developments of anesthesia have done much toward improvement of surgical treatment. Possibly the favor enjoyed by the simpler and cruder methods, the results of which were so unsatisfactory, was chiefly due to the lack of proper methods of anesthesia. There is no doubt about the influence of anesthesia on the opinion of many ophthalmologists as to the minimum age at which to operate on a child with strabismus. General anesthesia

was not favored in the older days because during the operation the deviation could not be seen, it was claimed, and consequently the surgeon had nothing to gauge the operation by. Lately however, as has been pointed out by Dunnington, accurate preoperative examination of the patient permits establishing a definite plan beforehand.

Peter (55) favors general anesthesia in all cases, as he believes that local anesthesia is always responsible for some degree of edema which may cause important landmarks to become obscured. Anyway for children under 12 and for those adults whose temperament or disposition prevent them from being co-operative with the operator, general anesthesia is essential.

For general anesthesia the use of ether, vinylene, diethyl ether, nitrogen peroxide, ethylene, cyclopropane (the two latter are inflammable) has been advocated. Magill's tracheal tube should always be used in order to keep the operative field unobtruded (Prangen, 58). Morphine sulfate 0.01 gram and atropine sulfate 0.0004 gram hypodermically, should be given about 30 minutes before general anesthesia.

Evipal, pentothal, and avertin are very useful too, but in most instances a small amount of ether will have to be added. Barbiturates are generally used as preoperative sedatives the night before, and on the morning of the operation both for general and for local anesthesia.

When local anesthesia is used, instillation of anesthetic drops, the gauze pack (Meller), and injection into the muscle sheaths will be found insufficient, and block anesthesia will have to be resorted to. But as it has been pointed out (Weill, Bressler) local anesthesia is unsatisfactory in many cases, especially in the case of undue traction of the muscles and tendons with the hook. The combination of local and general anesthesia has been favored too, with the purpose of reducing the amount of general anesthetic which will be necessary for the operation.

INSTRUMENTS

Many instruments have been built for the particular purpose of rendering one or more phases of a certain type of operation easier, and each operator becomes attached to the type of instruments he is used to. Lately new instruments have been perfected, and the use of others introduced. Thus, Spaeth (65) emphasizes the importance of the lids of the speculum covering the cilia to prevent tiny clippings falling into the wound. For the same purpose Durr uses a sterile rubber sheet in which he makes a slit to insert the speculum, the rubber tissue covering the eyelashes completely.

reported good results in a case of congenital absence of the inferior rectus, after having transplanted the external rectus to a spot midway between its former attachment and the insertion of the inferior rectus. Extension and depression of the eyeball were thereby achieved. Casten advocated simultaneous tenotomy of the inferior oblique if found necessary. Peter advocated the advancement of the inferior rectus attaching it a few millimeters temporward (and obviously nearer to the limbus) from its former attachment. Bartels, in a case of absence of the inferior rectus and fibrous band of the superior rectus, tenotomized the latter and pulled the eye down with sutures on the limbal conjunctiva tied on the skin of the lower lid.

Paralysis of the rectus externus. This appears to be one of the most common kinds of paralytic strabismus. Advancement or shortening of the external rectus and recessions of the internal rectus have been advocated.

A simple tenotomy of the internal rectus combined with special stitches meant to pull the eye toward abduction has been described by Vogt. The Hummelshelm type of operation with several improvements in its technique has been favored lately by Gifford (28) Bellav-Goodman, Lancaster, Alvaro (1) and several others, with fairly good results. Gifford reports abductions of 5 to 35 degrees after the operation. O'Connor instead of using the external halves of the superior and inferior recti, transplants the internal halves. Wiener prefers to sever the rectus externus 15 millimeters from the sclera, split the scleral part in two horizontal halves, and transplant the superior and inferior to the superior and inferior recti.

There is some controversy regarding the way in which the Hummelshelm type of operation works. Some as Bielachowsky and White (79) believe that results are due mostly to the recession of the overactive rectus internus and White is rather conservative about disturbing the vertical balance although Gifford (7) has never noticed any change in vertical balance after operations of this type. Spaeth (64) mentioned the results of experimental work done at the Graduate Hospital in Philadelphia according to which the action of the muscular slips is merely that of stays, thus permitting the tension of the other abductor muscles to act whenever reciprocal relaxation of the abductors occurs. Meyer using indiscriminately the nasal or temporal strips of the superior and inferior recti, stresses the importance of careful dissection in order to prevent too much pull on the sutures. Worth-Chavasse still favors bilateral

recession of the internal recti, but that method does not seem to be favored by the majority any longer. Apple calls attention to the fibrous tracts appearing under the contracted internal rectus, which have to be severed in order to get good results.

Paralysis of the superior oblique. Next to abducens paralysis this is the most common of ocular muscle paralysis. Bielachowsky calls attention to the fact that trochlear paralysis has become more common in the last 30 years and explains this by the more frequent operations of the Millian type in which the trochlea is easily loosened. Paralysis of the superior oblique causes some form of torticollis, and therefore an early operation is advisable especially in children.

Von Graefe and Alfred Graefe quite a long time ago had devised a surgical treatment for trochlear paralysis which was abandoned for many years and has now found general favor again, namely tenotomy (now substituted by recession) of the inferior rectus of the contralateral eye. With this method, as it was recently mentioned by Berens, Dunnington, McMillen, White, Arganaraz, Marx, and Plocus, results are quite good, although the patient looks down, the paretic eye is too high, and conversely too low when the patient looks down and away as it was mentioned recently by Messmann. Recession of the inferior recti has the disadvantage in many cases of causing a certain degree of ptosis of the lower lid. In order to prevent this, a careful suture of the conjunctival wound is essential. Bielachowsky prefers not to do the sutures of the receded tendon, in order to be able to tighten or loosen them according to results obtained in the next few days.

Tenotomy of the inferior oblique of the same eye is favored too (Morgan) and, according to Spaeth, Duane and Bielachowsky it should be used chiefly when there is an associated exophoria. The method formerly described of recession of the inferior rectus of the contralateral eye, is the method of choice when there is esophoria. White favors operating on the contralateral inferior rectus first, and then, if necessary, on the inferior oblique. Gifford, on the other hand, prefers to operate on the inferior oblique first. Dunnington, Messmann, Bornott, and others favor tenotomy of the inferior oblique only when there is a strong secondary contracture.

Jackson's method of transplantation of the superior rectus was recently favored by Vasquez Barriere and Savin still favors the method, now generally abandoned of recession of the superior rectus.

For measurements of the number of millimeters in advancement, shortening resection or recession operations, Berens built a special caliper on which the distance between the two points is easily readable, and Green described another model one point of which is very thin and guarded in order to enable easy fixation with little traumatism and no danger of perforation the other blade-like end of the instrument being meant for marking the sclera with gentian violet or fuchsin.

Tendon spreaders taking the place of the two books to be held by an assistant were built by Wursch in Berlin and by Grieshaber in Switzerland after the patterns of Streiff and Schweigger-Gutzeit respectively. Similar to these tendon speculums is the bodkin described by Lodge made of thicker stainless steel wire. The handle and the hook with its terminal eye are ground to the original gauge but the middle third is forged into a grooved director curved on the flat. The bodkin is meant to put the extraocular muscle at rest and render it more accessible to sutures.

SUTURES

A rather large number of methods for the operative treatment of strabismus have been devised just because the existing sutures were found to be unsatisfactory. Lancaster back in 1901 showed, by his experimental work, exactly how much tension was necessary to pull the simple sutures which were used in those days through the muscle fibers, and the results were not very encouraging. Since then several more reliable types of sutures have been described such as the stitches zigzagging through the muscle (Lancaster Thompson) Ziegler's "whipstitch," and the mattress suture.

By means of a double armed thread a great number of suture may be made with but one thread according to Jameson all other things being equal it is best to be able to bring about the apposition of all the tissues with one single suture. Fanlike spreading of the tendon on the sclera, however, is essential, and care must be taken that the sutures keep the tendon in proper position. Strangulation of all the muscular fibers should be avoided by all means, and for that purpose the central part of the muscle should be left free of sutures (Lancaster). The violation of this principle is responsible for many bad results, which change a tacking operation into a tenotomy the adhesions of the muscle and the capsule to the sclera at a point where the sutures rest on the sclera, being responsible for a less catastrophic result and for the still disappointing *status quo* (Spaeth 63). The careful handling of the muscles is just as necessary and forceps should be

applied only on those parts which are intended for resection.

The fact that silk could be used without any misgivings in buried sutures (Lancaster) made silk sutures more and more popular in the early thirties. Lately however, improvements in catgut, rendering it more reliable as to sterility and endurance (10 or more days without resorption and causing little reaction) and the appearance of atraumatic needles have turned the tide so that today catgut is gaining more in favor. Generally No. 000 catgut is used for resections and advancements and No. 00000 for recession and conjunctival sutures (Prangen, 58).

According to Muegge silk should be waxed before it is used (7 parts of yellow beeswax, 1 part of almond oil, 1 part of salicylic acid—Peter, 55). For advancements on the lateral muscles twisted silk No. 4 or braided silk No. 1 should be used, for the vertical recti, twisted silk No. 3 and for conjunctival sutures, twisted silk No. 1 (Peter 55).

Scleral sutures have become commonplace, and scleral perforations formerly a formidable occurrence are really rare (Butler).

SUMMARY AND CONCLUSIONS

The large number of operative methods and the almost infinite variations of sutures are an indication that, as it has been stated by C. Maynard Wheeler "There is no unanimity of opinion as to the proper handling of strabismus. Comparably favorable end-results can be achieved by several methods. The procedure of choice for any surgeon is the one with which he is most familiar and in the performance of which he is most skillful, provided of course the right type of operation for each case has been carefully chosen.

Regarding immediate postoperative dressing there appears to be some slight individual variation. Binocular occlusion for at least 1 to 7 days is almost generally accepted. Barraquer's occlusion bandage seems to be most comfortable to the patient.

Complications are rare. Butler in 30 years lost only one eye, due to panophthalmitis, because of infected catgut, and Kiehle and Henton in 156 operative cases had only one eye complicated with uveitis. Against local reactions, foreign protein has been advocated (Spaeth, 64) and recently sulfanilamide has given good results when administered orally and locally. The local use is conditioned by its solubility so that enough concentrated solutions can be used. For that purpose sodium-sulfanilacetylthylamide of which 30 per cent solutions can be easily obtained shows good results.

DEFENSE NEEDS SUGGEST TIMELINESS OF COLLEGE PROGRAM FOR GRADUATE TRAINING IN SURGERY

DANIEL B. PHILMISTER, M.D., F.A.C.S., Chicago, Illinois

At the third Annual Conference in 1931, the idea of forming the American College of Surgeons as a coordinating organization is rather typical of the members of the College at that time. As it represents high moral and ethical standards as well as professional qualifications in the profession. That purpose, therefore, is to help the surgeon and surgeon's education in the development of the College. Adaptation and enlargement of its program to meet the current needs have resulted for this organization its present student have position in directing the advancement of the art and science of surgery through its new standards of surgical education and practice.

At the present time, the activity that best explains the "outward" or "outer" "upward" tendency of the College is the program of graduate training in surgery. It has developed quite naturally in connection with Hospital Study direction. The stimulation that it is giving to the creation of more opportunities in the approved hospitals for surgical education is helping to secure our military forces policy of surgical service of high quality. It is also aiding our general population to continue having adequate service in civilian hospitals notwithstanding the enlistment of many surgeons in the Army and the Navy. The need for national defense, that includes health defense as a primary requisite, suggests the timeliness of increased effort by the College to provide additional opportunities for adequate training in surgery.

Interruption of training due to enlistment in military service is a problem that existing conditions present. We can ill afford to curtail training for surgery at a time when we urgently need more and better trained surgeons. As a partial solution, certain of the larger general hospitals of the Army and the Navy will probably arrange to provide opportunities for certain junior medical officers to continue their training in these institutions when it is interrupted by enlistment. For those exceptionally well qualified whose training could not be pursued in military hospitals, perhaps comp-

Chairman of the Committee on Graduate Training in Surgery.

tion or deferment from military service will be obtained. It was the consensus of the Committee on Graduate Training in Surgery held during the 1931 Annual Conference that in the ensuing year considerable effort should be devoted to the formulation of a definite plan for the solution of this problem. Each recent graduate of medicine has now completed his internship and now having an opportunity in a hospital approved for graduate training in surgery should be permitted to continue his training, if possible, without interruption. The American College of Surgeons can advise the War and Navy Departments that thousands of service to hospital patients are already available when the institution utilizes its resources for professional education. The atmosphere immediately becomes more scientific and more progressive and this reacts to the good of the patient. Difficulties encountered in providing advanced study of the basic medical sciences and research will no doubt be surmounted with the cooperation which may be expected of the medical schools and civilian hospitals. However, the needs of our military forces must be met and under the present world conditions some of our most desirable and ambitious plans may have to be changed.

As for the status of the program in general, it was announced at the 1931 Congress that 216 hospitals, 16 more than the previous year have acceptable programs for training in general surgery and/or the surgical specialties. Undergraduate teaching is being done in 143 of these approved hospitals. Connections with a medical school provide certain phases of the graduate teaching program in 158 of the institutions approved. Of particular interest is the fact that 31 hospitals without medical school connections are now utilizing their own facilities sufficiently to be included on the approved list. The College recognizes the educational opportunities existing in certain group clinics. Eight of these organizations are included in the present approved list and more are expected to be added from time to time as they develop sufficiently comprehensive programs. As proof that opportunities may be created in different types of hospitals, the 1931 report shows that 109 of the hospitals approved

the standards of the practice of surgery recognizes the stimulation to the younger surgeons which is promoted by the holding of a symposium on Fundamental Surgical Problems in connection with each Clinical Congress. Those who conceived and developed this idea which proved such a popular feature of the Boston meeting are to be congratulated and there is every reason for its repetition. This creation of opportunities to communicate the results of research will focus more interest on the basic science and research aspects of the graduate training program of the College.

In the October 1941 issue of the *College Bulletin* there were published revised and additional descriptions of approved plans for graduate training in general surgery and the surgical specialties. It was felt that the republication of these plans was justified by the changes wrought in the preceding year and by the intensification of interest in surgical training as a result of the national defense effort. The up-to-date published outlines of these educational programs provide information for the medical student and intern and also an easy method of comparison between institutions. If thereby a wholesome spirit of rivalry is engendered which will lead to the improvement of some of the plans and the inauguration of additional ones, one of the primary purposes of republication will have been accomplished.

The national emergency is placing obvious difficulties in the way of progress, but despite these difficulties the prospects are good for making 1942 significant year in the annals of surgical education. It is fortunate that the graduate training program is already so far advanced that it can prove its benefits in these critical times when the country is dependent to a greater extent than ever before upon competent surgeons for both military and civilian service.

assistant was in military service. They reported that the obtaining of adequate medical records was seriously affected by the shortage of internes and residents, and that maintaining adequate nursing service was threatened by the decrease in nursing personnel in many hospitals.

These conditions have interfered considerably in carrying out some of the requirements of Hospital Standardization, but field representatives found that in most instances adjustments were being made to continue to meet the standards. On the whole the performance was remarkably good and augurs well for a creditable war time record. The incentive supplied by the desire for approval by the College promises to be exceedingly helpful in maintaining the quality of hospital service. Administrators say that the public is becoming better informed on ratings of hospitals, and prospective patients frequently ask whether the hospitals in their community are approved. A further factor spurring hospitals to seek and hold approval is the stipulation by many agencies that patronage or aid go only to approved institutions. This is true of state county and city governments which subsidize hospitals for the care of indigent patients of group hospital service plans of chambers of commerce in endorsing campaigns for funds by local hospitals, of insurance companies when they grant reduced rates on liability insurance of banks and finance companies in making loans to hospitals of state boards of nursing education in accrediting schools of nursing of hospitals accepting affiliate students for special courses in nursing of the American Red Cross in its extension program of volunteer workers and of federal and state governmental departments charged with the granting of funds for indigent crippled children's care. It will doubtless also apply to aid extended by the federal government for financing additions to physical plants and for meeting the expense of training certain types of personnel. All of these agencies show by their use of it that the gauge of approval is a valued help to them in determining which hospitals merit their assistance.

In the first World War the War Department lacked reliable means of judging the competence of physicians, particularly specialists consequently many men were misplaced—as one surgeon expressed it, there were numerous round pegs in square holes. Now that hospitals are standardized, and their medical staffs are organ-

ized, it should be possible to ascertain directly from his hospital what standing the individual physician has in medicine, surgery or a specialty. The College and other medical organizations also now have complete information concerning their members. It is essential that during the war period the requirements of the College concerning appointments to, and organization and control of, the medical staff be met as usual, with a minimum of tolerance of practice outside the designated field in case of necessity only.

An interesting feature of the 1941 Hospital Standardization Conference was a series of panel discussions on the obstetrical department, the department of orthopedic surgery, the department of anesthesiology, the department of ophthalmology and otolaryngology and the department of urology, respectively. The discussion covered the essentials pertaining to efficient operation of these departments, and included consideration of education and training of the various specialists.

The 1941 list of approved hospitals, as announced at the Hospital Standardization Conference showed 2,526 institutions fully approved, 347 provisionally approved, a total of 2,873. The total number of hospitals under survey in 1941 was 3,688, of which 77.9 per cent were approved. With the country at war, it is especially encouraging to have so many military and civilian hospitals which are organized and equipped to afford the physician the greatest possible assistance in his endeavor to save life and minimize suffering and disability from illness and injury. This year it is planned to promote the standardization of those Army hospitals which have not been approved, owing to the fact that it has not yet been possible to survey them. Last fall in continental United States there were 218 Army hospitals with a total bed capacity of 79,019, which is rapidly growing.

The need now is to view our hospital situation as a whole, with due consideration for safeguarding both military personnel and civilians. We face total war which means total hospital service. Our 24 years work in active encouragement of the improvement of hospitals is yielding high returns today in preparedness to meet the needs of America at war. Unrelaxing effort to keep the standards high will bring us through the conflict with a brilliant record of service by our great modern hospitals and the personnel that they have trained.

THE SUPERIORITY OF FINE CATGUT OVER FINE SILK AS A MUCOSAL SUTURE IN GASTRIC SURGERY

JOHN O BOWER, M D , F A C S , and A E PEARCE, M D , Philadelphia, Pennsylvania

WHILE investigating the tissue reaction of various suture materials in abdominal surgery performed on animals, we were impressed by an outstanding and constant feature the sloughing of silk through the gastric mucosa when this material was used in surgery of the stomach. This was indicated by the presence of long, redundant, intraluminal loops of silk with areas of necrosis at their points of entrance and exit, as well as between them. Further, the presence of these loops has been noted gastroscopically by Schindler, as well as by us, in humans after gastric surgery in which silk was used as the suture material. In all instances when fine catgut was used, there was a minimal mucosal reaction and at no time were loose strands noted in the gastric lumen.

SUTURE MATERIALS

The argument concerning the use of catgut or silk for ligatures and wound closure has continued since 1869 when Lister noted a localized collection of cloudy fluid about a silk ligature which had been used for ligation of an aneurysm 10 months before. Kocher (7, 8) and Halsted, in the early days of aseptic

surgery, and Howes (4), Howes, Sooy and Harvey (6), Whipple, Elkins, in recent years, have championed the cause of silk.

Halsted stated

"Let the surgeon interested in making the comparison, take a running subcuticular stitch on the one side with catgut, on the other side with fine silk (No. A or AA) and observe the healing wounds from day to day. There is not only greater local reaction in the cases sewed with catgut, but in them the wounds will occasionally open at one or more points to discharge a few drops of clear or cloudy fluid."

It is noteworthy that Halsted did not mention the size of catgut. At that time (1913), Nos. 1, 2, and 3 catgut were the sizes most generally used, and, in 1914, Phillips speaks of No. 00 as the smallest size. In fact, No. 000 catgut which corresponds in size to No. A silk was not available until several years later. The present fine gauge catgut, including No. 0000 and No. 00000 which have diameters closely approximating that of No. AA silk, was placed on the market only in recent years. Therefore, Halsted's comparison was not a fair one, because in his time he did not have available sizes of catgut sutures as fine as the sizes of silk which he was using. It seems obvious that Halsted's superior results with fine silk as compared with those which he obtained with catgut were due to the fact that he used much smaller sizes of silk which, in

95 per cent) resorption of the petechial hemorrhages. One redundant loop is present, probably due to poor technique in the operation, because the mucosa is perfectly clean and healthy at the point of entrance and exit of the loop. In the silk specimen much of the traumatic hemorrhage is still present and 4 loops with early redundancy are seen. The wound shows more edema.

Four days. In the catgut specimen, the wound is clean with little evidence of edema or petechial hemorrhage. The silk wound has much edema, petechial hemorrhage, and many long redundant loops with evidence of mucosal sloughing from pressure necrosis at their points of entrance and exit.

Five days. The No 00000 wound is perfectly clean with four small redundant loops

whose points of entrance and exit show no evidence of necrosis. The No 0000 silk wound shows much delayed healing, delayed petechial resorption, much edema, 12 redundant loops with surrounding tissue necrosis.

Seven days. The catgut wound is perfectly healed with almost no evidence of the suture line in 60 per cent of its circumference (Fig 3). The silk wound is fairly clean with a few areas of necrosis still present but edema still notable. Many long redundant loops are present, undoubtedly these must have sloughed through their original entrance areas to have become so long (Fig 4).

Ten days. The catgut wound is healed—perfectly clean (Fig 5). The silk wound still shows areas of necrosis along the suture line, and redundant loops are present (Fig 6).

themselves, tended to provoke less of a foreign body reaction. Further the use of larger needles with larger sutures produces greater trauma and dead space which add to the insult to the tissues and invoke heavier inflammatory response.

We have repeatedly observed that tissue reaction to catgut is proportional to the size of the suture. When fine catgut is used, there is less tissue trauma from the suture itself and from its transit. Apposition is more nearly perfect since more stitches may be placed in given space lessening the possibility of dead space. These observations have been reported by Bower Burns and Mengle.

EXPERIMENTAL INVESTIGATIONS

In order to evaluate our observations concerning the behavior of catgut and silk as mucosal sutures, the following experiments were carried out.

Operation. A vertical bisection of the stomach of each of 14 dogs was made and the continuity of the organ re-established by using two rows of continuous sutures. The operating team used the identical technique on each dog. All animals had been on the same diet for 1 week and each weighed approximately 12 kilograms. Under morphine and atropine sedation and open drop ether anesthetic technique being used, an upper left chus incision was made. Bisection was accomplished on a line drawn from the anastomosis of the left and right gastric arteries on the lesser curvature to the anastomosis of the left and right gastropiploic arteries on the greater curvature. The lesser peritoneal cavity was entered by ligating the gastropiploic vessels approximately 1 centimeter to either side of the elective site. The stomach was then gently pulled down and ligation was performed on the gastric arteries of the lesser curvature, 1 centimeter to either side of the proposed bisection site. In this manner a minimal and constant diversion of blood flow was induced. The stomach was divided between two straight rubber clamps with fine right scissors. The bisection was closed with two layers of continuous, running sutures of catgut or silk in the posterior and anterior wall. The first suture line included the

serosa and muscularis, while the second included the mucosa and submucosa. Then the clamps were removed and the abdomen was closed in layers with continuous linen sutures. Animals were operated on in pairs; chromic catgut was used for the stomach sutures in one and black silk in the other of each pair.

Suture material. In order to eliminate the size of the suture as a possible factor in causing tissue reaction we decided to employ identical sizes of absorbable and nonabsorbable suture materials. We selected No. 00000 black silk which gauged 0.006 inch in diameter because this size corresponds to No. AA silk as used by Halsted. For the absorbable suture we chose medium chromic catgut having an average diameter of 0.006 inch which thus was the equivalent in bulk of the silk. This suture material is designated No. 00000 catgut.

The No. 00000 chromic catgut was more easily handled. It has more body than silk and does not cling to gloves or tissues. However the No. 00000 silk presented no real difficulty. Neither suture broke at any time during the experiments.

Postoperative care. The postoperative management was the same in all cases: small amounts of water on the second day, milk on the third day, milk and bread the fourth day, and unrestricted diet on the fifth day. All animals recovered and all wounds healed by primary intention.

Pathological specimens. Stomach specimens of each series were taken at 2, 3, 4, 5, 7, 10, and 14 day intervals. Colored photographs of the mucosal suture lines were made in each instance within an hour. Histological sections were made of each specimen.

Gross appearance. Two days. Both specimens show the same amount of traumatic petechial hemorrhage along the suture line due to the use of forceps and the needle transit. The No. 00000 catgut line is cleaner (Fig. 1). The No. 00000 silk shows two necrotic areas, one 0.5 centimeter and one 0.8 centimeter in length in the lower half of the specimen. In 6 areas, beginning redundancy of the silk loops is present due to sloughing through the mucosa (Fig. 2).

Three days. No. 00000 presents a very clean wound with almost complete (at least

Fig 13

Fig 16

Certain it is that the use of a continuous mucosal suture of silk stands contradictory to some of Halsted's five tenets first stressed in 1913

"(1) Use transfixion ligature, as finer material can be used by such a method, (2) use silk not coarser than No C, (3) use interrupted sutures, (4) use a greater number of fine stitches rather than a few coarse ones, and (5) avoid the combined use of silk and catgut"

Moreover, Halsted emphasized the use of silk in clean wounds, which is an impossibility in the alimentary mucous membrane

We have demonstrated that, when fine silk sutures are used, gross tissue necrosis is present in the mucous membrane long after the healing process has subsided in the wounds sutured with fine chromic catgut. It

is obvious, therefore, that there is more danger of intramural infection from the contaminating contents of the gastrointestinal tract when silk is used. The ideal suture material for the mucous membrane is one that seals it as quickly as possible and permits it to remain sealed. Bower, Burns, and Mengle showed that divided capillaries inoscuate as early as 4 days after suture of previously divided gastric mucous membrane of young dogs. Absorbable fine chromic catgut is superior to nonabsorbable fine silk in this respect.

CONCLUSIONS

1. Fine chromic catgut is more easily handled than silk of the same caliber.

2. The tissue reaction to fine silk in the mucosa resembles the reaction toward a

Moreover, Halsted emphasized the use of silk in clean wounds, which is an impossibility in the alimentary mucous membrane

We have demonstrated that, when fine silk sutures are used, gross tissue necrosis is present in the mucous membrane long after the healing process has subsided in the wounds sutured with fine chromic catgut. It

is obvious, therefore, that there is more danger of intramural infection from the contaminating contents of the gastrointestinal tract when silk is used. The ideal suture material for the mucous membrane is one that seals it as quickly as possible and permits it to remain sealed. Bower, Burns, and Mengle showed that divided capillaries inosculate as early as 4 days after suture of previously divided gastric mucous membrane of young dogs. Absorbable fine chromic catgut is superior to nonabsorbable fine silk in this respect.

CONCLUSIONS

1. Fine chromic catgut is more easily handled than silk of the same caliber.
2. The tissue reaction to fine silk in the mucosa resembles the reaction toward a

markedly foreign irritant. It is especially noticeable after 2 or 3 days when the unabsorbed silk produces pressure necrosis with sloughing of the mucous membrane.

3. Wound healing of the mucosa is more rapid when fine chromic catgut is used.

4. Fine absorbable catgut, designated No 00000 medium chromic, having an average diameter of 0.006 inch, has been shown to be superior to fine nonabsorbable black silk of equivalent size (No 00000 diameter 0.006 inch) as a suture material for the mucous membrane of the stomach because the silk produces pressure necrosis at the site of insertion with subsequent sloughing—as shown by redundant intraluminal loops.

ARTERIOGRAPHY OF ABDOMINAL ORGANS BY AORTIC INJECTION

A Preliminary Report

O. A. NELSON, M.D., F.A.C.S., Seattle, Washington

IN this communication we shall deal with our experiences in making 73 renoabdominal arteriograms—roentgenologic delineations of the renal and abdominal arteries after aortic injection of a radio-opaque medium. By visualizing the arteries and thus tracing the blood supply, we demonstrate the location and size of the organs.

Information thus obtained is of great aid in the diagnosis of certain abdominal masses and tumors. Our arteriograms show that an abnormal contour or caliber of the arteries is concomitant with certain diseases of the arterial tree or organs. Sometimes the arteries of an organ containing a tumor or an inflammatory process are of larger caliber than normal. On the contrary, when there is sclerosis or fibrosis of an organ, the caliber of its arteries is diminished. Tortuosity of the arteries usually means arteriosclerosis.

Further, in cases of duplication of the renal pelvis—when one unit is so diseased as to necessitate heminephrectomy—arteriography is of value, as it is also in certain cases of aberrant blood vessels in relation to hydronephrosis. Arterial aneurysms are readily visualized by this procedure.

The most striking results appear in arteriograms of vascular neoplasms of kidney or suprarenal gland, in such cases pooling of the opaque medium in the blood sinuses is shown and is pathognomonic of these tumors. In papillary tumors of the renal pelvis and in other renal tumors without blood sinuses, such pooling or laking of course does not occur.

Much of the pioneer work concerning arteriography by aortic injection was done by Santos, Lamas, and Caldas (28). They have performed more than 2,000 aortic punctures for arteriography, and many more to medicate the blood stream for various types of in-

fection. These clinicians have also done outstanding work in roentgenography of the peripheral arteries.

The literature contains many articles on the subject, of which only a few were accessible to us. Castellanos and Pereiras describe a method of obtaining roentgenograms of the cardiac chambers and thoracic aorta by injecting and reversing the stream in the humeral or brachial artery. These workers used a 50 per cent solution of perabrodil or thoro-trast, and contended that their procedure was not harmful to the intima of the arteries so injected.

As early as 1923, Berberich and Hirsch did cerebral arteriography by injecting 25 per cent solution of sodium iodide into the common carotid artery.

Arteriography of the extremities has been done with a varying degree of success. Allen and Camp (1, 2) believe that it is technically quite feasible but rarely indicated, and that in the majority of conditions of the extremities diagnosis can be made without resorting to arteriography.

TECHNIQUE

For clarity, we shall first describe the technique used, and then discuss the untoward reactions.

There are 3 important basic requirements for production of these grams: (1) the skiagraphic medium must be concentrated, (2) the injection must be completed within a few seconds, (3) the exposure of the film must be made the instant that the injection is completed.

Equipment. As injection of the opaque medium and exposure of the film must be well co-ordinated, the time element in exposure is very important. Hand-syringe injection is

FIG. 1. Pressure apparatus.

unsatisfactory, so the equipment includes a pressure apparatus for injection of the solution (Fig. 1). One also needs an 18 gauge needle about 12 centimeters long and a supply of opaque medium. We use 80 per cent solution of sodium iodide. The x ray machine should have potential power to deliver 500 milliamperes of current and the Bucky diaphragm must be of the high speed type so that exposure can be made within one fourth of a second.

In the main we have followed the technique devised and practiced by Santos and his co-workers.

Preparation of the patient. On the afternoon before the examination the patient is given 2 ounces of castor oil preferably in fruit juice with a little soda or 2 ounces of castor oil in root beer. Thereafter he is allowed only liquid nourishment containing a minimum amount of fruit juice and sugar.

It is well to make a trial film before the aortic puncture when the patient is supine to show whether the patient is in proper position and the x ray technique satisfactory.

When this has been established the patient is anesthetized we prefer pentothal sodium.

The aortic puncture. After anesthesia has advanced so that reflexes are abolished the left side of the back and lower chest are prepared by tincture of iodine and draped with sterile towels.

The aorta normally lies along the left border of the vertebral column. Therefore, if a needle is passed from the back close to and a few centimeters beyond the body of a lower thoracic vertebra, it will enter the aorta. Figure 2 illustrates aortic puncture.

For arteriography of the kidneys and upper abdomen the needle is passed through the skin below the twelfth rib and three finger breadths to the left of the spinous processes. It is then directed toward the body of the twelfth thoracic vertebra. As soon as that bone is encountered the point of the needle is deviated slightly laterally so as to pass over the vertebra. When that is accomplished, the stylet is removed, and the needle gradually advanced a few more centimeters. Entrance into the aorta is signaled by blood coming through the needle. The needle is then advanced 1 more centimeter.

After one has advanced the needle and still observes free flow of blood, he can be certain that the needle is well within the aorta.

Injection of contrast medium and exposure of film. When the needle has been adjusted the pressure apparatus containing the opaque medium is attached to it. As soon as the x ray technician is ready to make the exposure the outlet valve on the pressure apparatus is opened, and 8 or 10 cubic centimeters of the contrast solution is allowed to flow into the aorta. If the pressure is set at one atmosphere or higher it takes only a few seconds to inject 8 or 10 cubic centimeters of 80 per cent sodium iodide. It is our practice to signal the x ray technician to make the exposure just before the valve on the pressure apparatus is closed. After the film has been exposed, the pressure apparatus is detached from the needle and a few cubic centimeters of blood is allowed to run out. Then the needle is withdrawn.

At The Swedish Hospital Dr. Blake has devised a lead shield over the Bucky diaphragm

Fig 2 Aortic puncture

so that two films can be exposed at very short intervals. Such an arrangement gives us two chances to get a good film.

Although tourniquets on the thighs to constrict arterial flow at the time of injection are advised by Santos, we have not used them.

UNTOWARD REACTIONS AND COMPLICATIONS

Iodism. On first learning of this procedure, one is likely to believe it is beset with frequent and severe untoward reaction. The only complication we have encountered is acute iodism.

As the flow of blood is very rapid through the aorta and its abdominal branches, the sodium iodide solution must be rather concentrated to give visualization of the smaller arteries, and about 8 or 10 cubic centimeters of it must be used. Consequently, the dose of sodium iodide is rather large. Acute iodism occurred in 4 patients in our series, but in none were the symptoms alarming. In fact, we have seen more severe iodism following excretory pyelography with an organic iodide solution, than after arteriography with sodium iodide.

Santos contends—and we believe it a fact—that a person can tolerate much larger doses of iodide, if it is injected into the aorta and goes through the capillary bed, than if injected into the vein or taken orally. We have seen patients who could not tolerate 1 gram of sodium or potassium iodide after meals three times a day, who had no disturbance from 10 grams of sodium iodide given into the aorta.

We have tried to ascertain whether sodium iodide in the aorta causes irritation of the intima of the arteries. We have studied histologically the arteries of kidneys removed immediately after the injection, and also the arteries of those removed some days after arteriography. In none were we able to find any evidence of change in the intima or arterial wall from the sodium iodide.

We tried to use skiodan, and also 70 per cent diodrast, for contrast media, but the iodide content of these substances is too low to produce satisfactory pictures. Nevertheless some interesting films came out of that work. After injecting 70 per cent diodrast we

UNTOWARD REACTIONS AND COMPLICATIONS

Iodism. On first learning of this procedure, one is likely to believe it is beset with frequent and severe untoward reaction. The only complication we have encountered is acute iodism.

As the flow of blood is very rapid through the aorta and its abdominal branches, the sodium iodide solution must be rather concentrated to give visualization of the smaller arteries, and about 8 or 10 cubic centimeters of it must be used. Consequently, the dose of sodium iodide is rather large. Acute iodism occurred in 4 patients in our series, but in none were the symptoms alarming. In fact, we have seen more severe iodism following excretory pyelography with an organic iodide solution, than after arteriography with sodium iodide.

Santos contends—and we believe it a fact—that a person can tolerate much larger doses of iodide, if it is injected into the aorta and goes through the capillary bed, than if injected into the vein or taken orally. We have seen patients who could not tolerate 1 gram of sodium or potassium iodide after meals three times a day, who had no disturbance from 10 grams of sodium iodide given into the aorta.

We have tried to ascertain whether sodium iodide in the aorta causes irritation of the intima of the arteries. We have studied histologically the arteries of kidneys removed immediately after the injection, and also the arteries of those removed some days after arteriography. In none were we able to find any evidence of change in the intima or arterial wall from the sodium iodide.

We tried to use skiodan, and also 70 per cent diodrast, for contrast media, but the iodide content of these substances is too low to produce satisfactory pictures. Nevertheless some interesting films came out of that work. After injecting 70 per cent diodrast we

Fig. 3. Arteriogram of normal arterial tree. a, Aorta; b, splenic; c, gastrobepatic; d, renal; mesenteric, arteries.

Fig. 4. Pooling, x, of opaque medium outlines right renal tumor.

obtained marvellous excretory pyeloureterograms in patients whose renal function was too deficient to give satisfactory films after intravenous injection, and whose ureters could not be catheterized. Another type of interesting roentgenograms was developed in that some films show the outline of the renal parenchyma, making what we call renograms.

At present we have a biological chemist trying to ascertain the tolerance for sodium iodide injected into the aorta and the capillary bed, as compared with that when injected into the vein or taken by mouth.

We also have another chemist working on the problem of elimination of iodide through the kidneys after aortic injection, so that we may compare findings with iodide elimination after intravenous or oral administration.

While untoward reaction from the iodide has been neither severe nor frequent, it is to us the hazardous part of this procedure. We hope that in the near future a more satisfactory contrast medium will be found.

Injury to the aortic wall. Aortic puncture is not the formidable procedure it might seem. It should be remembered that the aorta has a thicker wall and will stand more trauma than any other blood vessel in the human body. It is a fact that in all the inadvertent aortic punctures made in attempting to produce splanchnic anesthesia complications are practically unknown. For a blowout or hematoma to occur from an aortic puncture the opening in the aortic wall must be large.

It goes without saying that anyone wishing to do an aortic puncture should familiarize himself very thoroughly with the anatomical parts involved, by doing several anatomical dissections. He should practice aortic puncture in the anatomical laboratory before puncturing the aorta in the living person. Santos advises against doing this on the dog, contending that it is not comparable to the human being as to arterial anatomy and physiology.

Extravasation of contrast solution. One complication that might seem dangerous is

Fig 5 Malignant tumor of right suprarenal gland. Note enlarged suprarenal artery, *a*, and pooling of medium *x*

Fig 6 Solitary cyst of left kidney. Note wide separation of spleen and kidney

extravasation of the opaque medium. But it has been found that 8 or 10 cubic centimeters of hypertonic sodium iodide solution is readily absorbed. Such an accident occurred twice in our early work. We now ascertain the position of the needle within the aorta before the injection is started. One of these accidents occurred in a patient suffering from melanotic sarcomatosis, who had a huge mass in the liver. He stated that there was no particular increase in the pain or backache after extravasation of 10 cubic centimeters of sodium iodide. The other patient was a woman in rather poor general condition. Because of her hirsutism and hypertension, an arteriogram was made to ascertain whether she had an adrenal tumor. After the periaortic injection, the right suprarenal gland was explored. At that operation the pleura was inadvertently opened. The patient suffered a massive collapse of the lung, and died on the third postoperative day. Postmortem examination

showed that massive collapse of the lung was the cause of death. There was a basophilic tumor of the pituitary gland. The tissue at the site at which the injection of iodide was made was red, but there was no evidence of necrosis.

It is not advisable to drain or explore, if periaortic injection occurs.

Our series of cases is yet too small to draw any definite conclusions. It is our impression that the procedure is valuable in certain diagnostic problems, and that it will yield information not obtainable by any other form of x-ray examination, nor even by surgical exploration, for even though a surgeon has a kidney in his hand, it is difficult at times for him to make a diagnosis with any degree of certainty.

The untoward reaction and suffering from arteriography of this type are usually less frequent and less severe than after retrograde pyelography.

Fig. 3. Arteriogram of normal arterial tree. Aorta, splenic, gastroduodenal & renal mesenteric arteries.

Fig. 4. Pooling of opaque medium outlines right renal tumor.

obtained marvellous excretory pyeloureterograms in patients whose renal function was too deficient to give satisfactory films after intravenous injection and whose ureters could not be catheterized. Another type of interesting roentgenograms was developed, in that some films show the outline of the renal parenchyma, making what we call renograms.

At present we have a biological chemist trying to ascertain the tolerance for sodium iodide injected into the aorta and the capillary bed as compared with that when injected into the vein or taken by mouth.

We also have another chemist working on the problem of elimination of iodide through the kidneys after aortic injection, so that we may compare findings with iodide elimination after intravenous or oral administration.

While untoward reaction from the iodide has been neither severe nor frequent, it is to us the hazardous part of this procedure. We hope that in the near future a more satisfactory contrast medium will be found.

Injury to the aortic wall. Aortic puncture is not the formidable procedure it might seem. It should be remembered that the aorta has a thicker wall and will stand more trauma, than any other blood vessel in the human body. It is a fact, that in all the inadvertent aortic punctures made in attempting to produce splanchnic anesthesia complications are practically unknown. For a blowout or hematoma to occur from an aortic puncture the opening in the aortic wall must be large.

It goes without saying that anyone wishing to do an aortic puncture should familiarize himself very thoroughly with the anatomical parts involved, by doing several anatomical dissections. He should practice aortic puncture in the anatomical laboratory before puncturing the aorta in the living person. Santos advises against doing this on the dog, contending that it is not comparable to the human being as to arterial anatomy and physiology.

Extravasation of contrast solution. One complication that might seem dangerous is

Fig 9 Large left hydronephrosis. The blood vessels can be traced going on outside of hydronephrotic sac. The outline of the parenchyma of right kidney can be seen.

Fig 10 A large calculus of right kidney. The arteriogram shows that there is a good blood supply to the kidney.

had had attacks of diarrhea and had noticed progressive weakness. For several months he had noted a mass in the left side of the abdomen. Pyelogram showed marked downward displacement of the left kidney with pyelectasis that was suggestive, but not diagnostic, of renal neoplasm. In the arteriogram the arteries in the spleen can be traced over the outline of the soft tissue shadow, showing that we were dealing with a case of splenomegaly. At the time the patient entered the hospital, the blood count was not definitely for polycythemia vera, but later showed the red count markedly elevated.

The following case is included to show the contrast between splenomegaly, pancreatic and renal cysts, and hydronephrosis.

Figure 9, case of Mrs. A. N. L., aged 31 years, who was referred for study because of pyuria and a mass and pain in the left side of the abdomen. During the last 3 years before our examination she had also had attacks of pain in the right kidney region. The urine contained many pus cells, with mixed pyogenic infection. Renal study showed, on the right side, a fair degree of renal function as measured by indigo-carmin. The pyelograms showed a moderately

large hydronephrosis, and an obstruction at the pelvoureter junction. On the left side, no urine could be obtained, and there was no evidence of dye secretion in 25 minutes. On this side all of the opaque medium injected for pyelography returned around the catheter into the bladder. The arteriogram showed the renal artery extending over a huge mass, without any of the blood supply going into the mass—which proved that we were dealing with an extensive hydronephrosis. After a plastic operation to correct the obstruction on the right side, a large hydronephrotic sac on the left side was removed. There was no evidence of parenchymal tissue.

Figure 10, case of Mrs. C. L., aged 60 years, who was referred for study and operation on account of pyuria and a shadow on the x-ray film of a large stone in the right kidney. The calculus filled the pelvis and calices of the kidney. The left kidney and ureter were normal. As the function of the kidney containing the stone could not be definitely ascertained, arteriography was advised and performed. The film showed ample blood supply to the kidney. However, at the operation nephrectomy was performed since it was found that the stone was very adherent to the mucosa of the kidney pelvis and calices.

Fig. 7. Pancreatic cyst. Although pyelogram is suggestive of renal tumor, arteriogram refutes that diagnosis.

Fig. 8. Splenomegaly. Note the course of arteries in the spleen.

CASE HISTORIES

In order to make our interpretations of the arteriograms clear we shall describe them. Figure 3 shows a practically normal arterial tree of the organs in the upper abdomen.

Figure 4, case of Mrs. L. C., aged 64. Patient gave a history of having had hematuria and pain in the abdomen, of 5 weeks' duration. Examination revealed a mass in the right kidney region, and gross hematuria, but no organisms were found in the urine. Study showed normal left kidney. The right ureter could not be catheterized. Consequently arteriography was recommended and done. The film showed a huge vascular tumor of the kidney. Findings of operation confirmed the diagnosis.

Figure 5, case of Miss N. Z., aged 29 years. Patient had marked *bluntness* of 2 years' duration. Although she had gained about 4 pounds in that time, she had also had progressive weakness. Blood pressure was 80/30, and excretory pyelograms showed no abnormality of the urinary tract. An arteriogram showed a malignant tumor of the right adrenal gland. This tumor weighed 730 grams. It was removed at operation.

Figure 6, case of Mrs. A. G. M., aged 59 years, who underwent arteriography on August 5, 1937. A few days before that time retrograde pyelograms had been made which were suggestive of left renal neoplasm, with no history of hematuria or other clinical findings conforming to that diagnosis. Arteriogram showed upward displacement of the spleen and downward displacement of the kidney, without blood vessels in the intervening tissue. From these findings, diagnosis of renal or pancreatic cyst was made. Ten months later the operative finding was solitary cyst of the superior pole of the kidney.

Figure 7, case of Mrs. G. L. C., aged 4 years, who was referred on account of *dull, aching pain* in the left side of the abdomen, here a cystic mass about 6 centimeters in diameter could be palpated. There was no history of gross blood in the urine. Laboratory findings showed many red blood cells. Secretory pyelograms left us in doubt whether we were dealing with renal tumor.

The arteriogram showed the mass to be extra-renal. Diagnosis of pancreatic cyst, as confirmed at operation.

Figure 8, case of M. J. H., Russian farmer, aged 64 years, who entered The Swedish Hospital April 1940. During the year previous to coming, he

Fig 9 Large left hydronephrosis The blood vessels can be traced going on outside of hydronephrotic sac The outline of the parenchyma of right kidney can be seen

Fig 10 A large calculus of right kidney The arteriogram shows that there is a good blood supply to the kidney

had had attacks of diarrhea and had noticed progressive weakness. For several months he had noted a mass in the left side of the abdomen. Pyelogram showed marked downward displacement of the left kidney with pyelectasis that was suggestive, but not diagnostic, of renal neoplasm. In the arteriogram the arteries in the spleen can be traced over the outline of the soft tissue shadow, showing that we were dealing with a case of splenomegaly. At the time the patient entered the hospital, the blood count was not definitely for polycythemia vera, but later showed the red count markedly elevated.

The following case is included to show the contrast between splenomegaly, pancreatic and renal cysts, and hydronephrosis.

Figure 9, case of Mrs. A. N. L., aged 31 years, who was referred for study because of pyuria and a mass and pain in the left side of the abdomen. During the last 3 years before our examination she had also had attacks of pain in the right kidney region. The urine contained many pus cells, with mixed pyogenic infection. Renal study showed, on the right side, a fair degree of renal function as measured by indigo-carmin. The pyelograms showed a moderately

large hydronephrosis, and an obstruction at the pelvoureter junction. On the left side, no urine could be obtained, and there was no evidence of dye secretion in 25 minutes. On this side all of the opaque medium injected for pyelography returned around the catheter into the bladder. The arteriogram showed the renal artery extending over a huge mass, without any of the blood supply going into the mass—which proved that we were dealing with an extensive hydronephrosis. After a plastic operation to correct the obstruction on the right side, a large hydronephrotic sac on the left side was removed. There was no evidence of parenchymal tissue.

Figure 10, case of Mrs. C. L., aged 60 years, who was referred for study and operation on account of pyuria and a shadow on the x-ray film of a large stone in the right kidney. The calculus filled the pelvis and calices of the kidney. The left kidney and ureter were normal. As the function of the kidney containing the stone could not be definitely ascertained, arteriography was advised and performed. The film showed ample blood supply to the kidney. However, at the operation nephrectomy was performed since it was found that the stone was very adherent to the mucosa of the kidney pelvis and calices.

Fig. Atrophic pyelonephritis. Note the complete blockage of the left renal artery at the border of the splenic artery. The tortuosity of the aorta connotes advanced arteriosclerosis.

The patient has been examined about every 6 months since the operation, nearly 4 years ago. The urine and blood pressure have remained normal, and she feels well.

Figure 1 case of Mrs. F. L., aged 43 years, who gave history of having had nosebleeds on several occasions during the months previous to coming to the clinic on January 3, 1934. She was also extremely nervous. The salient points in the findings were pyuria and blood pressure of 240/60. Renal study showed practically normal kidney on the right side and atrophic pyelonephritis on the left. It seemed likely that we were dealing with case of Goldblatt kidney. The arteriogram showed obstruction in the renal artery short distance from the aorta, and attempt at establishing collateral circulation for it can be seen that small arteries broke out from the stem of the obstructed renal artery. The marked tortuosity of the aorta made it clear that she had advanced arteriosclerotic condition likely making hypertension irreversible. Four weeks after the arteriography left nephrectomy was performed. However, there has been no material change in the blood pressure as it remained about 200/50. Her clinical condition symptomatically at least has improved.

SUMMARY

1. Arteriography of the upper abdomen is discussed. We have mentioned some of its advantages as a diagnostic procedure.
2. The technique is described.
3. Untoward reaction as a result of the procedure is discussed.
4. A small series of the arteriograms is shown and our interpretation of them is given.

SPONDYLITIS ADOLESCENS—STRUEMPPELL-MARIE DISEASE

Practical and Theoretical Considerations

HARRY C BLAIR, M D , Portland, Oregon

A PAPER by Scott, entitled "Spondylitis Adolescents with Associated Pathological Changes in the Sacroiliac Joints," was the inspiration for the present study. Scott suggested the name "spondylitis adolescents" for the ankylosing spinal arthritis which is found in young adults. And he was of the opinion that "wide field" radiation offered hope for patients suffering from this condition.

Spondylitis adolescents, designated variously as Struempell-Marie's disease, Bechterew's disease, ankylosing spondylitis, spondylose rhizomélisque, and spondylitis ankylopoetica, has for many years been differentiated from other types of arthritis. Yet this progressive and crippling disease, which ultimately leads to permanent deformity of the spine, had baffled all efforts to stop its course or to decrease the suffering and misery it causes until the introduction of roentgen therapy. When, however, the etiology and the pathology of this disease is considered, a number of questions arise. Why is spondylitis adolescents in the vast majority of instances to be found in young and otherwise healthy males? Why have pronounced changes already taken place in the sacroiliac joints, and often without the patient's having realized that anything is wrong, when symptoms of back pain first appear? Can a disease which is believed to be the result of an infectious process cause extensive destruction without giving rise to local pain or a general reaction? Why does this disease always involve both sacroiliac joints? Why are the sacroiliac joints, the spine, and occasionally the hip joints alone usually involved? Why are other joints ordinarily immune? Why if fusion has taken place in a hip joint and arthroplasty is attempted does immediate bony ankylosis occur? According to Buckley, Nelaton attempted arthroplasty three times on one patient, but even after

muscle had been imposed union took place. Is some metabolic process responsible for the destruction of connective tissue and cartilage? Iritis also occurs in this disease. Does a disturbance of the metabolic process control this?

In the present study, an attempt has been made to answer some of the questions raised. An attempt has also been made to determine the physiological action of roentgen rays inasmuch as in the cases reported herein, as well as elsewhere, roentgen therapy relieved pain and apparently also shortened the course of the spondylitis.

GENERAL CONSIDERATIONS

The clinical course of spondylitis adolescents is of long duration. The disease starts in early adolescence with indefinite low back pain and continues over many years with periods of remission and exacerbation. Pain may first be noticed at the age of 12, and ankylosis of the entire spine may not take place until the patient is 25 years of age or older. With ankylosis the active part of the disease is thought to be at an end. The previous clinical history at the time of the first examination may be short—a month or 6 months. Yet roentgenograms usually show advanced changes in the sacroiliac joints, indicating that these changes do not necessarily cause pain, disability, or other symptoms.

The erythrocyte sedimentation rate is usually increased in spondylitis adolescents, sometimes to a considerable degree. Apparently this increase is proportionate to the extent of involvement and the amount of activity visible in the roentgenograms. The sedimentation rate is said to indicate the infectious etiology of spondylitis. Inasmuch as the exact relationship of the sedimentation phenomenon and infection is not known, and inasmuch as the sedimentation rate is also in-

Fig. Atrophic pyelonephritis. Note the complete blockage of the left renal artery at the border of the splenic artery. The tortuosity of the aorta connotes an aortic arteriosclerosis.

The patient has been examined about every 6 months since the operation, nearly 4 years ago. The urine and blood pressure have remained normal, and she feels well.

Figure case of Mrs. F. L., aged 4 years, gave history of having had nosebleeds several occasions during the months previous to coming to the clinic January 3, 1934. She was also extremely nervous. The salient points of the findings were pyuria and blood pressure of 140/60. Renal study showed practically normal kidney; the right side atrophic pyelonephritis on the left. It seemed likely that we were dealing with case of Goldblatt kidney. The arteriogram showed obstruction in the renal artery short distance from the aorta and attempt to establish collateral circulation for it can be seen that small arteries had cut from the stem of the obstructed renal artery. The marked tortuosity of the aorta made it clear that she had advanced arteriosclerosis, condition likely making hypertension irreversible. Four weeks after the arteriography left nephrectomy was performed. However there has been no material change in the blood pressure as it remains about 100/50. Her clinical condition symptomatically at least has improved.

SUMMARY

1. Arteriography of the upper abdomen is discussed. We have mentioned some of its advantages as a diagnostic procedure.
2. The technique is described.
3. Untoward reaction as a result of the procedure is discussed.
4. A small series of the arteriograms is shown and our interpretation of them is given.

SPONDYLITIS ADOLESCENS—STRUEMPPELL-MARIE DISEASE

Practical and Theoretical Considerations

HARRY C BLAIR, M D , Portland, Oregon

A PAPER by Scott, entitled "Spondylitis Adolescents with Associated Pathological Changes in the Sacroiliac Joints," was the inspiration for the present study. Scott suggested the name "spondylitis adolescents" for the ankylosing spinal arthritis which is found in young adults. And he was of the opinion that "wide field" radiation offered hope for patients suffering from this condition.

Spondylitis adolescents, designated variously as Struempell-Marie's disease, Bechterew's disease, ankylosing spondylitis, spondylose rhizomélisque, and spondylitis ankylopoetica, has for many years been differentiated from other types of arthritis. Yet this progressive and crippling disease, which ultimately leads to permanent deformity of the spine, had baffled all efforts to stop its course or to decrease the suffering and misery it causes until the introduction of roentgen therapy. When, however, the etiology and the pathology of this disease is considered, a number of questions arise. Why is spondylitis adolescents in the vast majority of instances to be found in young and otherwise healthy males? Why have pronounced changes already taken place in the sacroiliac joints, and often without the patient's having realized that anything is wrong, when symptoms of back pain first appear? Can a disease which is believed to be the result of an infectious process cause extensive destruction without giving rise to local pain or a general reaction? Why does this disease always involve both sacroiliac joints? Why are the sacroiliac joints, the spine, and occasionally the hip joints alone usually involved? Why are other joints ordinarily immune? Why if fusion has taken place in a hip joint and arthroplasty is attempted does immediate bony ankylosis occur? According to Buckley, Nelaton attempted arthroplasty three times on one patient, but even after

muscle had been imposed union took place. Is some metabolic process responsible for the destruction of connective tissue and cartilage? Iritis also occurs in this disease. Does a disturbance of the metabolic process control this?

In the present study, an attempt has been made to answer some of the questions raised. An attempt has also been made to determine the physiological action of roentgen rays inasmuch as in the cases reported herein, as well as elsewhere, roentgen therapy relieved pain and apparently also shortened the course of the spondylitis.

GENERAL CONSIDERATIONS

The clinical course of spondylitis adolescents is of long duration. The disease starts in early adolescence with indefinite low back pain and continues over many years with periods of remission and exacerbation. Pain may first be noticed at the age of 12, and ankylosis of the entire spine may not take place until the patient is 25 years of age or older. With ankylosis the active part of the disease is thought to be at an end. The previous clinical history at the time of the first examination may be short—a month or 6 months. Yet roentgenograms usually show advanced changes in the sacroiliac joints, indicating that these changes do not necessarily cause pain, disability, or other symptoms.

The erythrocyte sedimentation rate is usually increased in spondylitis adolescents, sometimes to a considerable degree. Apparently this increase is proportionate to the extent of involvement and the amount of activity visible in the roentgenograms. The sedimentation rate is said to indicate the infectious etiology of spondylitis. Inasmuch as the exact relationship of the sedimentation phenomenon and infection is not known, and inasmuch as the sedimentation rate is also in-

creased in other destructive conditions, such an assumption is tenable only as presumptive evidence. The patients under my observation had all been healthy young individuals prior to the onset of back pain, and some had been subjected to rigorous examinations for foci of infection. The search for infection had been followed by all the usual types of treatment—removal of tonsils and suspicious teeth, sinus operations, stool cultures, vaccine and all forms of physiotherapy and supports. In no instance however had the course of the spondylitis been shortened. In spite of the varied treatment more and more joints had become involved. Flexion of the spine had increased and the disease had progressed until complete ankylosis had taken place.

If a general metabolic change is responsible for the absorption of cartilage it is reasonable to suppose that absorption would begin in an area of low vitality. Disease or destruction of a joint produces immobilization in that joint. Although immobilization is nature's method of relieving pain, it accelerates the absorption of cartilage and the atrophy of bone. And the process spreads until ultimately all cartilage is absorbed and bony ankylosis supervenes. The sacroiliac joints contain large amounts of cartilage. Normally there is very little movement in these joints. The tissues here there

fore are of low relative vitality. In spondylitis adolescents the sacroiliac joints are the first to be attacked by the fixation process. Fixation next takes place at the lower spinal segments because the muscles that control their movements to some extent also control the movements of the sacroiliac joints. Eventually the process extends to all the joints of the spine with the exception of the upper two cervical segments. And the cervical segments are spared because movements of the head or neck are normally relatively excessive. This progressive fixation is carried out in the same sequence in the hip joints. Movements of rotation and abduction are the first to be lost and are the least disabling because they are used least often in ordinary activity. Movements of flexion and extension are the last to be lost because they are used most often.

Roentgenographic examination is depended upon for an insight into the pathology of spondylitis adolescents since there are no early autopsies. The first abnormal change noted in the roentgenograms is a widening and an irregular fuzziness of the sacroiliac joints. Areas of localized bone absorption occur nearby or general atrophy of the adjacent sacrum or ilium ensues. This, however is usually 'spotty' in character. The cartilage is absorbed, the joints as such disappear and bony ankylosis takes place. This is usually followed by increased density of the bones in the sacroiliac region. The same process takes place in the remainder of the spine. The posterolateral articulations disappear as their cartilage is absorbed. The bodies of the vertebrae show considerable halisteresis. And as resorption takes place it is seen that the supporting ligaments have been involved since they become calcified and later ossified. This calcification and ossification do not appear to spread to other soft tissues in the body. The intervertebral discs do not lose width but show more or less calcification. Bechterew described a similar disease which involved the dorsal vertebrae first. One of the patients in the present group is thus clasped. It is significant that both sacroiliac joints were involved when this patient first complained of thoracic pain. Scott called attention to the fact that there is as yet no satisfactory explanation for

Fig. 2, a and b. Advanced case of spondylitis adolescens with complete ankylosis of the hip joints, sacroiliac joints and spine. It will be noted that the cartilage in the sacroiliac joints has been completely absorbed and is replaced by what is apparently normal bone. In the lateral view of the spine, a, it is seen that the width of the intervertebral discs has not changed.

the absence of sacroiliac pain during the active period of the disease.

ROENTGEN THERAPY

In Scott's opinion, roentgen therapy brings about some beneficial constitutional effect which suggests stimulation, or the reverse, of the ductless gland system. He advised that roentgen therapy for spondylitis adolescens be instituted early. But he warned against the use of high voltage roentgen therapy, and stated that serious damage could be done if large doses were used.

Smyth, Freyberg, and Peck called attention to the fact that subjective benefit following roentgen therapy may be of psychogenic origin. They reported 15 cases of spondylitis rhizomélisque in which roentgen therapy had been used. In 74 per cent of these cases there was definite subjective and objective evidence of benefit, and in 67 per cent the beneficial results were permanent. After careful search for a reason why roentgen therapy is bene-

ficial, they did not even find a theoretical explanation for its use. And they concluded that "the rationale for employment of roentgen therapy in rheumatic disease and its *modus operandi*" was a complete mystery to them.

In the present series of cases the "wide field" technique described by Scott was followed. The roentgen rays were of medium wave length, were passed through thin filters, and were distributed over a large body area. Treatments were given twice a week for 16 doses, the total dosage being 1000 roentgens. When it was deemed necessary, the treatment was repeated. There were no serious reactions of any kind. Some of the patients complained of slight nausea, but the treatments caused no real inconvenience. No other therapy was used. Vaccine, physiotherapy, braces when possible, and all analgesics were abandoned so that a better estimate of the results might be made.

It is generally realized that remissions do take place in spondylitis adolescens and that

Fig. 3. and b T. Brothers, ankylosing spondylitis. Although both of these patients are subjected to rigorous exercises, there is no infectious focus in the blood.

spontaneous recovery may take place also that the course of this disease is from 10 to 20 years, and that sufficient time has perhaps not yet elapsed to evaluate properly the results from roentgen therapy. On the other hand reports in the literature show an increasing number of encouraging results following the use of irradiation for this condition. Even though the present series is small and it has been only 4 years since the first treatment was given improvement has been so consistent in the comparatively early cases that it is felt the results obtained are worthy of being reported.

CASE REPORTS

CASE. W. H. male, aged 42 years, was first seen on January 3, 1935, complaining of pain in the hip. It had appeared first in the left hip then in the right

Fig. 4. Following ankyroplasty there is definite tendency for ankylosis to take place. The roentgenogram illustrates this phenomenon.

stiffness of the back and pain under the costal margins. Symptoms were of 3½ years duration.

The first irradiation treatment was given on December 9, 1935. The patient felt worse after this. Therapy, however, was continued, and the series of 6 treatments was completed January 3, 1936. Three days later the pain was no better than it had been at the start of the roentgen therapy. Improvement, however, was noticed within a few weeks, and continued over the succeeding years. The patient, as employed, steadily played tennis and golf and continued swimming. He had only an occasional large

Roentgenogram plus find 35. The first roentgenogram which the patient brought with him, had been taken on December 30, 1935. It was an anteroposterior view and showed an irregular outline of the sacroiliac joints and roughening of the lower lumbar posterolateral joints. Roentgenogram on January 4, 1936 showed considerable increase of the irregularity of these joints. The joint spaces were widened, and the adjacent bone was mottled in some areas; the bone as dense as others trochanter. The bodies of the last lumbar vertebra had fuzzy appearance. The posterolateral joints were not visible. On January 24, 1936, after irradiation, roentgenogram showed the sacroiliac joints to be completely fused. Bone striations had approached normal, and the increased density had disappeared. The texture of the vertebral bodies had lost its fuzzy appearance. And the two lower vertebral joints appeared to be ankylosed.

This boy's condition had grown progressively worse until he was treated with roentgen rays. Since then his symptoms continued to decrease. Roentgenograms revealed that the

Fig 5, a and b These photographs were taken some months after a course of roentgen therapy. There were no complaints of pain at that time, but rather pronounced rigidity was still present. At the beginning of the treatment this boy was walking on crutches because of pain.

texture of the bone in the involved areas had improved considerably. Ankylosis of the involved joints had, however, continued. It may be argued that this is a natural recession, as sometimes occurs in this disease. It was not caused by the psychologic effect of treatment since improvement did not take place until after the treatment was stopped.

CASE 2 A G, male, aged 18 years, was first seen on December 16, 1935 because of painful feet. At that time the patient had no symptoms referable to the back. On September 15, 1938, however, he complained of severe back pain with stiffness of the back and hips and flexion of the hips and spine.

A series of 16 roentgen treatments was started on March 14, 1939. This was followed by striking symptomatic relief, but the stiffness of the back and hips remained the same. On October 23, 1939, he returned. He was walking with the aid of crutches, and complained of severe pain in the lower back. Another series of roentgen treatments was started. Improvement during this treatment course was remarkable. Within a week the crutches were discarded. On January 18, 1940, the patient reported that he had no pain. He had gained 20 pounds. There was increase in the movements of the hips

Fig 6 While there are definite abnormal changes in the sacroiliac joints shown here, the changes consist only of irregularity of the anterior fissure and sclerosis of the adjacent bone, the ilia, and the sacrum. This indicates that spondylitis may not progress to complete ankylosis.

and probably also of the spine although this is difficult to estimate.

CASE 3 B C, male, aged 15 years, was first seen on June 5, 1940, complaining of back pain of 1 year's duration. No other joints were involved. The tonsils had been removed.

Examination revealed loss of normal lumbar lordosis. There was a slight flexion deformity of the hips (psoas spasm). The hip movements were normal otherwise, except for slight restriction of external rotation. Roentgenograms were normal except for slight irregularity of the sacroiliac joints and some widening. The bone texture was good. There was no evidence of involvement of the posterolateral vertebral joints from the roentgenographic standpoint, but clinical findings were very definite.

After 4 roentgen treatments the patient was not so stiff as he had been. Improvement continued without interruption. This patient, who had been so disabled that he could not take part in games or sports, was playing football by October, 1940. He had no pain, and almost all of his back stiffness had disappeared by that time. Roentgenograms taken on June 2, 1941, showed normal sacroiliac joints. There was no clinical evidence of disability, and there were no complaints. This boy gained 15 or 20 pounds, and was in excellent health.

CASE 4 D MacD, male, was first seen when he was 32 years old. When he was 16, he had noticed pain and swelling in his feet. Later he had also had pain in his back. No other joints had been involved.

Roentgenograms revealed extensive involvement of the bones of the pelvis and of the entire spine. Atrophy was pronounced. There was also fusion of the sacroiliac joints, some deformity of the pelvis, and ankylosis of the spine.

On December 8, 1938, roentgen therapy was started. After the first 8 treatments roentgenograms

Fig. 7. Myositis ossificans of long standing. This patient suffered for many years with spondylitis adolescents. About the time of the onset of his spinal symptoms he also developed the condition in his thigh which is shown in this roentgenogram. Some disturbance of the heparin content of the blood or the tissues may be responsible for this process.

showed beginning collapse of some of the vertebral bodies. This collapse had taken place while the patient was wearing a T 12-6 back brace and during the time he was being given radiotherapy. Treatments were stopped. The patient, however, began to improve. He gained 20 pounds and the swelling of his feet subsided. On November 8, 1930, treatments were resumed and 6 were given. Roentgenograms of the lumbar spine on April 24, 1931, showed that recalcification was taking place. The patient in general condition at that time was greatly improved. His appetite was better, the pain was less severe, and he was able to return to his work as saliceman.

Improvement in this instance took place at a time when retrogression of symptoms might be expected. Nevertheless, the improvement seems to have been directly associated with the roentgen therapy, since no improvement had occurred with any other form of treat-

ment. It is of interest to note that this patient's brother also had spondylitis adolescents. The brother, however, had no irradiation, and the disease progressed to ankylosis in spite of every known type of therapy.

CASE 5. A. R. male, aged 33 years, as first seen on April 20, 1930. I 1936 the patient had injured his back. He had taken 20 chiropractic treatments, but in spite of this he had become almost completely disabled. On December 9, 1938, 4½ months before admission, he had again injured his back while lifting a sack of wheat and throwing it into a truck. Following this he had pain across his hips.

Examination revealed stiffness of the spine and muscle spasm. There was some interference with straight leg raising. Roentgenograms showed irregularity of the sacroiliac joints with sclerosis of the adjacent bone and some decreased definite markings of the lower lumbar posterolateral articulations.

Irradiation was started on April 20, 1939. On June 3 the patient returned to work. On December 1, 1939, he reported that he had twisted his back and that this had caused a return of the pain. He stated, however, that the roentgen therapy had done him a great deal of good, that it had taken much of the stiffness out of his back and that he did not have the catches in his hips and back that he had had before.

Both sacroiliac joints of this patient were abnormal. The changes, however, consisted only of an irregularity of the joint outlines. It is possible that in some instances spondylitis adolescents does not progress to ankylosis.

RELATIONSHIP OF MAST CELLS AND HEPARIN TO SPONDYLITIS ADOLESCENS

It has been demonstrated that the mast cells of Ehrlich are present in wide distribution in the body and are especially abundant in the connective tissue surrounding blood vessels. It has also been shown that the distribution of these cells is proportionate to the abundance of heparin in the various organs. Holmgren and Wlinder found that heparin is contained in the granules of the mast cells. Before this, Lison had observed that the presence of mucotin and chondroitin sulfuric acids is responsible for the metachromatic reaction shown by mucoid and cartilaginous tissues when stained with toluidine blue and that this staining reaction is specific for these sulfur acid esters of high molecular weight. And Jorpes pointed out that heparin, which is a polysulfuric ester with a high molecular

weight, gives a color "a hundred times stronger than that obtained with the same quantity of chondroitin sulphuric acid," also, that "toluidine blue possesses an extremely strong affinity for heparin"

In an excellent and exhaustive review of the chemistry, physiology, and clinical application of heparin, Mason called attention to the fact that "the ester sulfate content of tissues was found to parallel its content in mast cells, as was the content of crude heparin. The morphologic and chemical observations," he stated, "all strongly support the conclusion that (1) the metachromatic granules in these cells contain heparin, (2) that the cells have secretory activity, and (3) that their function is to supply the circulation with the physiologic anticoagulant." Mason cited the important studies carried out by Jorpes and his associates on the chemistry of heparin, and he summarized Jorpes' chief contentions as follows: Heparin is a mucitin polysulfuric ester of variable composition—these variables being the number of sulfuric acid groups substituted into the individual mucitin units, the degree of polymerization (the number of mucitin sulfuric acid units which are linked together to form its polysaccharide structure), and the relative esterification of each unit. Chondroitin and mucitin sulfuric acids, Mason explained, "are the prosthetic groups of the corresponding chondroproteins and mucoproteins. They consist of units of an hexuronic acid, presumably glycuronic, an amino sugar, sulfuric and acetic acids. The acetic acid is present as an N-acetyl group on the amino sugar, and sulfuric acid, one or more moles, is bound by an ester linkage to the free hydroxyl groups of the hexuronic acid and/or the hexosamine, the latter being galactosamine in chondroitinsulfuric acid and glucosamine in mucitinsulfuric acid."

Cartilage is composed of approximately 70 per cent water, 28 per cent organic solids, and 2 per cent inorganic matter. The organic solids are for the most part chondroitin sulfuric acid. Chondroitin sulfuric acid is found not only in cartilage but also in tendons, ligaments, aorta, sclera, and probably, according to Levene, in osseomucoid. Logan stated that the conversion of cartilage to organic matrix

Fig 8 Structural formula of chondroitin sulfuric acid (Levene). Chondroitin sulfuric acid contains galactosamine. Mucitin sulfuric acid (heparin) contains glucosamine. The hydroxyl on the fourth carbon of the hexosamine group is inverted in mucitin sulfuric acid as compared with chondroitin sulfuric acid. These compounds are closely allied in their physical and chemical properties.

of bone is characterized by the loss of organic sulfates.

Tumors such as carcinoma are surrounded by a great number of mast cells. After treatment with high voltage roentgen therapy the mast cells disappear. Sylvén attempted to determine what happened to mast cells after such therapy, and conducted experiments on rats. The animals were covered with lead plates except for a field on the abdominal wall measuring 5 by 5 centimeters. Two series of animals were given 1000 and 1500 roentgens, respectively, in one treatment. One or two days after irradiation there appeared in all connective tissue of the corium and the subcutis substances exhibiting metachromatic staining reaction. These substances were diffusely distributed in the cell territories of the fibroblasts. Sylvén observed that after treatment of low dosage, 1000 and 1500 roentgens, a great many granules in the mast cells had disappeared, but there had been no increase or decrease in the number of mast cells. The results indicate that some of the sulfuric acids in the granules was excreted from the cytoplasm of the mast cells and spread diffusely over the surrounding connective tissue after exposure to roentgen rays. The threshold dose seems to be less than 1000 roentgens. Smyth *et al* used 600 roentgens in 3 doses in treating spondylitis.

IRITIS

It has been noted by many observers that iritis occasionally occurs during the course of

spondylitis adolescens. In the cornea there are normally very few mast cells but during the course of an infection such as a serpyginous ulcer the number of these cells increases. There is also an increase of the mast cells in the eye when iritis and glaucoma occur. The aqueous and vitreous humors consist of mucotin sulfuric acid. The fact therefore that the eye is composed of substances closely related to the chondroitin sulfuric acid of cartilage together with the fact that the eye is involved during the course of spondylitis adolescens, indicates a direct relationship of metabolic origin. Furthermore the increase of the mast cells may be an effort toward healing. Ehrlich in 1879 stated that these cells were related to the nutrition of tissues. Because of this he labelled them mast (food) cells.

EVALUATION

It would seem logical to believe (1) that the pathological changes which occur in spondylitis adolescens are caused by an absorption of cartilage and not by an infectious process (2) that the beneficial results obtained from the generalized exposure of the body to roentgen ray dosage of medium wave length is brought about by the liberation of sulfur within the body in such a form that it can replenish a sulfur deficiency in any part of the body (3) that in spondylitis adolescens chondroitin sulfuric acid is absorbed from the cartilage, ligaments and bone in and around the sacroiliac joints and spine and (4) that this absorption probably occurs because of a deficiency of sulfur or mucotin or chondroitin sulfuric acids elsewhere in the body. It is of interest to note that Cawadiaz in 1923 stated that it is not illogical to assume that a certain hereditary or constitutional predisposition exists for sulfur demineralization. He expressed the belief that sulfur demineralization is a special metabolic disturbance in rheumatoid arthritis, and that the tissues in this condition lose the power which they have of retaining sulfur.

SUMMARY

1. Cartilage consists of chondroitin sulfuric acid a substance like mucotin sulfuric acid.
2. Mast cells contain granules composed of mucotin sulfuric acid. These cells are located mostly in the connective tissue around blood vessels as well as in synovial tissue.
3. Irradiation causes mast cells to give up their sulfuric ester granules.
4. Roentgen ray dosage of comparable strength gives striking relief of the symptoms associated with spondylitis adolescens.
5. The hypotheses are presented (1) that spondylitis adolescens is caused primarily by an absorption of cartilage from the joint involved and not by an infectious process (2) that the beneficial results of roentgen therapy are brought about apparently by liberation of sulfur within the body in a usable form and (3) that iritis a condition associated with spondylitis, is caused by the same metabolic disturbance and possibly may react favorably to the same treatment.

A CLINICAL AND PATHOLOGICAL STUDY OF LEIOMYOSARCOMA, HEMANGIOENDOTHELIOMA OR ANGIOSARCOMA, AND FIBROSARCOMA OF THE STOMACH

ROBERT G LEMON, M D, and ALBERT C BRODERS, M D,
Rochester, Minnesota

A GREAT deal has been written on the subject of sarcoma of the stomach, although it is a comparatively uncommon lesion. Much confusion has resulted from the lack of a uniform nomenclature and classification for these tumors. It is our belief that the leiomyosarcomas, hemangioendotheliomas and fibrosarcomas of the stomach comprise a group of nonepithelial neoplasms quite distinct clinically and pathologically from the group of lymphosarcomas. The purpose of this paper is to correlate the clinical and pathological features of sarcoma of the stomach with special reference to the foregoing three types and to present a simplified classification.

Fourteen histologically proved cases of gastric sarcoma, exclusive of lymphosarcoma, in which operation was performed at the Mayo Clinic between 1908 and 1938 inclusive, have formed the basis for this paper.

The first case of sarcoma of the stomach in the literature was that recorded by Bruch in 1847. In 1901 Fenwick reported 53 proved cases of sarcoma of the stomach and in 1914 Forni made a complete analysis of the subject, bringing the total cases reported to 200. A review of the literature in 1930 by D'Aunoy and Zoeller increased this figure to 335 cases.

ETIOLOGY

As in all forms of malignant lesion, very little is known concerning the causation of gastric sarcoma. Various hypotheses have been advanced but in general it may be said that probably no single specific factor is responsible for the origin of sarcoma. Trauma,

inflammation, or some form of chronic irritation is believed to act on normal tissue cells, benign tumors, ulcers, or congenital isolated cell rests of the stomach to produce proliferation of mesoblastic cells and ultimately sarcomatous change.

Trauma is thought to play an important etiological rôle. Numerous cases are cited in which the patient associated the onset of symptoms with some form of trauma, and such observers as Brooks, Sherrill and Graves, and McWhorter have called attention to this relationship.

Farr explained the relative infrequency of sarcoma of the stomach as compared with carcinoma by the fact that the connective tissue elements of the stomach from which sarcoma takes its origin are less exposed to injury than the carcinoma forming epithelial surfaces which are exposed constantly to chemical and mechanical assault.

Some observers contend that sarcomas do not develop from previously normal cells but rather from congenital cell rests, but this contention has not been proved. Mallory stated that hemangioendotheliomas are often congenital and frequently, perhaps always, arise from abnormalities of the blood vessels.

There is little doubt that sarcomatous change does occur occasionally in benign gastric tumors and may even take place rarely in chronic gastric ulcers. This relationship has not been proved satisfactorily but has been suggested many times. D'Aunoy and Zoeller claimed that it is theoretically possible because gastric ulcers can stimulate prolonged formation of connective tissue, and such chronic reactions to irritation have been shown conclusively to act as etiological factors in the production of malignant processes in other organs.

From the Department of Surgery, Mayo Foundation, and the Section on Surgical Pathology, Mayo Clinic.

Abridgement of thesis submitted by Dr. Lemon to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

Fig. 5. Fibrosarcoma of the stomach. It is myxomatous changes (hematoxylin and eosin, $\times 30$).

In this series 8 of 14 patients, or 57.1 per cent, had one or more reasonably definite features of ulcer. These consisted of periodicity, epigastric pain coming on after meals, relief of pain after ingestion of food and alkali, nocturnal pain, and a history of previous roentgenological diagnosis of ulcer. The preoperative clinical diagnosis in 2 cases was peptic ulcer, while in 3 cases a roentgenological diagnosis of ulcer had been made previously.

Incidence Sarcoma has been estimated variously to comprise from 1 to 8 per cent of all neoplasms of the stomach. Ewing estimated its frequency at 1 per cent, while Fenwick expressed the opinion that it comprises from 5 to 8 per cent of all gastric neoplasms.

Age Sarcoma of the stomach affects all age groups, although the period between 40 and 60 years of age comprises the largest group. The youngest patient appearing in the literature is that reported by Finlayson, a child 3 years of age with a fatal outcome 6 months later. The oldest patient, 91 years of age, was reported by Di Giacomo.

The average age of patients who have gastric sarcoma is considerably less than that estimated for carcinoma. Douglas quoted the average age for gastric carcinoma from the United States census figures as 61.2 years.

In this series the average age of the patients was 43.2 years, the youngest being 10 years of age. Almost half of our patients fell in the age group of 40 to 50 years. In 11 of our 14 cases the lesion was leiomyosarcoma, the average age of the patients was 46.6 years. There were 2 cases of hemangioendothelioma, in which the patients were 10 years and 29 years of age, respectively. In the case of fibrosarcoma the patient was 54 years old.

Sex The average reports in the literature state that the sex is divided about equally, although such observers as Balfour and McCann, and D'Aunoy and Zoeller report a preponderance in males.

In our 14 cases, 9 of the patients, or 64.3 per cent, were males and 5, or 35.7 per cent, were females. Only 3 of the 11 leiomyosarcomas were found in females while both of our cases of hemangioendothelioma were in females. The 1 case of fibrosarcoma occurred in a male.

PATHOLOGY

Attempts to classify sarcomas of the stomach pathologically have met with varying degrees of success. Seventeen different classifications have been encountered in the literature and these appear to have little uniformity.

It is apparent, therefore, that some simple inclusive classification should be decided on. It is recognized fairly generally that lymphosarcomas make up a definite class of gastric tumors, not only clinically and pathologically, but also in regard to their treatment and prognosis. The remaining types of gastric sarcoma, which comprise about a fourth of the total number, may be divided into three groups: leiomyosarcoma, hemangioendothelioma or angiosarcoma, and fibrosarcoma.

Frequency Confusion exists regarding the relative frequency of the different histological types of gastric sarcoma. Fenwick stated that lymphosarcoma comprises 62 per cent of the sarcomas of the stomach, fibrosarcoma, 22 per cent of the cases, and leiomyosarcoma and angiosarcoma make up the remainder.

In Balfour and McCann's 54 cases, lymphosarcoma comprised 71.3 per cent, fibrosarcoma 13.3 per cent, and myosarcoma 6.7 per cent.

In reviewing our specimens, it was found that 11 of them, or 78.6 per cent, were leiomyosarcomas, 2 were hemangioendotheliomas, and 1 was a fibrosarcoma. These figures seem reasonable because of the abundance of smooth muscle tissue in the stomach as compared with the amount of vascular endothelial tissue and fibrous connective tissue present, although they are contrary to the general belief that fibrosarcoma is next in frequency to lymphosarcoma of the stomach.

Location The location of these tumors is a fairly constant feature. They differ from carcinoma in that they rarely involve the orifices. Ewing stated that they usually arise from the curvatures, rarely from the pylorus, may project into the peritoneum, remain interstitial, or protrude into the cavity of the organ.

Balfour and McCann concluded that the lesser curvature is involved chiefly and the lesion is situated usually in the antrum, rarely at the pylorus, and never in the cardia.

The location of the tumor was determined in all of our cases and bears out the fact that

These consisted of periodicity, epigastric pain coming on after meals, relief of pain after ingestion of food and alkali, nocturnal pain, and a history of previous roentgenological diagnosis of ulcer. The preoperative clinical diagnosis in 2 cases was peptic ulcer, while in 3 cases a roentgenological diagnosis of ulcer had been made previously.

Incidence Sarcoma has been estimated variously to comprise from 1 to 8 per cent of all neoplasms of the stomach. Ewing estimated its frequency at 1 per cent, while Fenwick expressed the opinion that it comprises from 5 to 8 per cent of all gastric neoplasms. Age Sarcoma of the stomach affects all age groups, although the period between 40 and 60 years of age comprises the largest group. The youngest patient appearing in the literature is that reported by Finlayson, a child 3 years of age with a fatal outcome 6 months later. The oldest patient, 91 years of age, was reported by Di Giacomo.

The average age of patients who have gastric sarcoma is considerably less than that estimated for carcinoma. Douglas quoted the average age for gastric carcinoma from the United States census figures as 61.2 years.

In this series the average age of the patients was 43.2 years, the youngest being 10 years of age. Almost half of our patients fell in the age group of 40 to 50 years. In 11 of our 14 cases the lesion was leiomyosarcoma, the average age of the patients was 46.6 years. There were 2 cases of hemangioendothelioma, in which the patients were 10 years and 29 years of age, respectively. In the case of fibrosarcoma the patient was 54 years old.

Sex The average reports in the literature state that the sex is divided about equally, although such observers as Balfour and McCann, and Lunov and Zeller report a preponderance in males.

In our 14 cases 9 of the patients, or 64.3 per cent, were males and 5, or 35.7 per cent, were females. Only 3 of the 11 leiomyosarcomas were found in females while both of our cases of hemangioendothelioma were in males. The 1 case of fibrosarcoma occurred in a male.

PATHOLOGY

Attempts to classify sarcomas of the stomach pathologically have met with varying degrees of success. Seventeen different classifications have been encountered in the literature and these appear to have little uniformity.

It is apparent, therefore, that some simple inclusive classification should be decided on. It is recognized fairly generally that lymphosarcomas make up a definite class of gastric tumors, not only clinically and pathologically, but also in regard to their treatment and prognosis. The remaining types of gastric sarcoma, which comprise about a fourth of the total number, may be divided into three groups: leiomyosarcoma, hemangioendothelioma or angiosarcoma, and fibrosarcoma.

Frequency Confusion exists regarding the relative frequency of the different histological types of gastric sarcoma. Fenwick stated that lymphosarcoma comprises 62 per cent of the sarcomas of the stomach, fibrosarcoma, 22 per cent of the cases, and leiomyosarcoma and angiosarcoma make up the remainder.

In Balfour and McCann's 54 cases, lymphosarcoma comprised 71.3 per cent, fibrosarcoma 13.3 per cent, and myosarcoma 6.7 per cent.

In reviewing our specimens, it was found that 11 of them, or 78.6 per cent, were leiomyosarcomas, 2 were hemangioendotheliomas, and 1 was a fibrosarcoma. These figures seem reasonable because of the abundance of smooth muscle tissue in the stomach as compared with the amount of vascular endothelial tissue and fibrous connective tissue present, although they are contrary to the general belief that fibrosarcoma is next in frequency to lymphosarcoma of the stomach.

Location The location of these tumors is a fairly constant feature. They differ from carcinoma in that they rarely involve the orifices. Lwing stated that they usually arise from the curvatures, rarely from the pylorus, may project into the peritoneum, remain interstitial or protrude into the cavity of the organ.

Balfour and McCann concluded that the lesser curvature is involved chiefly and the lesion is situated usually in the antrum, rarely at the pylorus, and never in the cardia.

The location of the tumor was determined in all of our cases and bears out the fact that

Fig. 1. Leiomyosarcoma of the stomach of low grade malignancy (hematoxylin and eosin, $\times 30$).

Fig. 2. Benign leiomyoma of the stomach showing mature smooth muscle tissue in its characteristic arrangement. Mitotic figures are present (hematoxylin and eosin, $\times 30$).

Fig. 3. Highly malignant leiomyosarcoma of the stomach. Note the rapidly growing, highly undifferentiated cells and the presence of mitotic figures (hematoxylin and eosin, $\times 314$).

Fig. 4. Hemangioendothelioma, or angiosarcoma, of the stomach. Notice how the endothelial cells, in an attempt to form new vessels, have arranged themselves into cord-like structures some of which have already been cannalized and contain erythrocytes (hematoxylin and eosin, $\times 30$).

Fig. 5. Fibrosarcoma of the stomach. Mark myxomatous changes (hematoxylin and eosin, $\times 30$).

In this series 8 of 14 patients, or 57.1 per cent, had one or more reasonably definite features of ulcer. These consisted of periodicity, epigastric pain coming on after meals, relief of pain after ingestion of food and alkali, nocturnal pain, and a history of previous roentgenological diagnosis of ulcer. The preoperative clinical diagnosis in 2 cases was peptic ulcer, while in 3 cases a roentgenological diagnosis of ulcer had been made previously.

Incidence Sarcoma has been estimated variously to comprise from 1 to 8 per cent of all neoplasms of the stomach. Ewing estimated its frequency at 1 per cent, while Fenwick expressed the opinion that it comprises from 5 to 8 per cent of all gastric neoplasms.

Age Sarcoma of the stomach affects all age groups, although the period between 40 and 60 years of age comprises the largest group. The youngest patient appearing in the literature is that reported by Finlayson: a child 3 years of age with a fatal outcome 6 months later. PATHOLOGY

Attempts to classify sarcomas of the stomach pathologically have met with varying degrees of success. Seventeen different classifications have been encountered in the literature and these appear to have little uniformity.

It is apparent, therefore, that some simple inclusive classification should be decided on. It is recognized fairly generally that lymphosarcomas make up a definite class of gastric tumors, not only clinically and pathologically, but also in regard to their treatment and prognosis. The remaining types of gastric sarcoma, which comprise about a fourth of the total number, may be divided into three groups: leiomyosarcoma, hemangioendothelioma or angiosarcoma, and fibrosarcoma.

Frequency Confusion exists regarding the relative frequency of the different histological types of gastric sarcoma. Fenwick stated that lymphosarcoma comprises 62 per cent of the sarcomas of the stomach, fibrosarcoma, 22 per cent of the cases, and leiomyosarcoma and angiosarcoma make up the remainder.

In Balfour and McCann's 54 cases, lymphosarcoma comprised 71.3 per cent, fibrosarcoma 13.3 per cent, and myosarcoma 6.7 per cent.

In reviewing our specimens, it was found that 11 of them, or 78.6 per cent, were leiomyosarcomas, 2 were hemangioendotheliomas, and 1 was a fibrosarcoma. These figures seem reasonable because of the abundance of smooth muscle tissue in the stomach as compared with the amount of vascular endothelial tissue and fibrous connective tissue present, although they are contrary to the general belief that fibrosarcoma is next in frequency to lymphosarcoma of the stomach.

Location The location of these tumors is a fairly constant feature. They differ from carcinoma in that they rarely involve the orifices. Ewing stated that they usually arise from the curvatures, rarely from the pylorus, may project into the peritoneum, remain interstitial, or protrude into the cavity of the organ.

Balfour and McCann concluded that the lesser curvature is involved chiefly and the lesion is situated usually in the antrum, rarely at the pylorus, and never in the cardia.

The location of the tumor was determined in all of our cases and bears out the fact that

these lesions are found most frequently arising from the lesser curvature of the stomach in which location they occurred 5 times. Other locations were encountered in the following order: posterior wall, 3 times; anterior wall, greater curvature, and pyloric end of stomach, each 2 times.

Gross characteristics. Sarcomas of the stomach vary considerably in their gross characteristics, depending on their cell of origin, location and rapidity of growth. Generally speaking they are fairly rapidly growing tumors with a tendency to grow expansively in the connective tissue and vascular framework of the organ rather than to grow by infiltration as is so common with carcinomas.

The types of sarcoma under discussion here usually are sharply limited from the surrounding normal tissue, although a true capsule usually is wanting. They are usually highly vascular and for this reason often reach an enormous size. One of the largest was that reported by Cantwell which weighed 13 pounds (5.4 kilograms).

Because of their rapid growth and great size attained, secondary changes are encountered frequently. Some of these such as edema, hemorrhage and mucoid degeneration, tend to increase the bulk of the lesion further. When the limit of growth is reached, as determined by the blood supply, infarction and necrosis occur. Infection may follow and often accounts for the febrile course seen in certain cases of gastric sarcoma. Degenerative cysts and abscesses likewise may form. Perforation is fairly common. Hense stated that perforation occurs in 8 per cent of cases.

Ulceration of the mucous membrane occurs late in the course of the disease and is usually the result of pressure necrosis; the mucosa not being involved primarily in the growth. Hemorrhage occurs either in the gastric lumen or in the tumor itself as a result of ulceration and rupture or thrombosis of the blood vessels.

Leiomyosarcoma originates in the smooth muscle cells of the muscularis, is fairly slow growing, and usually is well demarcated from the rest of the gastric layers.

Hemangioendothelioma has its origin in the endothelial cells of blood vessels. Being a

connective tissue tumor it can be classed as a sarcoma. Growthy, it may simulate leiomyosarcoma and fibrosarcoma very closely and is usually well circumscribed frequently pedunculated and but rarely infiltrating.

Fibrosarcoma of the stomach takes its origin from the wall most frequently in the submucosa. It rarely assumes the form of an infiltrating growth and usually remains as a well demarcated intramural tumor.

These types may remain confined to the stomach wall as intramural growths, but, more frequently, they grow inward or outward to form sessile or pedunculated endogastric or exogastric tumors. The exogastric is perhaps the most common form, and because of the relative ease of its surgical removal and its slowness to metastasize, it is considered less malignant than the endogastric or infiltrating forms.

Microscopic characteristics. The histological appearance of sarcoma varies considerably but usually resembles that of its tissue of origin. In the slower growing well differentiated tumors, little difficulty is encountered in diagnosis but, with increasing anaplasia, the form of their originating cells is lost and classification may be difficult. The cells themselves may be divided into two groups for all sarcomas of the stomach, namely, round cells and spindle cells. These may be subdivided further into small and large round cell or spindle cell sarcomas. These different cell types may be present alone or in combinations in any of the four types of sarcoma. As a rule, however, the round cells are confined to the lymphosarcoma type, while the spindle cells make up the leiomyosarcomas, hemangioendotheliomas, and fibrosarcomas.

The microscopic picture of leiomyosarcoma consists of immature smooth muscle cells of varying degrees of differentiation grouped into interlacing bundles and bands separated by a fibrous stroma whose amount depends on the compactness of the tumor structure. When of low grade malignancy (Fig. 1) these tumors appear very similar to benign leiomyomas (Fig. 2) and frequently one is mistaken for the other. The finding of mitotic figures, however, establishes the malignant nature of the lesion (Fig. 3).

Microscopically, hemangioendothelioma are composed of large oval or spindle shaped endothelial cells arranged in a manner attempting to form new blood vessels (Fig 4). These are very vascular tumors containing numerous blood spaces and sinuses filled with erythrocytes. Their cells are usually quite mature and therefore they are easily confused with benign hemangiomas. Here, again, the presence of mitotic figures establishes the diagnosis of malignancy.

The fibrosarcoma is made up of connective tissue cells varying in appearance from that of immature fusiform fibroblasts to that of almost mature fibrous connective tissue cells (Fig 5). The same general interlacing pattern is noted. The cells themselves usually are elongated, oval, or spindle shaped with large granular nuclei. Mitotic figures are always present.

Degree of malignancy. As in all types of malignant tumors, the degree of malignancy of these gastric sarcomas varies according to the proliferative activity and differentiation of their cells. As a general rule they are less malignant than lymphosarcomas, not only in regard to cellular proliferation but also because they are usually noninfiltrating, more or less circumscribed, and often pedunculated growths which are more easily extirpated surgically.

Metastasis. Metastasis has been estimated variously by different observers as occurring in from a third to three-fourths of all cases of gastric sarcoma.

Most authors agree that metastasis occurs most often in the regional lymph nodes of the stomach and in the liver. The liver was involved by secondary deposits at the time of operation in 3 cases, or 21.4 per cent, in this series. In each of these 3 cases the location of the metastatic deposits was noted as being in the liver, and in 2 of them, metastatic nodules were found in the omentum and peritoneum, respectively. In 1 of these inoperable cases, the involvement of the liver was not found until operation, the abdomen was closed after a specimen for biopsy had been secured from the tumor, which proved to be a hemangioendothelioma. More than 6 years later this same patient returned to the clinic

and exploration was performed again. Metastatic deposits were found again in the liver and, this time, also in the omentum. A biopsy was made which confirmed the first report, and no further surgical intervention was attempted. The patient died about 6 months after the last operation. In 2 of the operable cases metastasis was reported in the liver 6 years and 3 years, respectively, after operation, which brings the total known metastatic growths in the liver to 5 cases, or 35.7 per cent.

CLINICAL MANIFESTATIONS

The clinical manifestations of sarcoma of the stomach generally are considered indistinguishable from those of any other malignant or sometimes benign tumor of the stomach. The sarcomas are confused most often with gastric carcinoma, peptic ulcer, and benign bleeding gastric leiomyomas.

There are no definite pathognomonic signs, symptoms, or laboratory criteria on which a diagnosis of sarcoma of the stomach can be made before operation. Recognition of the malignant nature of the lesion, however, is the matter of prime importance, whereas the particular type of neoplasm is only of secondary consideration.

The onset of the disease, although usually insidious, may be sudden and the symptoms may vary from the mildest dyspepsia to the severest manifestations of gastric carcinoma.

The course of these tumors is relatively slow. In 1 of our patients, one or more gastric symptoms had been present for as long as 15 years, while $3\frac{1}{2}$ years was the average duration of symptoms before medical aid was sought here. The shortest period in which symptoms had been present was 4 months.

Symptoms. The symptoms which bring the patient to seek medical aid are not generally such early ones as mild dyspepsia, epigastric distress, nausea, and anorexia. Usually it is the onset of severe abdominal pain, a rapidly enlarging abdominal mass, hemorrhage from the growth in the form of melena or hematemesis, vomiting, or marked loss of weight which brings the patient to consult his physician. By this time, of course, the disease is well advanced and secondary complications often have occurred.

Pain, hemorrhage, vomiting, and the production of severe digestive disturbances occur late in the course of the tumor after it has invaded the mucous membrane or become large enough to produce pressure necrosis and ulceration of the mucosa. Following this, cachexia soon may become manifest. Most observers agree that it occurs at a later stage in this disease than it does in carcinoma. Pain was found to be the most frequent presenting complaint. It occurred in 13 of 14 cases, or 92.9 per cent.

Nausea and vomiting were second in order of frequency and were present in 8 cases, or 57.1 per cent. In only 3 of these or 31.4 per cent, did the patient give a history of hematemesis. In 2 of our cases the pylorus was involved in the growth but in only 1 of these did the patient complain of vomiting. No hematemesis had ever been noted in this case and the vomiting was not of the type usually seen in pyloric obstruction. Almost all observers agree that vomiting and hematemesis occur less frequently in sarcoma than they do in carcinoma of the stomach.

The presence of an abdominal tumor mass was the next most frequent finding occurring in half of our cases. In 5 of these the mass had been discovered by either the patient or his local physician before admission to the clinic. The shortest duration of the tumor was 2 weeks, the longest 9 years, while the average duration was more than 4 years. In all cases the mass was located in the upper part of the abdomen, usually the left part of the epigastrium, and in most cases was said to be movable.

Melena occurred in 6 or 42.9 per cent, of our cases, and was the fourth most frequent complaint. Its usual duration was a few months but in 1 case it had been present intermittently for 15 years. Both Reeves and Fenwick have called attention to the frequency of hemorrhage in their patients and the latter estimates that it occurs in 50 per cent of cases.

Weakness and pallor occurred in 4 cases and were attributed to the secondary anemia present. The average concentration of hemoglobin for these cases was 46 per cent (6 grams per 100 cubic centimeters of blood). The

erythrocyte count averaged less than 3,500,000 cells in each cubic millimeter of blood.

Indefinite digestive disturbances were complained of in 4 cases, or 28.6 per cent. These were variously referred to by the patient as "gas on the stomach," "heart burn," dyspepsia, or indigestion. In the majority of cases they preceded other symptoms of the disease and in 1 case they had been present for 24 years.

Loss of weight was recorded in 3 or 21.4 per cent, cases but was not striking. The loss of 25 pounds (11.3 kilograms) in approximately 2 years was the greatest decrease noted.

The remaining symptoms occurred in an occasional case and consisted of constipation, anorexia, fever and dizziness or fainting in order of frequency. The only significant ones in this group are fever, dizziness, and fainting. Fever, though not common, was present in 3 of our cases and represented secondary infection of the tumor or formation of abscess. Dizziness and fainting were noted in 2 cases and in each case they heralded a severe gastric hemorrhage which soon became manifest by hematemesis or melena.

The arrangement of the foregoing symptoms into an ulcer pattern was noted a number of times. This was suggestive enough in 3 cases to enable a preoperative diagnosis of peptic ulcer to be made.

In a few cases the only symptoms complained of by the patient were those resulting from secondary complications of the gastric tumor. Infection, formation of abscess, perforation of the stomach, peritonitis, and other complications present typical clinical pictures with their characteristic type of pain, febrile course, and other symptoms.

Laboratory methods of diagnosis. No laboratory criteria have been established by which a definite diagnosis of gastric sarcoma can be made. Roentgenological examination is the most satisfactory, however, and while the type of malignancy may not be determined by this method, the diagnosis of a malignant gastric tumor almost always can be made. Kirkin and Weber, in discussing roentgenological diagnosis of neoplastic disease, stated that sarcoma of the stomach is rare and

"although unmistakable roentgenological evidence of the malignant nature of the process usually can be elicited, the roentgenologist is prone, on account of its comparatively low incidence, to designate the process carcinoma rather than sarcoma "

Gastroscopy has been employed recently in an effort to diagnose gastric sarcoma before operation Schindler expressed the opinion that this condition "may present a characteristic picture in the gastroscope which is entirely different from all other diseases of the stomach " In 1 of our cases a diagnosis of recurrent sarcoma of the stomach was made gastroscopically 2 years after surgical excision of the tumor

In former years considerable importance was attached to gastric analysis in the diagnosis of these lesions It was believed that the amount of free hydrochloric acid was normal or excessive in gastric sarcoma and, as we know, usually absent in carcinoma of the stomach This was used as a point of differential diagnosis In none of our cases in which the gastric analysis was reported was there complete absence of free hydrochloric acid All had approximately normal free and total hydrochloric acid determinations with the exception of 1 case which was slightly higher than normal Westphalen reported a case in which he made a diagnosis of gastric sarcoma by microscopic examination of a bit of tumor tissue obtained by gastric lavage

It would seem, then, that in order to make a diagnosis of sarcoma of the stomach, the clinical picture and laboratory findings must be considered carefully as a whole and differentiated from those characteristic of other gastric lesions without too much reliance being placed on any one particular finding Frazier summed up the picture well by saying, "in a patient presenting gastric symptoms of several months' duration with a readily palpable, freely movable tumor of the stomach but without loss of weight, general debility and cachexia common to carcinoma of the same duration, one might be justified in suspecting sarcoma "

Differential diagnosis In the differential diagnosis of leiomyosarcoma, hemangioendothelioma, and fibrosarcoma of the stomach,

the lesion which simulates them most closely, of course, is lymphosarcoma In view of the fact that sarcoma is practically never differentiated clinically from other malignant and, in some cases, benign lesions, it would be absurd to attempt to establish criteria here by which specific types of sarcoma could be recognized clinically

There are, however, a few differentiating characteristics which may be mentioned Lymphosarcoma is likely to occur in younger persons, 30 to 40 years of age, is of higher grade malignancy and so runs a more rapid course with earlier metastasis than other types of gastric sarcoma The pylorus is involved more frequently and, while it often remains unobstructed in spite of this, disturbances of gastric motor function are more common A palpable abdominal mass is encountered less often Involvement of the mucosa by infiltration occurs relatively early, resulting in earlier and more severe pain and greater tendency to gastric hemorrhage, infection, and perforation Cachexia is more severe and earlier in its occurrence There is more likely to be an associated enlargement of the spleen, and lastly, lymphosarcoma is highly sensitive to irradiation therapy

Carcinoma is by far the easiest lesion to confuse with sarcoma of the stomach and in most instances is practically impossible to differentiate with any degree of accuracy Certain differentiating features exist, however, but none is conclusive Gastric carcinoma, as a rule, occurs late in life, the average age being about 60 years It is a tumor of epithelial origin and consequently involves the mucosa first Because of this, ulceration with its resultant hemorrhage, infection, and perforation occurs earlier and more frequently than in gastric sarcoma Carcinoma is usually infiltrative and involves the pylorus in about 60 per cent of the cases For this reason symptoms of pyloric obstruction and gastric retention are much more common Carcinoma of the stomach is a much more rapidly growing lesion than sarcoma, is more malignant, runs a considerably shorter course, metastasizes earlier, and is accompanied by more severe systemic effects such as secondary anemia, emaciation, and cachexia A palpable

abdominal mass is less likely to be encountered unless very late in the course of carcinoma and then it usually is fixed.

There remain so many lesions which must be considered and ruled out when arriving at a diagnosis of gastric sarcoma that it is impossible to give their distinguishing features here. Of these, benign gastric ulcers are probably the most important because of their frequent occurrence. Benign leiomyomas may simulate sarcoma if they attain considerable size. These are considered the most common tumor of the stomach by Rlenlets, who found them present in 16 per cent of routine necropsies. Other benign gastric lesions to be considered are pedunculated polyps and gastric syphilis.

Tumors and cysts of almost any of the abdominal viscera may be confused with gastric sarcoma. Splenomegaly especially that occurring in Banti's disease, in which associated gastric hemorrhages and secondary anemia are common is often difficult to differentiate from gastric sarcoma.

PROGNOSIS

The prognosis in all forms of gastric malignant neoplasia necessarily must be guarded and sarcoma is no exception to this rule. The particular type of sarcoma has a great deal of bearing however on the ultimate prognosis. It is accepted by most observers that the types discussed here namely leiomyosarcoma, hemangioendothelioma or angiosarcoma, and fibrosarcoma, offer the best prognosis.

W. J. Mayo stated that in his experience he was impressed by the longer course and better surgical results obtained in gastric sarcoma as compared with gastric carcinoma.

Hemangioendotheliomas offer the best prognosis of any of the gastric sarcomas. Clignoz called attention to the chronic course of hemangioendotheliomas and maintained that symptoms develop gradually and are not pronounced until late in the course of the disease, and that emaciation and metastasis are absent. One of our patients was living and perfectly well when last heard from, 13 years after partial gastrectomy at the age of 10 years, for a hemangioendothelioma of the stomach.

The pedunculated form of gastric sarcoma offers a better chance of cure than the infiltrating type because it is more easily removed surgically and is usually one of the less malignant types. The diffuse infiltrating forms, almost always lymphosarcoma, are rapidly growing tumors and less amenable to surgical removal. For this reason they may offer even a worse prognosis than does carcinoma of the stomach.

In our group of 14 cases, comprising only leiomyosarcomas, hemangioendotheliomas and fibrosarcomas, 7 of the patients are known to be dead at the time of writing. Six patients were living when last heard from and 1 patient was lost track of soon after operation. Of the patients who have died the average duration of life after operation was 3 years and 4 months. In the 6 patients who were living when last heard from, the average duration of life following operation was more than 4 years.

TREATMENT

The treatment of sarcoma of the stomach, regardless of cell type is surgical. Leiomyosarcomas, hemangioendotheliomas and fibrosarcomas usually remain locally operable and without metastasis until rather late in their course. Counseller and Collins emphasized the fact that these tumors at first appear to be inoperable because of their size and the adherence to them of the greater omentum and viscera. They expressed the opinion, however that the sharp line of demarcation from normal stomach wall makes extensive resection possible. For this reason Balfour and McCann recommended abdominal exploration in spite of a roentgenological report of inoperability.

Glenn and Douglas claimed that sarcoma has a better operative prognosis as a group than carcinoma and that of sarcomas, leiomyosarcoma, hemangioendothelioma, and fibrosarcoma are more amenable to surgical measures than lymphosarcoma.

In our patients partial gastric resection was carried out in 8 cases, of which 5 were of the posterior Polya type, 1 was an anterior Polya resection, and 2 were segmental resections. Local excision of the tumor was done in 3 cases and 3 cases were simply abdominal explorations in which specimens for biopsy

re removed from inoperable tumors for microscopic diagnosis

Additional surgical procedures were performed in 2 cases. In 1 of these pyloroplasty was done in addition to the segmental resection. In another in which the tumor had been excised locally gastrostomy was performed and radium was inserted.

There were no postoperative deaths in our series of 14 surgical cases. The shortest duration of life following operation was 3 months. Only 1 case was any serious postoperative complication mentioned and this was bilateral bronchopneumonia from which the patient made a satisfactory recovery.

Aside from surgical intervention, irradiation offers the only method of treatment of sarcoma of the stomach. Its field is limited, however, and it rarely proves of value in sarcomatous lesions other than lymphosarcoma. Lymphosarcoma is highly sensitive to irradiation and Desjardins stated that early lesions of this type may be cured by irradiation alone. Repeated series of roentgen irradiation were used as an adjunct to operation in 2 of our cases, in 1 of which radium was also used as a supplement. In 1 of these cases the lesion was inoperable and the patient lived more than 6 years with metastatic growths present in the liver all the time. The other patient suffered a recurrence 2 years after operation.

SUMMARY

Fourteen histologically proved cases of gastric sarcoma, exclusive of lymphosarcoma and including 11 leiomyosarcomas, 2 hemangioendotheliomas or angiosarcomas, and 1 fibrosarcoma, in which operation has been performed at the Mayo Clinic between 1908 and 1938, inclusive, were studied clinically and pathologically.

An attempt has been made to simplify the terminology and classification of sarcoma of the stomach and to point out the clinical and pathological features distinguishing the leiomyosarcomas, hemangioendotheliomas, and fibrosarcomas as a group separate from lymphosarcoma.

CONCLUSIONS

The cause of sarcoma of the stomach is unknown. Evidence may be found pointing to

its origin in normal cells, congenital isolated cell rests, traumatized or inflamed tissues, benign tumors, and gastric ulcers. Males were affected in 64.3 per cent of our cases. The average age for the group was 43.2 years.

All sarcomas of the stomach may be classified into four types: lymphosarcoma, leiomyosarcoma, hemangioendothelioma or angiosarcoma, and fibrosarcoma. The last named three most often involve the curvatures of the stomach, more rarely the pylorus or cardia. They originate in the submucous or muscular layers of the stomach wall, are usually well circumscribed, are often pedunculated, and tend to assume an exogastric or endogastric form, although in rare cases, they may be infiltrating.

They may be composed of round cells or spindle cells, large or small, depending on the proliferative activity of the growth and the amount of cellular differentiation. Histologically the cells group themselves in a characteristic arrangement of interlacing bundles and whorls.

Leiomyosarcoma, hemangioendothelioma, and fibrosarcoma are usually of an average grade of malignancy. Metastasis occurs in about a third of the cases, the most common sites being the regional perigastric lymph nodes and the liver.

There are no pathognomonic clinical findings or laboratory criteria on which a definite diagnosis of sarcoma of the stomach can be made. The clinical and laboratory picture must be considered as a whole and the fact that the malignant nature of the lesion is recognized is the one of prime importance. The onset may be sudden or insidious. Symptoms usually appear late and the duration of symptoms before treatment averages $3\frac{1}{2}$ years. The chief signs and symptoms in their order of frequency are pain, nausea and vomiting, abdominal tumor, melena, weakness and pallor, digestive disturbances, hematemesis, and loss of weight. Frequently patients give a history suggestive of peptic ulcer. No laboratory procedures are considered definitely diagnostic, although roentgenographic examination usually establishes the malignant nature of the lesion. Carcinoma of the stomach offers the greatest differential diagnostic

problem. Other lesions to be considered are benign gastric tumors and ulcers and tumors or cysts of almost all the abdominal viscera.

The prognosis, while guarded is better than that of lymphosarcoma or carcinoma. Secondary complications, such as ulceration, hemorrhage, infection, formation of abscess, perforation, peritonitis, and metastasis, make for a much poorer prognosis. The particular cell type is a factor in the prognosis. The more mature the cells and the slower the growth, the better is the prognosis. There were no operative or immediate postoperative deaths among our 14 patients.

The treatment of choice is operation and it is the only treatment that has anything to offer in leiomyosarcoma, hemangioendothelioma, or fibrosarcoma. Lymphosarcoma responds readily to irradiation but this form of treatment is of little value in other types of gastric sarcoma.

PNEUMONIA AS A COMPLICATION OF BILIARY COLIC

SAMUEL LEVINE, M D , and J JACOB SCHNEIDER, M D , Brooklyn, New York

ONE of us began to practice medicine more than 31 years ago, and almost immediately encountered cases in which the illness started as a frank attack of biliary colic and soon after developed into pneumonia. At the onset there was no fever, cough, dyspnea, or abnormal physical signs in the lungs. On the contrary, severe epigastric or right upper quadrant pain prompted the patient to seek help, the pneumonia came as an unpleasant surprise to us and to the patient's family. While the usual abdominal complications of biliary colic had been explained, we did not expect the complication of pneumonia which proved to be most annoying and at times even hazardous. About 20 years ago one of our patients, a middle aged woman, died of pneumonia although the coexisting gall-bladder attack had subsided. During the first 15 years, in a large general practice, no time or opportunity was afforded to study this problem. We kept no record of the cases, but there must have been 6 or possibly 9 during that period. The case referred to was the only one we can remember which terminated fatally. As a result of this experience we began to fear pneumonia more than the other better known complications, and it was always a source of amazement to us that neither the current medical literature nor discussions in medical societies made mention of this complication.

However, during the past 16 years we have had an opportunity to practice in a hospital, and this has given us a better chance to study such cases. Laboratory facilities were also thus available, in addition to knowledge obtainable from cases of other members of the staff. As a result of our study we have become convinced that our early impressions were correct.

A search of our hospital files for the years 1921 to 1940 revealed 11 instances which exemplify the complication here described. A number of other cases of biliary disease with

pneumonia were noted, but the histories failed to reveal the sequence of events described so they are not included here. Cases of postoperative pneumonia were properly excluded, although it seemed to us that in many instances the pneumonia probably existed before the operation.

CASE 1 No 108367 R G, female, aged 48 years. She had had an attack of biliary colic 4 years ago. On October 6, 1940, the patient was seized with an attack, in the right upper quadrant of the abdomen, of severe pain which radiated to the back. She vomited several times. An injection of morphine was given. The next day she had another similar attack, for which she again received morphine. The temperature was normal and the lungs were clear. The pain continued. She then began to cough a little, but there was no expectoration. On October 10 the patient was admitted to the surgical service of the Beth-El Hospital with a diagnosis of acute cholecystitis. The temperature on admission was 104 degrees F, the pulse was 120, and the respirations, 42 per minute. Bronchovesicular breathing and moist râles were heard over both lower lobes posteriorly, more on the right than on the left. The gall bladder was greatly enlarged, reaching almost to the iliac crest, and was very tender. The patient was transferred to the medical service. X-ray examination of the chest confirmed the clinical diagnosis of bilateral pneumonia. The white blood cells numbered 17,700 with 86 per cent polymorphonuclear cells. The blood culture was negative. Sul fapyridine was given, but was discontinued on October 14 because of the appearance of jaundice and bile in the urine. Oxygen was also given. The temperature came down to normal by October 12. On October 15 she had another attack of biliary colic which required morphine. Following this her temperature rose to 102 degrees F. On October 24 there was another rise in temperature following another attack of colic. The pulmonary signs gradually cleared up, but the gall bladder remained palpable. A flat plate of the gall-bladder region on October 20 revealed numerous gall stones.

It is noteworthy that although this patient was extremely ill she had only a slight cough and no expectoration at all. She refused operation and was discharged on November 4, 1940.

CASE 2 No 28542 L E, female, aged 60 years. Illness began on June 1, 1928, with pain in the right upper quadrant of the abdomen. On June 9 there

From the Medical Service, Beth El Hospital

was pain in the left lower chest. The next day the patient began to cough and expectorated bloody sputum. She was admitted to the hospital on June 3.

The gall bladder was enlarged and tender and there was consolidation of both lower lobes more extensive on the left side. Two days later an x-ray examination of the lungs showed slight haziness of the left base. The temperature reached normal in 6 days, and the patient made an uneventful recovery.

CASE 3 No. 86 R. H., female aged 36 years. This patient gave a history of repeated attacks of biliary colic with jaundice extending over several years. Her present illness began on August 6, 1937 with a typical attack of biliary colic. On August 8 she began to cough, and the temperature rose to 100.8° F. She was admitted to the hospital on the following day with a large tender gall bladder and with pneumonia of the right lower lobe. The patient made an uneventful recovery.

CASE 4 No. 85600 Z. C., female aged 47 years. One year before admission to the hospital the patient had a typical attack of biliary colic. Her present illness began on August 15, 1937 with diarrhea, chills, fever and headache. 24 hours later she developed severe abdominal pain which became localized to the right upper quadrant of the abdomen. Morphine was administered. Two days later she was admitted to the hospital. The gall bladder was enlarged and tender; the lungs were clear. Three days later there was a definite pneumonia of the left lower lobe and 4 days after that the right lower lobe also became involved in the pneumonic process. An x-ray film confirmed the diagnosis of bilateral pneumonia. The gall bladder increased in size reaching almost down to the iliac crest, and the leucocyte count rose to 15,000, with 80 per cent polymorphonuclear cells. An operation was advised. However the patient refused operation and signed herself out of the hospital on August 26. (We learned later that the symptoms gradually subsided and the patient got well, without operation.)

CASE 5 No. 66907 A. A., female, aged 70 years. The patient had an attack of biliary colic 6 years ago and another attack 3 months ago. The present illness began on April 20, 1939 with pain in the right upper quadrant of the abdomen. On examination large, tender gall bladder was found. On April 25 she was admitted to the hospital. In addition to the large gall bladder a lag of the right chest was noted, and a few rales were heard at the right base. Within the next few days she developed a full-blown pneumonia involving the entire right lung and the left lower lobe. This was confirmed by an x-ray film of the chest. There was very little cough and no sputum. The patient made an uneventful recovery and left the hospital on May 5, 1939.

A search of the literature pertaining to this subject revealed very little. Neither text

books on general medicine nor special books on the gall bladder make mention of pneumonia as a complication of biliary colic. The most recent book on this subject (6) published in 1940 discusses at great length the various complications of biliary disease but entirely omits pneumonia. Carter Greene and Twiss describe impairment of resonance and diminution of breath sounds due to elevation of the diaphragm secondary to sub-diaphragmatic pathology. Wilkie states that due to the rigidity of the right half of the diaphragm, as proved by x-ray examination, the picture may therefore resemble a primary right-sided lung affection. The chill at the onset, the thoracic pain, the catch in the breathing combined with the fact that owing to the immobile diaphragm and deficient expansion of the right base crepitations are frequently to be heard on auscultation all these features may divert attention from the abdomen to the chest. Many of my patients gave a history of previous attacks diagnosed as congestion of the lung. The pulmonary signs should always be looked for and assessed at their true value. In 1912 Bahrdt (2) described cases of obscure fever with the physical signs of pneumonia either in the right or left, or in both bases, without the symptoms or signs of gall bladder disease. The fever subsided but frequently recurred. Eventually gall-bladder tenderness, or perhaps icterus, developed and the diagnosis of gall bladder disease became evident. He thinks that the gall bladder was the cause of the infection. His cases ran a protracted but mild course. However they differ from ours, because ours began as frank attacks of biliary colic without any signs or symptoms of pneumonia. The following case is an example of the type described by Bahrdt.

CASE 6 No. 82995 A. S., female, aged 60 years. The patient gave a history of repeated attacks of biliary colic. Cough and expectoration were also present for many years. The present illness began March 1937 with fever, cough and expectoration. She was admitted to the hospital on March 20. Her temperature was 100.8° F, pulse rate 6 respirations per minute. X-ray examination revealed pneumonia of the right lower lobe. Tenderness in the right upper quadrant of the abdomen was noted on admission, but this was over

shadowed by the pneumonic symptoms. On March 22, jaundice developed and the gall bladder was found to be enlarged. The patient made an uneventful recovery.

This case makes us speculate whether a more careful history might not have revealed symptoms of biliary colic preceding the pneumonia.

In 1929, Akaiwa and Ishida reported 7 cases, a few of which are good examples of the type described by us. They called attention to the fact that "lung and bronchial inflammations very often follow biliary tract infections."

ETIOLOGY

The exact mechanism which operates to bring about inflammation of the lungs in gall-bladder disease is not known. Moreover, inflammations of other abdominal organs are also frequently complicated by pneumonia. We can recall a number of instances of pyelitis and pyelonephritis in which this complication arose. We were frequently at a loss to explain the fever of long duration by the renal infection alone. A careful examination of the lungs revealed the pneumonia. When this cleared, the fever subsided. Furthermore, it is very likely that the factors which are responsible for the production of pneumonia after abdominal operations are also responsible for the pneumonia that follows intra-abdominal inflammations. Intra-abdominal infection is commonly present in both cases. Also, spasm and elevation of the diaphragm and the shallow breathing induced by morphine are present in both conditions. Pulmonary atelectasis and bronchopneumonia may then ensue. The recumbent posture makes proper feeding difficult and tends to bring about aspiration pneumonia. Waters made "An attempt to reduce to a common denominator the etiological factors involved in the production of pulmonary complications," and came to the conclusion that, "with rare exceptions, such morbidity follows a period of interference with the normal functions of the respiratory mechanism, whether due to drug action, trauma, or illness."

Direct extension of the infection through the diaphragm to the lungs is a possibility, Kehling and Kehr, according to Akaiwa and

Ishida, favor this idea. However, there is no proof that this really takes place. One of Bahrdt's (3) cases came to autopsy 13 years after the pneumonia, no pathological changes were found in the right diaphragm, pleura, or lung. Akaiwa and Ishida injected pneumococci and staphylococci into the gall bladders of dogs, and succeeded in producing acute pneumonitis in some of the animals, provided the organisms were virulent and the common bile ducts were tied off. They think that the infection spreads through the blood stream. This is also Bahrdt's (3) opinion. If this were so, we would expect to find an equal distribution in all lobes. Actually, in our 11 cases as well as in those of Bahrdt and Akaiwa and Ishida, we found that although the lesion was usually bilateral, it was almost always confined to the lower lobes, with the right side predominating both in frequency and extent. In 7 of our 11 cases the lesions were bilateral, 3 involved the right lower lobe only, and 1 the left lower lobe only. While we realize that the number of cases is not sufficiently great to be significant statistically, this distribution suggests that no single factor can satisfactorily explain this complication.

CLINICAL FEATURES

One of the features which struck us particularly in these cases was the almost complete absence of cough and expectoration in most of the patients. We have no explanation for this. All 11 of the patients were females, varying in age from 29 to 70 years, with an average of 54.1 years. The interval between the onset of the biliary colic and the pneumonia was usually from 2 to 6 days, but in a few cases it was as long as 2 to 3 weeks. The white blood cell count varied from 8,400 to 21,000 (average 13,200), with from 71 to 92 per cent polymorphonuclear cells (average 83 per cent). Blood culture was done in 3 cases and was negative in each instance. Sputum typing could not be done in most of the cases because of the lack of sputum. All of the patients recovered. This we feel is noteworthy in spite of the smallness of the series, because of the advanced age of most of the patients, and the fact that they were suffering from two severe acute illnesses at the same

STUDIES IN DIETHYLSTILBESTROL

II Differences In Response of Radium Induced and Physiological Menopause

III Effect on Liver

ROBERT C. GRAUER, M D and ELLEN NUGENT R.N.

Pittsburgh, Pennsylvania

THE need for an effective estrogenic substance that does not require parenteral administration appears to have been met with the synthesis of diethylstilbestrol (4,4-dihydroxy- α -beta diethylstilbene). This compound was developed in 1938 by Dodds, Goldberg, Lawson and Robinson who showed it to be active in oil, alcohol, water and as the acetate. They found it to be two to three times as potent as estrone under similar conditions. It bears no chemical relationship to estrone since it possesses no phenanthrene ring, but it produces almost identical physiological effects. The only biological differences that were observed were that stilbestrol has an appreciably less stimulating action on the mammary tissue than does estrone (5) that though stilbestrol like estrone will inhibit the comb growth in capons when injected simultaneously with androsterone, it does not inhibit comb growth when applied to the comb by inunction (9, 10). This latter phenomenon has not yet been explained. However percutaneous absorption does occur and estrus can be produced in spayed mice whose necks are painted with stilbestrol in oil (10). Palmer and Zuckerman further showed that it was absorbed through the vaginal mucous membrane of spayed mice causing estrus to supervene.

The action and the effect of this synthetic estrogen on the human has been the subject of reports in Europe (16) and in this country (2, 7, 15). The reports all agree as to its effective use in producing clinical improvement in the symptoms of the menopause and in producing biological changes similar to those obtained with parenteral estrone or

estradiol but they vary in their evaluation of the development of undesirable side effects. It is with justifiable trepidation, therefore that this product was employed in preliminary studies and that its unqualified recommendation for general use was held in abeyance. Our study on several groups of patients, supplemented by laboratory observations, is presented in the hope that more information may be gained concerning the manner of its action and that a better evaluation of its indications and manner of administration may be secured.

METHODS EMPLOYED

The stilbestrol was administered orally in varying doses to two groups of women. One group consisted of patients who were suffering from the menopause syndrome and the other of postpartum women in whom large doses of stilbestrol were employed in order to observe its efficacy to inhibit or stop lactation. The latter group is discussed in a subsequent communication. The first group consisted of 28 menopause cases, 10 of which were radium induced, 11 surgically produced and 7 physiological cases. The subjective symptoms of each were observed before treatment was instituted and a definite routine was followed in the course of the study. It was believed desirable to study the three types of menopause cases separately since it had been our experience that radium induced cases were generally more refractory to treatment and because such patients required considerably larger doses in order to be controlled. The patients were seen at weekly intervals for a period of 4 to 5 months. During their visits vaginal smears were done and interpreted according to the criteria of Papanicolaou and Shorr. Endometrial biopsies were performed before treatment was J, then again 2

From the Department of Research in Endocrinology and Metabolism of the Wm. H. Sanger Memorial Research Laboratory of the Allegheny General Hospital, Pittsburgh, Pennsylvania.

TABLE I—SIDE EFFECTS OF STILBESTROL

	No of patients	Nausea	Vomiting	Breast pain	Abdominal or pelvic pain	Muscle cramps	Skin eruptions	Pruritus vulvae	Daily dose mgm	Relief of menopausal symptoms—%	Bleeding response
Radium menopause	10	6	5	1	8	3	1	4	2-3	100	3
Surgical menopause	11	6	5	3	8	0	0	1	0.1-1.0	100	
Physiological menopause	7	4	1	0	6	2	0	3	0.1-1.0	100	6
Total side effects	28	16	11	4	22	5	1	8			
Complete recoveries		13	11	4	10	5	1	7			

eks after treatment was started, and finally weeks after beginning the administration of stilbestrol. Urinalyses were done and the patients' subjective complaints tabulated regularly. The degree of amelioration of the menopause symptoms was observed during treatment, and the development and duration of toxic disturbances were noted simultaneously.

The radium treated patients had suffered from a bleeding dysfunction and varied in age from 42 to 50 years at the time that the radium was inserted. Previous to the radium treatment, diagnostic endometrial curettements had been done in order to rule out the possible existence of malignancy. These curettings served as a means of comparing subsequent endometrial biopsies that were secured after a period of treatment with stilbestrol. The patients were given 3 milligrams of stilbestrol daily by mouth so that a total of 14 milligrams had been administered in 5 weeks. Using a Meig's curette to secure endometrial biopsy tissue after 2 weeks' treatment, only 4 patients yielded sufficient material for examination. After 5 weeks' treatment, 8 of the 10 radium cases studied yielded enough material for examination. The 2 other patients exhibited complete closure of the external os, thus preventing the introduction of the curette. All the cases thus studied showed a proliferative nonsecretory endometrium which tended to duplicate in every way the picture of the endometrium before the radium was inserted. The modifying effect of the radium on the response of the endometrial glands, stroma, and myometrium to the stilbestrol was quite interesting and has been reported elsewhere (6). After the maximum

biological effect of stilbestrol was observed, the patients were maintained on treatment for a total period of from 3 to 4 months, during which time each had received approximately 324 milligrams of the drug.

OBSERVATION OF CLINICAL EFFECTS

In the hope that the side effects of the stilbestrol might be reduced to a minimum, it was decided to employ smaller doses at the beginning of treatment. Whereas 2 to 3 milligrams of stilbestrol were given daily to the radium induced cases, only 0.1 to 0.3 milligram was given daily to the surgical castrates and to the physiological menopause cases. The dose was then gradually increased. With the exception of vomiting, this did not appear to make an appreciable difference in the number of undesirable side effects that were experienced. Reference to Table I shows the range of undesirable or toxic symptoms experienced by our patients as well as the percentage of improvement. In all cases the well known symptoms of hot flashes, irritability, depression, and lassitude were either eliminated or so much relieved that they could be regarded as complete recoveries. Several patients who had received previous treatment with natural estrogens in single doses of 10,000 international units volunteered the information that the stilbestrol was much more effective and gave them a more pronounced feeling of well-being. This was especially true in the radium induced cases. The type of menopause apparently did not influence the development of toxic symptoms, though considerably more stilbestrol was necessary to control the menopause symptoms in the radium cases than for the physiological and surgi-

TABLE II.—INFLUENCE ON ENDOMETRIUM AND VAGINA IN RADIUM INDUCED CASES

	Uterine reaction	Atrophic vaginitis	Endometrial hyperplasia	Secondary amenorrhea	Atrophic vaginitis	Endometrial hyperplasia
Before radium	Not taken					
After radium	Menstrual pause	3				
5 weeks treatment (all smears)	No response					
3 weeks treatment (14 smears)	responded					

cal types. With the exception of 3 of the 16 patients who complained of transient nausea and 11 of the 23 patients who stated that the recurring abdominal pain persisted all toxic symptoms disappeared as the treatment progressed. Five patients complained of intermittent cramps in the calf and thigh muscles and one patient experienced this discomfort in the muscles of the forearm. The cramps occurred chiefly during the night while the patients were lying down or during sleep, causing the patients to be awakened. It would also occur at times when arising in the morning. Fifty per cent of the radium induced cases experienced vomiting early in the course of treatment while only 14 per cent of the physiological cases were thus affected. This can be explained by the fact that the radium treated patients received 10 to 30 times as much stilbestrol as did the physiological cases. The only reference to the drug's effect on muscle was that made by Dawson and Robson whose studies were limited to its inhibitory influence on smooth muscle. No reference to its effect on skeletal muscle was found. None of the patients who experienced the undesirable side effects considered the discomfort sufficient to discontinue the drug. It is interesting to observe that none of the postpartum patients who were given large daily doses (5 to 10 mgm.) suffered side effects.

The proliferative endometrium produced by stilbestrol apparently results in bleeding which may (17) or may not (6) be regarded as a type of so called "withdrawal bleeding." All of our patients were treated without a rest period and we are therefore reluctant to consider the bleeding that ensued following treat-

ment for variable periods of time as due to sudden deprivation. Six of the 7 cases of the physiological group bled when a total dose of 90 to 100 milligrams was administered over a period of 4 to 6 weeks. Of the radium treated patients only 3 of the 10 showed bleeding during treatment extending over a period of 4½ months. In all cases in which bleeding occurred it began after treatment was in progress for approximately 6 weeks. We consider the fact as being of significance that bleeding ensued regardless of whether or not we employed the "deprivation method," especially since bleeding occurred in 86 per cent of the physiological cases but in only 30 per cent of the patients in whom the endometrium had been exposed to the effects of radium. Discussion of this fact will be taken up later.

LABORATORY STUDIES

The important laboratory studies concerned themselves chiefly with the vaginal smears, endometrial biopsies (Table II) and liver function tests (Table III). The potent biological effect of stilbestrol as mirrored by the vaginal smear method and the stimulation of the endometrium to proliferation has been amply observed (5, 10, 15). Our experience with but one exception, is in agreement with those of other workers in the field. The exception observed was a distinct difference in the time of biological response in the radium cases as compared to the physiological and surgical cases. It has been generally observed that vaginal epithelial and endometrial response occur after 2 milligrams of stilbestrol has been administered daily for a period of 1 to 2 weeks. This occurred in those patients in whom no irradiation had been employed. The patients treated with radium gave no endometrial or vaginal epithelial response after 2 weeks treatment. At the end of 5 weeks treatment a proliferative endometrium was observed and definite vaginal smear response took place. The physiological and surgical patients showed no such tendency toward a refractory state.

STUDIES OF THE EFFECT ON LIVER

During the course of the study we were especially concerned with the effect of stil-

bestrol on the liver In view of the moot question as to whether there is an impairment of liver function in consequence of treatment, 2 different liver function tests were performed on each of 14 patients and a single test on each of a group of 9 patients The bromsulphthalein test (13) was done 6 to 8 weeks after treatment was initiated and again 9 weeks after treatment was started Cognizant of the limitations of any single test as an indication of hepatic function, we supplemented this test with the hippuric acid synthesis test of Quick at intervals of between 3 and 5 months When the dose of stilbestrol was not very large, the hippuric acid synthesis test alone was employed The results obtained by Shorr and others who performed preliminary tests, indicate that the discrepancies observed in the hippuric acid synthesis test cannot be explained on the basis of resultant liver damage Ten patients showed an excretion of hippuric acid of less than 30 grams in 4 hours Of this number only one showed an excretion of less than 20 grams The 9 others were within a range of 25 grams It would be hazardous to suggest that this slight decrease can be interpreted as indicating liver damage, especially since it has been observed in some cases (15) that the hippuric acid synthesis shows improvement following administration of stilbestrol No retention of the bromsulphthalein was observed at the end of one-half hour in any of the cases studied As a result of our analyses it appears that the employment of stilbestrol in physiological doses gives no evidence of demonstrable liver damage in the human

STUDY OF THE EFFECT ON DOG'S LIVER

The important consideration regarding the possible toxicity of diethylstilbestrol concerned itself with the effect of this drug on the liver Aware of the limitations of present methods of evaluating liver function in the human, we turned our attention to the possible development of some anatomical (histopathological) disturbance as a result of its use Twelve full grown dogs were employed in the study The dogs were raised in our own laboratory and all had been on a standard ration since birth They were divided into 3

¹ Treatment started in each case October 30 1939

groups of 4 each, the sexes being equally divided The first group received 5 milligrams of stilbestrol dissolved in oil which was injected intramuscularly daily The second group received 10 milligrams daily, and the third group served as a control Treatment was continued for approximately one month—from November 29, 1940 to December 24, 1940 It should be observed that weight for weight, the amount of stilbestrol administered to the dogs as compared to the average human

dose was approximately 6 times as large. At the end of the injection period the dogs were anesthetized with nembutal and biopsy specimens of the liver were obtained.

Microscopic examination failed to show any difference between the livers of the treated dogs and those of the controls. These findings indicated that if a deleterious effect were present as a result of the use of diethylstilbestrol it was not reflected microscopically in the liver.

EVALUATION OF STUDY

Response of the uterus and vaginal epithelium to treatment in the menopause patient varies with their ability to be influenced by the drug. When physiological involution has occurred, stimulation can be readily accomplished with the natural and synthesized estrogens. Radium induced menopause presents a decidedly different problem due to the type of injury resulting from its use. The radium treated patient affords an excellent means of evaluating the potency of an estrogenic substance. Stilbestrol, by mouth was found to be effective in radium treated patients who had been refractory to previously employed parenteral preparations.

The differences in response to treatment between the physiological cases and the radium induced menopause are several. It required a longer period of preliminary treatment and the use of a dose five times as large to secure a satisfactory clinical response as well as comparable endometrial and vaginal epithelial change, as determined by biopsies and smears, in the radium treated patients as in the physiological cases. In addition to this, it is striking that only 30 per cent of the radium treated patients experienced vaginal bleeding while it occurred in 86 per cent of the physiological cases. In 2 of the 3 radium cases that had vaginal bleeding the duration was $\frac{1}{2}$ to $\frac{1}{3}$ days and was extremely scanty. In all of the physiological cases patients showed more profuse and extended periods of bleeding. An explanation of this observation lies in the effect of the radium on the uterus as reported by us (6) previously. The radium produces a marked degree of hyalinization of the stroma and portions of the myometrium as well as tending to destroy practically all of the gland

ular structures. There is an associated endarteritis with a consequent interference in capillary permeability. It may be this latter condition which accounts for the diminished bleeding response that is observed in the patients treated with radium.

We limited our studies of toxicity of stilbestrol to clinical evaluation assisted by liver function tests. The knowledge that the natural occurring estrogens are metabolized in the liver centered most of the attention on that organ. Our animal studies were chiefly concerned with the possible acute toxic effects on the liver. As previously mentioned we were unable to demonstrate any lesion in our treated dogs. Russell and co-workers recently reported their findings of chronic toxicity studies with stilbestrol. Employing rats, they found no pathological lesions in any of the organs save for an instance of cloudy swelling of the kidneys, although 5 times the average human therapeutic dose was used. When 26 times the therapeutic dose was employed, cloudy swelling of the kidneys was found to be present in 4 of 49 rats treated. Gastric hemorrhage and hemorrhage into the adrenals were observed in 1 animal. More extensive damage was reported when doses 523 times the human therapeutic dose were employed. It would apparently be the height of folly to condemn a drug because doses of such magnitude produced untoward effects. Morrell recently reviewed all of the clinical reports in this country and abroad and found no permanent toxic effects as evidenced by liver function tests, blood and urine chemistry and histological examination of the blood and bone marrow.

CONCLUSIONS

1. Diethylstilbestrol was employed to observe the differences in response to treatment of physiological menopause cases and radium induced cases. Its influence on liver function was also studied.

2. Radium induced menopause patients require larger doses and more prolonged treatment with stilbestrol than do physiological cases.

3. Bleeding response to treatment occurred in 86 per cent of the physiological cases and in only 30 per cent of the radium induced cases.

4 The undesirable side effects of stilbestrol are transient and are not sufficient to act as a deterrent to its use

5 Liver function tests and histological studies of dogs' livers failed to show hepatic damage after excessive doses of stilbestrol

A STUDY OF THE MECHANICS OF BILE FLOW

II Responses to Intraduodenal Solutions

DONALD D KOZOLL, M.D. and H. NECHELES, M.D. Ph.D. Chicago, Illinois

In a previous paper we presented a method for simultaneous observation of the responses of the three factors we considered most important in determining the flow of bile, namely the contractility of the gall bladder the resistance of the sphincter of Oddi, and the tonus and motility of the duodenum. We confirmed the repeated observations of others on the independent activity of the sphincter and duodenum. In addition we reported our observations on the influence of physiological intravenous solutions on these structures (13).

Using the same experimental procedure on anesthetized dogs, we have studied the effects of various solutions introduced into the duodenum through a glass cannula which, projecting beyond the recording balloon, was tied around the cannula. All solutions were retained within the duodenum for a uniform length of time (2 minutes).

Intraduodenal instillation of 20 cubic centimeters of fresh gastric juice procured from dogs with Pavlov pouches of 1:12 to 1:14 1/10 normal hydrochloric acid concentration was observed on 13 occasions in 10 dogs. In every instance not complicated by previous medication an immediate marked elevation in sphincteric pressure coincident with a marked duodenal spasm was elicited both persisted for a considerable length of time after the juice had been permitted to drain out of the duodenum (Fig. 1). The gall bladder usually showed no characteristic response but in 2 instances there was a slightly increased tonus associated with an increase in motility. Blood pressure frequently revealed a 10 to 15 millimeter drop immediately following the injection.

From the Department of Gastro Intestinal Research, Michael Reese Hospital.

A preliminary report was read at the meetings of the American Physiological Society, April 16, 44, Chicago.
Dr. Kenneth Bernard Forde Research Fellow in Surgery

Injection of similar amounts of tenth normal hydrochloric acid into the duodenum was followed by identical responses, although our gastric juice was slightly more acidic. Oddi, in his original work, stated that dilute hydrochloric acid caused a spasm of the sphincter but later work has been contradictory (5, 8, 9, 18).

Antispasmodics, such as atropine and trauentil, did not prevent the effect of gastric juice (refer to previous paper Fig. 4). No significant changes in gall-bladder tone or motility were observed following intraduodenal administration of hydrochloric acid or gastric juice. This is contrary to the experience of others (9, 18) but agrees with that of Bainbridge and Dale.

Twenty cubic centimeters of 1/20 normal sodium hydroxide instilled into the duodenum of 3 dogs, produced marked responses in each case. These were characterized by sphincteric spasm producing a prolonged rise in intraductal pressure (100 mm. and above). The duodenum responded with a marked increase in tonus and motility which did not always parallel the change of the sphincter resistance. The gall bladder showed no characteristic response, the blood pressure was unaffected, but this solution frequently produced hyperpnea (Fig. 3). These findings are consistent with the work of others (1, 5, 9). It is to be noted that sodium hydroxide produces much more marked and prolonged spasm of the duodenum and the sphincter than does hydrochloric acid of the same strength.

Injection of 5 to 10 cubic centimeters of a 1:1000 solution of peppermint water into the duodenum produced marked responses in practically all of 5 animals in which it was used. This agent produced a sphincteric spasm amounting to as much as 100 millimeter increase in intraductal pressure which frequently preceded and was out of proportion

Fig 1 At 2, gastric juice intraduodenally, produced a concurrent spasm of sphincter and duodenum, but a recurrent sphincter spasm was not associated with further duodenal response. At 3, 1/10 normal hydrochloric acid had a similar effect. At 4, magnesium sulfate, intraduodenally, produced marked sphincter spasm with little effect on duodenal tone.

Fig 2 At 1, magnesium sulfate, intraduodenally, produced an initial marked spasm of sphincter (130 mm increase in pressure) coincident with duodenal spasm. Subsequently there was a lowering of sphincter tone below the control level, whereas duodenal tone and motility was restored to normal. At 2, glucose, intravenously, produced a 50 millimeter gradual rise in sphincter pressure, while depressing duodenal activity. At 4, disodium sulfate, intraduodenally, produced similar effects as did magnesium sulfate. At 5, isotonic glucose, intravenously, again raised sphincter pressure while depressing duodenum. At 6, magnesium oxide intraduodenally, produced marked recurrent spasms of sphincter which were coincident initially with duodenal spasms, but later were independent of it.

to a duodenal increase in tonus and motility. This effect is quite surprising in view of the fact that peppermint water is a time honored carminative. There was no effect on the gall bladder.

Twenty cubic centimeters of fresh dog's gall-bladder bile, introduced into the duodenum, produced no effect other than the transitory mechanical effect due to distention of the duodenum (Fig 3). As control, 20

cubic centimeters of normal saline was given, with similar negative results.

Twenty cubic centimeters of 25 per cent peptone solution, injected into the duodenum caused a moderate increase in sphincteric resistance and duodenal activity, which was of relatively short duration, and no gall-bladder response (Fig 3). Peptone has been described as a cholagogue secondary in effectiveness to egg yolk (1, 18).

A STUDY OF THE MECHANICS OF BILE FLOW

II Responses to Intraduodenal Solutions

DONALD D KOZOLL, M D and H NECHELES M D Ph D Chicago, Illinois

IN a previous paper we presented a method for simultaneous observation of the responses of the three factors we considered most important in determining the flow of bile, namely: the contractility of the gall bladder, the resistance of the sphincter of Oddi, and the tonus and motility of the duodenum. We confirmed the repeated observations of others on the independent activity of the sphincter and duodenum. In addition we reported our observations on the influence of physiological intravenous solutions on these structures (13).

Using the same experimental procedure on anesthetized dogs, we have studied the effects of various solutions introduced into the duodenum through a glass cannula which, projecting beyond the recording balloon, was tied around the cannula. All solutions were retained within the duodenum for a uniform length of time (2 minutes).

Intraduodenal instillation of 20 cubic centimeters of fresh gastric juice procured from dogs with Pavlov pouches of 1:12 to 1:24 1/10 normal hydrochloric acid concentration was observed on 13 occasions in 10 dogs. In every instance not complicated by previous medication, an immediate marked elevation in sphincteric pressure coincident with a marked duodenal spasm was elicited both persisted for a considerable length of time after the juice had been permitted to drain out of the duodenum (Fig 1). The gall bladder usually showed no characteristic response but in 2 instances there was a slightly increased tonus associated with an increase in motility. Blood pressure frequently revealed a 10 to 15 millimeter drop immediately following the injection.

Injection of similar amounts of tenth normal hydrochloric acid into the duodenum was followed by identical responses although our gastric juice was slightly more acidic. Oddi, in his original work, stated that dilute hydrochloric acid caused a spasm of the sphincter but later work has been contradictory (3, 8, 9, 18).

Antispasmodics, such as atropine and transtentil, did not prevent the effect of gastric juice (refer to previous paper Fig 4). No significant changes in gall-bladder tone or motility were observed following intraduodenal administration of hydrochloric acid or gastric juice. This is contrary to the experience of others (9, 18) but agrees with that of Baldwin and Dale.

Twenty cubic centimeters of 1/20 normal sodium hydroxide instilled into the duodenum of 3 dogs, produced marked responses in each case. These were characterized by sphincteric spasm producing a prolonged rise in intraductal pressure (100 mm. and above). The duodenum responded with a marked increase in tonus and motility which did not always parallel the change of the sphincter resistance. The gall bladder showed no characteristic response, the blood pressure was unaffected, but this solution frequently produced hyperpnea (Fig 3). These findings are consistent with the work of others (1, 5, 9). It is to be noted that sodium hydroxide produces much more marked and prolonged spasm of the duodenum and the sphincter than does hydrochloric acid of the same strength.

Injection of 5 to 10 cubic centimeters of a 1:1000 solution of peppermint water into the duodenum produced marked responses in practically all of 5 animals in which it was used. This agent produced a sphincteric spasm amounting to as much as 100 millimeter increase in intraductal pressure which frequently preceded and was out of proportion

to a duodenal increase in tonus and motility. This effect is quite surprising in view of the fact that peppermint water is a time honored carminative. There was no effect on the gall bladder.

Twenty cubic centimeters of fresh dog's gall-bladder bile, introduced into the duodenum, produced no effect other than the transitory mechanical effect due to distention of the duodenum (Fig 3). As control, 20

cubic centimeters of normal saline was given, with similar negative results.

Twenty cubic centimeters of 25 per cent peptone solution, injected into the duodenum caused a moderate increase in sphincteric resistance and duodenal activity, which was of relatively short duration, and no gall-bladder response (Fig 3). Peptone has been described as a cholagogue secondary in effectiveness to egg yolk (1, 18).

Fig 4 At 1, the intraduodenal instillation of olive oil produced a contraction of the gall bladder and an initial coincident transitory spasm of the sphincter and duodenum, subsequently, the sphincter resistance fell to a level lower than what it was prior to injection. At 2, 32 per cent cream instilled into the duodenum, at 3, egg yolk, and at 4, a mixture of 32 per cent cream and egg yolk, had an almost identical effect, except that the latter two preparations produced more effective contractions of the gall bladder

duced into the duodenum produced similar effects—an immediate contraction of the gall bladder associated with a simultaneous increase in sphincter and duodenal tone of 3 to 4 minutes' duration (Fig 4). Following this, sphincter tone falls to a level below that prior to injection for a similar interval and subsequently rises to its control level. We found a mixture of egg yolk and cream to produce the greatest contraction of the gall bladder of all agents injected into the duodenum. This response was not influenced by previous antispasmodic medication with atropine or traseptin (diphenylacetyldiethylaminoethanol hydrochloride).

In summary of our results with agents injected into the duodenum, acid substances such as gastric juice and 1/10 normal hydrochloric acid produced relatively short increases in resistance to bile flow. Relatively neutral media, such as magnesium sulfate and sodium sulfate, increased the tone of the sphincter out of proportion to their effects on the duodenum. Alkaline media such as sodium hydroxide and magnesium oxide, produced marked simultaneous responses in the sphincter and duodenum which would appear to oppose the flow of bile the longest. It is to be remembered that it is an increase in duodenal tone, and not so much of motility, that opposed the flow of bile. None of these agents introduced into the duodenum showed a con-

sistently uniform effect on the gall bladder. The latter may have been due to the washing-out effect of the constant perfusion with 0.9 per cent sodium chloride solution, by which substances like cholecystokinin may have been eliminated. This is not probable, however, because a number of tests were carried out in the beginning of experiments when little washing-out could have occurred.

ANALYSIS OF STUDY

The entrance of gastric juice or rather of the hydrochloric acid of the gastric juice, has been held responsible chiefly for the liberation of cholecystokinin in the duodenum and jejunum. Therefore small quantities of gastric juice or dilute hydrochloric acid were perfused through the duodenum. Contraction and rise of tone occurred simultaneously in both sphincter and duodenum, but the gall bladder was hardly affected in most experiments. We know from experience with pancreatic secretion following introduction of hydrochloric acid into the duodenum that the secretin mechanism may be fatigued. It is possible, therefore, that the absence of gall-bladder contraction following injection of gastric juice into the duodenum may be explained on a similar basis, namely that the constant perfusion of the duodenal segment by the saline solution may have washed out preformed cholecystokinin. This is questionable, how-

ever because in the numerous experiments performed a number were done after a short perfusion only of the duodenum and yet with the same negative results on the gall bladder. Furthermore various fats were effective when introduced in a like manner.

If gastric juice or hydrochloric acid produce spasm of the sphincter and duodenum this may explain why bicarbonate or other antacids are beneficial in certain cases of disease of gall bladder and extrahepatic system. The effects of gastric juice and of hydrochloric acid were unaffected by small intravenous doses of atropine or trerentin.

The effect of alkaline solutions administered intraduodenally deserves discussion because some of the alkalies taken by mouth will appear in the duodenum as sodium hydroxide, and because magnesium oxide is used largely in the treatment of upper abdominal distress. Figures 2 and 3 illustrate that administration of magnesium oxide and sodium hydroxide was followed by marked subtetanic contraction of duodenum and sphincter the latter being more prolonged than the former (Fig. 3). Although the degree of dilution in the stomach and gastric emptying time in the human after ingestion of alkalies may modify such a response considerably the above observations should be kept in mind.

The ability of egg yolk and cream to act as gall-bladder evacuants has been amply described by Boyden, but its effect on the sphincter has not been emphasized. The initial phase of spastic contraction of sphincter and duodenum might well account for the two minute pause described by Boyden (4) as elapsing between the entrance of this material into the duodenum and the evacuation of the gall bladder.

SUMMARY

1. The introduction of various agents into the duodenum was associated with immediate spasms of the sphincter of Oddi and of the duodenum of varying duration the more alkaline media (such as sodium hydroxide and

magnesium oxide) appearing to oppose the flow of bile the longest.

2. Magnesium or sodium sulfate had a variable effect on the sphincter of Oddi and duodenum of the dog with no consistent effect on the gall bladder.

3. Fats introduced into the duodenum effectively contract the gall bladder the most effective preparation was a mixture of egg yolk and cream.

4. The initial spasm of the sphincter of Oddi and duodenum produced by intraduodenal instillation of fats is suggested as a possible explanation of the "two-minute pause" described by Boyden as the initial phase in the evacuation of the gall bladder.

5. The independent activity of the sphincter and duodenum during various phases of the response to magnesium sulfate is offered as further evidence that they are independent physiological mechanisms, although frequently similar in their reaction.

A NEW METHOD OF REPAIR FOR INDIRECT INGUINAL HERNIA CONSIDERED IN REFERENCE TO PARIETAL ANATOMY

W KENNETH JENNINGS, M D , F A C S , BARRY J ANSON, Ph D (Med Sc), and
ROBERT R WRIGHT, M D , Chicago, Illinois

THE problem of repairing inguinal hernia remains unsolved despite the memorable contributions of Bassini and Halsted. The numerous modifications of the operation introduced by those pioneer surgeons, indicate that, although both methods have shown the way to far better results than were obtained earlier, neither has proved to be a completely satisfactory solution. Prior to the introduction of these techniques, recurrences were so common that most physicians despaired of curing the condition, one reads of recurrence rates in a single series reaching as high as 90 per cent. It is little wonder, then, that a method which enabled surgeons to reduce this high incidence of failures to a figure around 10 per cent should be widely adopted and accepted by most as a satisfactory operation.

A survey of the literature convinces one of the lack of agreement among authorities as to the frequency of recurrence with present day surgical methods. This may be attributed to a number of factors, chief among which is the difficulty of accurate follow-up examinations over a sufficient period of time in any large series of cases. Zimmerman warns against the fallacy of accepting verbal or written communications from patients as reliable information, he maintains that only by careful examinations, covering a period of several years, is the surgeon justified in drawing conclusions as to results. Few series of cases have been reported in which such re-examinations have been carried out for more than 75 per cent of the patients in the series. Moreover, it is probable that the rate of recurrence is much higher among the cases not followed, for many of those who suffer a return of the original trou-

ble are quite likely to go elsewhere for further advice and treatment. Most hernia sufferers have a friend who has experienced a recurrence following an attempted surgical repair and all have been warned concerning this danger, it is only natural that many of those who suffer a recurrence should abandon hope of securing permanent relief through surgery, and consult the truss-maker for further help. Aversion to the truss is the factor usually responsible for the return of the patient to the doctor—probably a new doctor. Of the last 4 cases of recurrent inguinal hernia in which patients were operated upon by one of the authors (WKJ) 3 had been patients of other surgeons who knew nothing of the secondary rupture. Although it is well known that a careful repair is seldom followed by recurrence under 6 months, the majority of statistical reports include patients recently operated upon as well as cases which have been observed for longer periods. Inasmuch as most surgeons today employ the Bassini technique, or one of its numerous modifications, it is difficult to reconcile the widely divergent results reported by men whose experience in this field should establish them as authorities. It would seem, therefore, that the higher figures for recurrence are most reliable (Table I). This contention is further substantiated by the abundant literature on the subject, as well as by the numerous operative procedures recommended for its correction.

A new principle in the treatment of femoral hernia was recently proposed by Professor Henry, of Cairo, Egypt, who described a procedure in which the femoral ring was exposed by a retroperitoneal approach through a low midline incision. The advantages which such an operation provide are (1) direct exposure of the opening through which the hernial sac

*Zimmerman, L. M. Internat. Abstract Surg. 329, 66

protrudes, (2) guarantee of high ligation of the sac, and (3) avoidance of scar tissue in the inguinal sector of the abdominal wall. In the carrying out of this procedure it was observed that excellent exposure of the abdominal inguinal hiatus was possible by a slight additional retraction of the rectus muscle laterally. This observation suggested that a procedure, similar to the one proposed by Henry but adapted to the requirements of indirect inguinal hernia, might possess fundamentally the same advantages.

The standard accounts, to which the anatomist and surgeon have accustomed themselves, describe the inguinal canal as an indefinite "space" of oblique course whose parietal constituents are strong representations of the layers which make up the abdominal wall. In

these accounts the subcutaneous orifice of the canal is loosely termed a "ring" and the degree to which muscle fascicles of the internal oblique are drawn outward through this orifice is often exaggerated the fascial contribution from the transversus abdominis is inadequately described and the adipose continuation of the preperitoneal connective tissue is usually disregarded. In almost every instance inguinal anatomy is presented as if it always conformed to a definite pattern. In view of these facts, it was considered desirable to re-examine the inguinal strata carefully—and by dissection, in the order in which they would be encountered by a hernia. This posterior approach proved to be particularly applicable to the surgical method presented since the latter technique affects primarily the deeper abdominal layers

I ANATOMY

Serial dissections were carried out in an unusually favorable, muscular, white male,¹ and an accurate drawing was prepared of each of the several stages in the dissection. In the descriptions of the important anatomical features thus recorded, the innermost stratum will be considered first, the external oblique last, since this is the succession in which a hernial mass encounters the series of parietal laminae.

a Peritoneum The peritoneum of the left side of the specimen illustrated is of the normal adult disposition, elevated in low folds over the middle and the lateral umbilical ligaments (Fig 1).² On the right side, in addition to being draped over subperitoneal ligaments, the peritoneum is carried outward as a serous hernial sac which is the persistent processus vaginalis (Fig 1). Through the serous layer are visible the linea semicircularis, rectus muscle, inferior epigastric vessels and the line of the inguinal ligament—the muscle, artery, and ligament bounding the triangular space (of Hesselbach) to the lateral aspect of which the hernia protrudes.

b Preperitoneal tissue Through much of the inguinal area the layer of preperitoneal connective tissue is of cobweb-like texture, almost devoid of fat (Fig 1, left half). Within it are imbedded the several umbilical ligaments, and the inferior epigastric vessels. The

preperitoneal layer, along the pelvic wall, is considerable in amount, traced outward from the abdominal inguinal “ring” it is lost in the proximal part of the inguinal canal. In many specimens, however, this funicular continuation of the retroperitoneal tissue is appreciable in amount, forming a lobulate collection deep to the internal spermatic fascia, in bulk it may then equal the combined mass of the other constituents of the cord. It would, assumedly, constitute a resilient tissue easily compressible under pressure of an advancing indirect inguinal hernia.

c Transversus abdominis muscle The transversus abdominis muscle is almost universally described as forming a superior boundary for the inguinal canal, its fascia a posterior wall, the fascial layer which is invariably described is the internal investing, or transversalis, fascia, the thinner external layer is disregarded.

In the specimen herein illustrated, the transversus abdominis, as usual, becomes aponeurotic and fascial as the inguinal canal is approached (Figs 2 and 3, cf Fig 5, McVay and Anson, 1940), the lower part of the transversus (i.e., the area at the inguinofemoral border) is totally fascial, no aponeurotic fibers being seen in the part prolonged upon the cord. The layer is so thin that the yellow fat preperitoneal is plainly visible through it, in spite of the fascial character, it is removable, as a whole layer, from the fat.

In the standard accounts the transversalis fascia—which is the internal one of the two investing fascial layers of the transversus—is treated as if it were the sole contributor to the internal spermatic fascia. Yet the thinner external layer of investing fascia contributes part of the substance of the latter, although to lesser degree, the external investing layer is traditionally disregarded, assumedly because, in the course of regular dissection, it is removed to expose the muscular portion of the transversus.

In the current specimen the transversalis fascia is a strong and definite layer on the inner aspect of the transversus abdominis. On the right side, carried into the inguinal canal, it forms a fascial diverticulum situated just lateral to the inferior epigastric vessels (Fig 2, right half), this is, of course, the tubular pro-

¹The specimens are adult white cadavers of average height and weight.
²In addition to the descriptions presented in the legends, the following comments on the dissections may be of interest to the reader. In Figure 1, for service in topography, the pelvic and perineal structures are included in the drawing. In the pelvis urinary bladder, prostate (hypertrophic sectioned in the plane of the prostatic urethra), pelvic diaphragm, obturator internus muscle, alae ischiopubic rami, acetabula, etc., in the perineum, urogenital diaphragm (superior to which the dorsal veins of the penis enter the pelvis), erectile bodies (with muscles) at the level of the bulb of the urethra. The most inferiorly placed layer is the fascia of Colles (deep layer of the perineal superficial fascia). Structures situated external to the pelvis have been removed. The outline of the margin of the rectus sheath, the boundaries of Hesselbach's triangle are seen. In Figure 2 the urinary bladder has been drawn backward to expose the pubic part of the bony pelvis, the obturator vessels and the pubic branches of the obturator arteries. The pelvic diaphragm is included in the area illustrated but not the structures inferior thereto. In Figure 3 the bladder and prostate (with large plexiform veins) have been excised to show the important bony structures in the anterior part of the pelvis. Further in removal of the obturator and superior diaphragmatic fasciae, the pubic portions of the levator ani and obturator internus have been exposed on both sides, the pubic symphysis, inferior pubic rami and pubic arcuate ligament are shown, also the dorsal penile vein in relation to the arcuate ligament and the transverse pelvic ligament. The bulb of the urethra (marking the level of the superficial perineal compartment) remains as an additional landmark. Vessels have been removed except for the following: distal parts of the external iliac arteries and veins, upper reaches of the inferior epigastric arteries with branches laterally to the muscles of the inguinal wall, dorsal vein of the penis (at the pubic arcuate ligament), the arterial plexus (left side) from the pubic branch of the obturator artery. In Figure 5 the urogenital and pelvic structures are also removed, in order to demonstrate fundamental bony relations, symphysis and rami (superior and inferior) now freed of muscular and aponeurotic attachments.

Fig. Internal aspect of the anterior abdominal wall. Peritoneum and preperitoneal connective tissues (see also footnote). The pelvis has been coronally sectioned, the line of section passing through the iliac fossae, acetabula, and ischial ramus. On the right (hernial) side the peritoneum is intact; on the left (normal) side it has been removed to expose the preperitoneal layer in which lie the umbilical ligaments. The preperitoneal layer has been removed only along the course of the inferior epigastric artery. Through it (right side) are visible rectus abdominis, inferior epigastric artery, linea semicircularis. The iliac fascia of the greater pelvis has been freed from muscle as has, likewise, the thin preperitoneal layer from the muscle fascia. The peritoneum remains on the right half of the superior surface of the urinary bladder; on the left the combined preperitoneal and endopelvic fascial layers are exposed.

elongation of internal spermatic fascia dilated by hernial protrusion. Medially it is carried upward in the midline as a thickened, pointed process, the adminiculum. Where the transversalis fascia reaches the lateral margin of the rectus muscle it splits to form the rectus fascia (Fig. 3). It is easily dissectable from the muscle in the area below the semicircular line; however it cannot be easily separated as a distinct layer from the aponeurosis of the transversus either along the lateral border of the rectus abdominis or upon the latter muscle itself above the level of the semicircular line.

d. Internal oblique muscle. The lower inguinal part of the internal oblique—with the subjacent and corresponding portion of the

transversus abdominis—arises from the iliopectineous fascial tube, not from the inguinal ligament (McVay and Anson, 1940, Figs. 1 and 3). The attachment to the inguinal ligament is accomplished only through the fasciae which cover the opposed surfaces of the muscle and ligament. The muscle fibers usually descend, closely grouped on the posterolateral aspect of the spermatic cord. It is exceptional to find more than a fascial remnant of this stratum ascending on the medial side of the cord to a pubic insertion.

The statement (see Martin) that the superficial muscle fasciae of the external oblique and internal oblique are continuous into the thin spermatic fascia, etc., is entirely erroneous, as is derived from the aponeurosis. When the general layer of external spermatic fascia (the lowermost posterolateral fibers are merely local specializations), the fascial layer prolonged, the fibers happening to be situated just lateral to the part of the fascia which is displaced, the fibers are not spermatic.

Fig. 2 Abdominal wall from within transversalis fascia. The preperitoneal tissue has been removed, the transversalis fascia and iliopsoas fascia exposed.

On the right side the layer is displaced from its natural site, lengthened to invest the protrusion (Fig. 4), as if incapable of excessive prolongation, the muscular fascicles are carried but a fraction of the way, the more resilient fascia through the full extent of the testicular descent. Just as the investing fascial layers of the external aponeurosis are protruded between crura, so the comparable layers of the internal muscle are stretched between adjacent muscle fascicles. The cremasteric fascia is, then, a definite sheet, not merely an areolar filling—so definite that, although muscle fibers are commonly sparse in the cremasteric fascia, it remains as a layer so readily separable that it is demonstrated in virtually all student dissections.

c. External oblique muscle. It should now be clear that in a consideration of the three abdominal layers, a sharp distinction must be drawn between the musculo-aponeurotic and

the fascial elements, failure to do so accounts for the ambiguity of some current descriptions and for the incorrectness of others. Although muscular fascicles and aponeurotic bands may terminate rather abruptly to form free margins, the associated fascial layers continue uninterrupted to bone, aponeurosis, or other fascia, when drawn away from its original site, each stratum maintains its continuity with the undisplaced portion of the same layer. Because these simple concepts are not carefully regarded, the true nature of the subcutaneous inguinal ring is not made clear in some textbook descriptions.

The interval in the aponeurosis is triangular in outline, any annular character is due to the presence of fascial tissue. The cleft, in the authors' experience, is elongate, not uncommonly extending superolaterally as far as the muscle belly or even to the anterior superior iliac spine.

Fig 3 Abdominal wall, continued: transverse abdominis muscle and aponeurosis, and the layers' contribution to the spermatic cord. The transversalis fascia has been removed from both sides. On the right side additionally the transverse abdominis muscle has been cut away in a V-shaped area, exposing the internal oblique. At the lateral border of the right rectus abdominis has been cut to expose the layer of rectus fascia (derived from the trans crura) which passes in front of the muscle. The aponeurosis of the trans crura (medially) is intact, and is distinguishable from the layers of rectus fascia. The trans crura has been circularly cut on the left side, additionally the internal oblique is cut away in a V-shaped piece near the anterior superior spine showing the muscular part of the external oblique, and the foremost fascial layers on the abdominal aspect of each of the muscles. The atrophic muscles have been removed from the iliac fossae except near the inguinal ligament. The transected external iliac vessels rest upon the iliopectineus of each side.

The superior crura and the neighboring fibers spread out evenly upon a flat surface of pubic attachment: there is no evidence of marginal thickening or of local clumping; the front of the pubis, inferior to the level of the crest, is wholly covered by aponeurosis (Fig 1 Anson and Ashley, 1941). All descriptions emphasize the concept of crural boundary of a triangular intercolumnar space; but when the superior crus is cut and turned aside the attachments of the crura are shown to be surprisingly far apart, the external orifice broad

when the horizontal distance is considered (Fig 2 Anson and Ashley, 1941). The superior crus attaches along a line on the front of the pubic body, several centimeters inferior to the level of the crest (when the oblique distance between crura is 1.0 cm for example the transverse may be as great as 3.0 cm). The orifice therefore extends almost to the symphysis. When levated by a herniating mass, the superior crus would be merely a constricting band on the anterosuperior aspect of triangular osseoponeurotic foramen.

Fig 4. Abdominal wall, continued internal oblique layer On the right (hernial) side the transversalis fascia and transversus abdominis remain at the marginal attachments only, and upon the sac, the internal oblique, is, therefore, almost entirely exposed For purposes of comparison, on the left side the exposure is similar

Fig 5 Abdominal wall from within, concluded external oblique muscle and aponeurosis (freed of internal investing fascia except in a small area on the right side) The internal oblique has been almost entirely removed, the rectus and pyramidalis muscles have been excised to show the anterior layer of the rectus sheath, the transversalis and rectus fascia have been removed except at the attachment along the pubic crest. The internal spermatic fascia is present as a constituent of the hernial sac The transversus abdominis muscle appears merely as a narrow strip along its inferior attachment The funicular part of the internal oblique is chiefly fascial The triangular cleft in the external oblique aponeurosis of each side is demonstrated (margins indicated by arrows), as is the thin fascial layer which crosses the space in the aponeurosis

Fig 6 Exposure, in an anatomical specimen, of the structures at the abdominal inguinal ring, through median incision (anastomosis to epiphysis) simulating that proposed, surgically in the current article. The margins of the incision have been retracted, the peritoneum has been displaced by blunt dissection. By this procedure the ring is exposed retroperitoneally, also shown are the following structures which are associated with the abdominal ring: external iliac vessels as they near the femoral canal, the inginal process of the peritoneum, the spermatic vessels and the ductus deferens as they cross, the inferior epigastric vessels as they lie to the medial side of the abdominal inguinal ring.

The inherent weakness in the area of the "subcutaneous inguinal ring" is not due to a lack of intercrural fibers medially. Strong fibers of this type are not placed with such restricted and definite distribution, usually being lodged in the outer layer of investing fascia of the external oblique aponeurosis above and to the medial side of the aponeurotic cleft (McVay and Anson 1940). It is the general fascia, not these special fibers which forms the funicular covering. The intercrural fibers are quite subsidiary and are not carried downward on the cord.

The fascia at the aponeurotic hiatus is not merely external investing (innominate) fascia. It is bilaminar in origin, consisting of an internal investing layer as well as the two fused back-to-back. Thus fused as an intercrural or intercolumnar fascia, the single (conjoined) layer is prolonged upon the cord as the external spermatic fascia. As already stated the separately definable intercrural fibers do not extend in their distribution to the medial area of the aponeurotic cleft and, consequently, do not contribute to the substance of the funicular tube. In fact, the intercolumnar fascia is thinest near the site of prolongation. This means that there is regularly an area of weakness between the aponeurotic crura. In herniating the mass merely separates further the crural boundaries of a triangular area whose covering tissue

is fascial only (Fig 5).¹ Having widened the thin funicular "sac" formed by external spermatic fascia, the hernial mass pushes outward through the intercrural space. The strong crura then tend to return to normal position, with the result that the external fascial sac, the contained saccular coverings derived from the successively deeper abdominal strata, and the true hernial contents, are clamped between columnar (crural) "ligaments" (see Figs 1 and 2 Ashley and Anson 1941). Therefore not only does the fascial part of the external oblique constitute an inefficient barrier against hernial protrusion but the marginal aponeurotic bands are readily displaced to permit of egress.

II. SURGERY

These anatomic studies afforded a better understanding of the structural relations as encountered in a retroperitoneal approach to the inguinal canal and convinced us that in principle any operation which effects a high ligation and removal of the hernial sac, closure of the so called abdominal inguinal ring and avoidance of any trauma to the transversalis fascia, or other structures about the inguinal canal is fundamentally sound. Accordingly a technique was planned in which the low mid

¹It should be noted as a matter of record that the deepest fascia near and over the transversalis muscle, here the femoral vessels near vein. The transverse artery from the superior iliac and bone is superficial border of the inguinal ligament. In selective hernioplasty without internal herniation, then hernial sac is up and down, repair.

Fig 7 Technique for the repair of indirect inguinal hernia through low midline incision A, Skin incision, B, incision through the fascia adjoining recti muscles, C, Separation of the left rectus muscle from the peritoneum by blunt dissection—the muscle is retracted laterally to expose the inguinal ligament, the structures of the spermatic cord and the abdominal inguinal hiatus A tape encircles the cord to aid in identifying and separating the hernia sac (small hydrocele of the cord is present) D, The sac, having been dissected free from the spermatic cord, is now opened, E, high ligation of the sac is completed and the sac is excised, 2 interrupted silk sutures have approximated the transversalis fascia in order to reduce the size of the abdominal inguinal ring (the lower leaf of transversalis fascia is obscured by adipose tissue), F, The fascia is closed with interrupted silk sutures

line incision described by Henry is used (Fig 7, a), this is carried down through the rectus fascia at the linea alba (Fig 7, b) to the peritoneum, the latter being separated from the posterior surface of the rectus muscle by blunt dissection The urinary bladder may appear

in the lower field, in which case it is carefully pushed away from the overlying structures The lateral dissection is easily accomplished because of the loose areolar tissue between the peritoneum and the rectus muscle which separates readily The dissection is carried as far

TABLE II—INDIRECT INGUINAL HERNIA OPERATED UPON BY MIDLINE RETROPERITONEAL APPROACH

Patient	Age	Date of operation	Followed	Recurrence	Remarks

M S		24-27	3 wk		Scrotal hernia

as the inguinal ligament in order to expose adequately the abdominal inguinal opening. With good relaxation of the abdominal muscles the rectus muscle now can be retracted laterally, thus exposing the "ring," which is identified by locating the inferior epigastric vessels (Fig. 7 c cf Fig. 6). It is seen to lie across the inguinal ligament from the femoral ring in relationship to which it lies slightly anterior and lateral. The hernial sac is easily recognized as it enters the inguinal canal. Occasionally it is necessary to ligate and divide the epigastric vessels which may lie across the inferior margin of the ring. In order to facilitate mobilization of the sac. Gentle traction on the sac at the level of its junction with the peritoneum, together with combined blunt and sharp dissection, results in its easy separation from the other cord structures in the canal (Fig. 7 d). A sac which descends into the scrotum or one associated with dense adhesions may offer difficulty. In such instances it may be necessary to section and leave a portion of the sac. After removal of the sac (Fig. 7 e) the abdominal inguinal hiatus is closed with two or three interrupted silk sutures which merely approximate the transversalis fascia across the opening (Fig. 7 e). It is felt that unless the aperture is so large that it comes to underlie the subcutaneous inguinal opening, thus producing in effect a direct hernia, the obliquity of the angle by which any secondary

peritoneal protrusion would have to enter the newly closed abdominal ring together with the strength of the intact wall are sufficient to insure against any danger of recurrence. The operation is concluded by the suture of the fascia in the midline (Fig. 7 f) and the approximation of the incised skin margins with interrupted silk sutures or Michel clips.

The advantages of such a procedure are several. Protection is offered against recurrence afforded by the avoidance of distortion trauma and the formation of scar tissue in the vulnerable inguinal area. The technique itself is much simpler than that employed in the orthodox methods for repairing an indirect inguinal hernia. The procedure can be carried out more rapidly. There is little danger of injury to the ilioinguinal nerve and to the structures of the spermatic cord finally, there is less likelihood of wound infection than with an inguinal incision.

It should be pointed out, however, that the operation has certain limitations. Obviously such a method of repair is unsatisfactory for a direct inguinal hernia and for a large indirect hernia in which the orifices of the canal have become so dilated as to create a window in the inguinal wall. The latter should be recognized and repaired in the same manner as a direct hernia. Good relaxation of the abdominal wall is essential to adequate exposure when the midline approach is used. Hence the use of general anesthesia is excluded. Novocain infiltration anesthesia offers greater difficulty than it does with the inguinal approach because of the necessity of infiltrating a much wider area. The danger of entering the peritoneal cavity might be considered an objection to any retroperitoneal approach. However we are of the opinion that such an accident is not of serious importance. In only one of our cases was the peritoneum opened and this was repaired at once with no subsequent disadvantage to the patient.

We have operated upon 11 patients during the past 2 years using the technique described. It is appreciated that such a small series of cases, only 5 of which have been followed for a year, can hardly be entered as proof of this method's superiority over other procedures. However, a number of interesting observations have been made in following this group

which deserve recognition (Table II) An elderly obese male (Case 3, D P), was operated upon 14 months ago under spinal anesthesia for a large right indirect hernia, on the third postoperative day he developed type VII bilateral lobar pneumonia, there followed 2 weeks of violent coughing without damage to the repair and when he was last examined, 13 months after operation, there was no evidence of recurrence Another patient (Case 2, C H) was operated upon for a scrotal hernia, and it was necessary to leave the scrotal portion of the sac because of dense adhesions, when last examined 12 months later there was no evidence of hernia or hydrocele although this patient has been at his regular work (manual labor) since the second postoperative month The youngest patient in the series was 4 years of age, the oldest, 62 All cases have been accepted without regard to the size of the inguinal "rings," although it is felt that the procedure should not be used in cases in which these apertures have been dilated to a condition which constitutes a direct opening in the abdominal wall There have been no recurrences in any of the cases followed for a period beyond 3 months (2 patients recently operated upon have not been re-examined)

CONCLUSIONS

A re-study of the anatomy of the inguinal canal by means of dissections which begin with the abdominal inguinal hiatus and proceed through the successively deeper layers, indicates the accessibility of a hernial sac from a retroperitoneal approach and serves to re-emphasize the importance of the peritoneum and transversus abdominis layer and the transversalis fascia in determining the strength of the abdominal wall about the inguinal canal In the specimen illustrated — and in many others examined during the progress of laboratory study — the inferior part of each of the abdominal layers is found to be an almost totally fascial area, aponeurotic fibers and muscle fascicles are sparse in the lower inguinal territory The transversus abdominis and the internal oblique are there quite uniformly thin,

while the external oblique is locally weak at the intercrural hiatus in its aponeurosis, these strata, with the preperitoneal and peritoneal layers, all are to a degree attenuated where, in the form of funicular investments, they are prolonged from inguinal to scrotal level as a set of concentrically lamellated sacculations When, in a case of indirect inguinal hernia, the innermost or peritoneal, sac is occupied by herniating intestine or omentum, the other saccular extensions share in its dilatation, as a consequence the wall of each sac is stretched, the abdominal orifice of each is dilated and displaced

In the restoration of an adequate parietal barricade to hernia the serous sac is, of course, the fundamental anatomical element, its space is the only true inguinal "canal" Since its congenital presence offered the initial route for hernial progress, its obliteration logically constitutes the primary step in surgery of repair Furthermore, in carrying out the ligation of the peritoneal sac, that method would seem most rational which brings minimal distortion and stretching to overlying parietal layers which have already been inordinately stretched

A method of repair for indirect inguinal hernia which is designed to preserve intact the transversalis fascia and other structures about the inguinal canal, and which simplifies high ligation of the sac, is described To date 11 patients have been operated upon, and of these 6 have been followed for a period longer than 6 months with no evidence of recurrence We believe that the operation is anatomically sound, and we are confident that it provides certain definite advantages over the conventional methods

Fig. Female perineum. Subcutaneous layers, specimen 1. On the (observer's) right side the superficial layer of the superficial fascia has been removed to expose the deep (Colles') layer in the anterior (urogenital) part of the perineum; in the posterior (anal) part of the perineum the superficial layer locally thickened and adipose remains intact behind the line of cut. In the rectorectal fossa the sleeve of fascia lata, shown by transecting the thigh, has been freed from the muscle fascia, the latter is shown as it invests the sartorius (at *) and the adductors, freed from the muscles and retracted. The darticular process has been mobilized and lifted (marked with star). On the opposite half of the perineum the skin remains intact. Successively deeper dissections of the same specimen follow (Figs. 2 to 4).

FURTHER STUDIES IN GYNECOLOGICAL ANATOMY AND RELATED CLINICAL PROBLEMS

ARTHUR H. CURTIS, M.D., F.A.C.S., BARRY J. ANSON, Ph.D. (Med.Sc.),
and FRANKLIN L. ASHLEY, M.D., Chicago, Illinois

IN continuing a re-study of the female pelvis and perineum in relation to the modern practice of surgery, additional anatomical features of gynecological importance have been established. Since many of these features are quite evidently not known to anatomists or surgeons because of dependence upon stereotyped accounts, the authors believe that a record of their experiences should prove serviceable.

In this third contribution concerned with a further study of the female pelvis and perineum, fifteen life-sized drawings were prepared by Tom Jones from three specimens.¹ Each drawing is an exact portrayal of the anatomy of a particular phase of the dissection, and none is a composite picture.

I PERINEUM SUPERFICIAL LAYERS

The superficial fascia of the perineum is fatty and is divided by heavy bands of fibrous tissue into lobules. The bands, in attaching themselves to the deep membranous layer in the urogenital part of the perineum (Fig. 1), render it difficult to find a definite plane of cleavage.

The fatty layer is relatively thin in the anterior part of the urogenital subdivision of the perineum,

but it increases in bulk as the base of the urogenital diaphragm is approached (Figs. 1 to 4). The greater lips are mound-like (Fig. 1), the elevation on each side being due in large measure to the presence of a fatty diverticular extension, into the labial tissue, of the inguinal superficial fascia (Figs. 2 and 3).

The prolongation is tapered and bluntly pointed (Figs. 1 and 3). This fatty process lies against the deep layer of the superficial fascia, therefore, in palpating the deeper perineal structures, the bulb of the vestibule is not felt, it is masked by the presence of the more superficially placed fatty process,² which is definitely demarcated from the surrounding tissue in which it is embedded, resembling a finger-like lipomatous tumor. Into it, for a short distance beyond the level of the subcutaneous inguinal ring, all the layers of the inguinal parietes are traceable as exceptionally thin investments (see Anson and Ashley, 1940). It contains the round ligament, which is, however, soon lost in the tissue which houses it.

The deep (membranous) layer of superficial perineal fascia is as distinct from the overlying fatty pannicle as the corresponding abdominal layer of Scarpa is from the layer of Camper (Figs. 1 and 2). The deep layer of superficial fascia is firmly attached at the sides along the ischiopubic rami, behind it fuses with the inferior fascial layer of the urogenital diaphragm, in front it is continuous, over the pubis, with the layer of Scarpa on the abdominal wall. The layer is complete, usually, save for the presence of small hiatuses—placed chiefly at the dorsal margin for the transmission of the clitoral branches and tributaries of the pudendal arteries and veins, posterior labial vessels sometimes pass through lesser hiatuses.

II PERINEUM SUPERFICIAL COMPARTMENT

On the next deeper level, within the superficial perineal compartment, lies the inferior perineal fascia (of Gallaudet), it is a thin, yet clearly

²The fatty process is 8.5 cm. long (measured from its root at the subcutaneous inguinal ring) it is 1.5 cm. wide at the midpoint. It extends posteriorly to a point opposite the hinder limit of the vestibule; its failure to turn medialward in the area between the vestibule and the anal orifice accounts for the indistinctness of the posterior labial commissure.

¹A contribution from the Department of Obstetrics and Gynecology and the Department of Anatomy (contribution Anatomy No. 325) Northwestern University Medical School. Presented in part at the annual meeting of the South Atlantic Association of Obstetricians and Gynecologists, Richmond, Virginia, February 10, 1940, in part at the Annual Meeting of the Kentucky State Obstetrical Society, Louisville, Kentucky, September 30, 1941, in part at a meeting of the New York Obstetrical Society, New York City, November 11, 1941. Certain of the anatomical features were presented at the 1941 (Chicago) meetings of the American Association of Anatomists, April 9, 1941 (abstract Anat. Record vol. 79, no. 3, suppl. no. 1, pp. 4 and 5).

²As in previous contributions the accompanying illustrations are two thirds actual size. Specimen I (Figs. 1 to 4) was a white female, 30 years of age, of average height, weighing about 90 pounds, embalmed. Specimens II (Fig. 5) and III (Figs. 6 to 15) were also white, of approximately the same age, et cetera. All were entirely free from gross pelvic or perineal pathology. In the current and in the preceding study (Curtis, Anson and Beaton, 1940) specimen III was employed for 10 and 7 illustrations, respectively. Figure 6 of the current set continues the dissection from Figure 7 of the earlier series. These two sets of illustrations constitute an atlas of musculofascial anatomy, extending from the peritoneum on the pelvic aspect to the superficial perineal muscles on the perineal aspect of a single female specimen. It is the belief of the authors that such an inclusive treatment of an anatomical region in one specimen is unique. Specimen I was used in the detailed study of the superficial strata; specimen II for special dissection of the external anal sphincter.

Fig. 2

Fig. 3

(Legend on opposite page)

separable, layer of deep fascia (Figs 2 and 3) Like a typical deep fascia (e g, of thigh, at λ , in Fig 1), it can be lifted away from the bulbocavernosus and ischiocavernosus as a thin sheet (Fig 3)

Internal to the inferior perineal fascia just described, immediately investing the bulbocavernosus muscle, there exists a much thicker layer which constitutes a rather loose sheath for the muscle (slit longitudinally to X in Fig 3) As determined by an examination of microscopic section, this sheath is chiefly fibrous, however, it contains scattered fascicles of skeletal muscle Apparently this ample sheath, not merely the muscle enveloped by it, is employed by Martius in his operation for relief of incontinence due to destruction of the urethra

The deep layer of the superficial fascia forms the floor of the superficial perineal compartment (Figs 1 and 2), into it are implanted fibers of the external anal sphincter (Fig 4, cf Fig 5) The roof of this compartment is the inferior fascia of the urogenital diaphragm (Fig 4, cf Fig 8) Since the two fascial layers (and the deeper elements as well) are attached directly to both sides of the pubic arch, they, with the external anal sphincter, form a sling-like support for the pelvic organs which is auxiliary to the pelvic diaphragm, the sling is narrow behind at the coccygeal attachment, broad in front of the ischial tuberosity (Figs 8 and 9) Within the superficial perineal compartment are contained the bodies of erectile tissue and superficial perineal muscles which are related to them, the muscles are, on each side, the

superficial transverse perineal, the bulbocavernosus and the ischiocavernosus (Figs 4 and 8)

1 *Superficial perineal muscles, vulvovaginal glands of Bartholin*¹ Within the superficial perineal compartment the crus of each side, although small, is definitely outlined, easily palpable against the ischiopubic ramus The bulb, on the contrary, is so flattened that its limits are not easily discovered

The bulbocavernosus muscles are situated on the sides of the vestibule (Fig 4, removed in Fig 8) As stated, a firm sheath of fibromuscular tissue encases the relatively thin inner layer of muscle, which, in turn, closely invests a bulbus vestibuli Posteriorly the muscle fibers of the opposite sides join behind the vaginal opening where they meet those of the superficial and deep transverse perineal muscles and the external anal sphincter Anteriorly, the bulbocavernosus divides, the medial division covering the so called intermediate mass of the erectile tissue, the lateral division covers the ischiocavernosus muscle (Fig 4) Contrary to accepted belief, it is the firm musculofascial sheath rather than the thin bulbocavernosus muscle which is of value in reconstruction operations on the female urethra, such as that employed by Martius The fibrous tissue of the bulb and the underlying firm tissues of the urogenital diaphragm offer additional surgical support (Figs 8 to 11)

The paired vulvovaginal (Bartholin) glands, outgrowths from the epithelium of the urogenital canal, are immediately adjacent and posterior to the bulbs, where they lie buried in cellular tissue, not definitely within the deep perineal compartment, as commonly described, but at the base of the compartment where the division between the

Fig 2 On the left, the superficial layer of the superficial fascia has now been exposed by reflection of the skin, it has been incised longitudinally where it covers the labial portion of the diverticular process (at star), the width of the latter demonstrated by retraction of the margins of the incision On the right, the deep layer of the superficial fascia has been cut, the flap turned lateralward, to show the inferior perineal fascia as the latter covers the muscles in the superficial perineal compartment. In the anterior portion of the anal part of the perineum, on each side, much of the fat of the superficial layer has been removed from the ischiorectal fossae, over the front of the pubis it has been removed in three levels to show, successively, the immediately subcutaneous tissue, *a*, the covering of the diverticulum, *b*, the diverticulum itself, at star, and the subjacent fascia lata, *c*

Fig 3 On the left side the fatty inguinal process (at star) has been further freed from the superficial layer of the superficial fascia by retraction of the margins of the now lengthened labial incision On the right the corresponding structure has been transected at pubic level, the membranous (deep) layer of the superficial fascia and the muscle fascia have been reflected Over the bulbocavernosus muscle the thick fibrous investment has been incised (to point marked X), the margins retracted Here five successive strata are demonstrated (skin to muscle)

¹Very frequently it is important to know the dimensions of structures in the perineal compartments equally important may be their relation to palpable landmarks Since such data are almost totally absent from standard descriptions and excessively rare in the literature it is thought worthwhile to furnish records of this kind especially where they are directly referable to accurate drawings made from the dissections illustrated

For specimen I (see esp Fig 4) the following measurements may be recorded The ischiocavernosus muscle is 10 cm long 1 cm wide at the midpoint The bulbocavernosus is 7.5 cm long the maximum width is 1.6 cm (midbulbar) the thickness is 1.0 mm The vulvovaginal (Bartholin) gland is 0.8 cm long 0.35 cm wide From the medial extremity the duct is given off the latter is 1.25 cm long It empties into the vestibule 1.8 cm from the anterior limit 1.6 cm from the posterior (measured along an anteroposterior midline) The duct is 0.1 cm in diameter at the termination, 0.15 at the origin The superficial transverse perineal muscle (each) is 0.3 cm thick (at midpoint) 4.2 cm long (to midline from tuberosity) The external anal sphincter ani is 7.3 cm long (tip of coccyx to perineal body) 1 cm wide On the lateral wall of the ischiorectal fossa the distance between the urogenital and the pelvic diaphragm is 3.5 cm (this is the height of the anterior recess of the fossa at the latter's posterolateral boundary) Along the same line the distance from the pelvic diaphragm to the surface of the skin is 6.5 cm — which is the depth incidentally of the mass of the fat filling the fossa it is 3.0 cm from the urogenital diaphragm (inferior fascia) to the skin In specimen III the superficial transverse perineal muscles together are 10.5 cm long which measurement is also that of the maximum width of the urogenital triangle Each muscle is 0.2 cm thick 0.3 cm deep and 0.7 cm wide The fibers of the ischiocavernosus muscle extend to a point 3 cm beyond (dorsalward) the attachment of the clitoridal crus

superficial and deep compartments is not clearly defined (Fig. 4). The body of the gland is transversely placed on a level with or slightly deeper than the bulb parallel with its base, the duct passing medio-anteriorly at an angle of approximately 75 degrees and directed slightly outward toward the vulva. The Bartholin glands are not palpable when normal, since their outlines are masked by enveloping structures (Figs. 3 and 4). When diseased, because limited posteriorly and superficially by firm musculo-fascial tissues, they enlarge in the direction of least resistance often to a depth of several centimeters, and extend anteriorly palpable at the point of junction of the middle and posterior thirds of the vagina.

The superficial transverse perineal muscle, slender yet definite, arises out of the trigonal musculature as if it were a true derivative thereof (Figs. 4, 8 and 9, exposed in Fig. 9 by removal of bulbs and fascia). Posteriorly the superficial transverse perineal muscle lies directly against the external anal sphincter (Fig. 8) anteriorly it almost reaches the posterior wall of the vagina (Fig. 9). At the central tendinous point the deep and superficial transverse perineal muscles merge, and with them the external anal sphincter and bulbocavernosus. The superficial transverse perineal muscle is important as a surgical landmark, for around its posterior border near its origin from the tuberosity of the ischium the pudendal nerve and artery turn upward to reach the perineum (Figs. 8 and 9). Here one may block the pudendal nerve for obstetrical delivery; destruction of its anterior perineal branches and ramifications is resorted to for relief of pruritus vulvae.

Each ischioanal emissary muscle begins well back on the tuberosity of the ischium, its hinder fascicles being traceable to the point at which the posterior fibers of the urogenital diaphragm arise (Fig. 6). Anteriorly muscle fibers give way to aponeurotic halfway between the tuberosity and the pubic arcuate ligament (Fig. 9). The investing fascia (inferior perineal fascia) which then continues onward covers the front of the pubis (and clitoral body in specimen III, Fig. 9). On the abdomen it becomes the outer investing layer

In specimen III the body of the clitoris is on each side, the urethra opens on posterior to the tip of the glans. The anterior end of the clitoris, rounded off by distance of cm from the pubic crest, by cm from the central tendinous point of the perineum. Posteriorly between the lesser vestibular and the anal sphincter (which latter overlaps and obscures part of the bulb) the bulb is cm wide. The maximum width of each bulb is cm narrowing anteriorly each joined by cm—distance of cm from the central tendinous point at the middle, each cm cm in width, twice that wide near the anterior end.

In specimen I each bulb is cm long (at point of narrowest base), cm in the maximum width, cm thick. The urethra opens about 1 cm from the clitoris, cm thick. It joins the body cm proximal to tip, cm distal to the point at which the body becomes free, and cm distal to the superior or anterior limit of the clitoral body. The body of the

of the external oblique (McKay and Anson, 1938). The muscle and the outer investing fascia are separable from the tissue of the erectile crus, when removed (Fig. 10) a very heavy trunk is exposed.

3. *Erectile bodies.*¹ The vestibular bulbs are much less vascular than conventional figures would lead one to expect; they are composed chiefly of fibrous material resembling that of the tunica albuginea of the testis. This is in accord with surgical experience: the erectile tissues, reputedly extremely vascular, are not more than generously so, and constitute no particular hazard at operation.

In one of the specimens (No. III) the conjoined bulbs are not connected anteriorly with the conjoined crura; that is, there is no intermediate mass between pairs of erectile bodies, differing from the arrangement usually described, the bulbs, then, do not contribute to the formation of the clitoris (contrast specimen in Fig. 6, Curtis, 1938) the inferior perineal fascia completely separating the sets of erectile bodies. This fascial layer in specimen III, forms a complete envelope for the pubic extremities of the clitoral crura, covering the inferior surface of the conjoined ends so that the body of the clitoris appears merely as an elevation (Fig. 9) in resting the superior surface and resting upon the pubic symphysis (Fig. 10). Continued upward in inguinal position, the fascia becomes the innominate fascia (trussed around the clitoral body in Figs. 9 and 10). The extent to which the clitoris is covered by heavy fibrous laminae doubtless accounts for the fact that its plexiform content occasions little difficulty in lacerating injuries to the perineum. In some specimens (e.g. specimen III in the current group) vascular tissue is slight in amount, the fibrous capsule being the more prominent as seen in gross section in others (e.g. specimen I) the type of plexus present is that usually illustrated in textbooks.

III. PERINEUM DEEP COMPARTMENT

The roof of the superficial perineal compartment is, at the same time the floor of the deep compartment (Fig. 8) it is one of the two fascial

clitoris is cm wide at the broadest part, cm at the narrowest (just proximal to the "glans"). The hind fourth of the clitoris is cm distal of the free part cm the maximum height cm (at the penile end of the free portion).

The muscular part of the urogenital diaphragm in specimen II, is cm in maximum width (at base) two-thirds of the set cm above up at maximum, one-third short (two-thirds, vaginal orifice). The main part of the diaphragm is cm long, narrowed at the middle cm from the pubic arcuate ligament to the deep transverse perineal part. The thickness varies from to cm. The deep transverse perineal muscle about cm wide.

At this level the following additional measurements are important: depth of the pouch at symphysis, cm (measured in the plane of symphysis) distance from the superior border to the top of the pouch, cm width of vestibule, cm.

Fig 4. In the anal part of the perineum the levator ani and external anal sphincter muscles of each side are shown by removal of the superficial fatty tissue. In the urogenital part of the perineum on the right side by cutting away the muscle fascia, the ischio-cavernosus, superficial transverse perineal, and bulbo-cavernosus muscles have been brought into view. On the left side the bulbo-cavernosus muscle has been reflected to expose the bulb of the vestibule and greater vestibular (Bartholin's) gland and duct. Anteriorly are seen the glans body, and intermediate mass of the clitoris.

laminae which invest the musculature of the urogenital diaphragm, the fasciae' (ofttimes as strong as aponeuroses), together with the muscle, make up the diaphragm.

The urogenital diaphragm is regularly described as triangular in outline, actually it is of quadrangular form. The pouch which its fascial layers forms does not completely segregate the contained muscles, since the deep and the superficial transverse perineal muscles blend medially (Fig 9). The musculature not only serves as a urethral sphincter (sphincter urethrae membranaceae) but extends superior to the coccygeal extension of the

external anal sphincter to a firm coccygeal insertion (Fig 10). In this respect it resembles the pubococcygeal part of the levator ani (Figs 6 and 7). When the urogenital diaphragm has been entirely separated from its posterior attachments, and reflected, the pelvic diaphragm still remains as a complete partition (Fig 12). Thus, the urogenital diaphragm does not fill a defect in the pelvic diaphragm but, rather, constitutes an additional re-enforcing layer for support of the pelvic organs.

In the specimen illustrated, a subdivision of the muscular components of the diaphragm into deep

transverse perineal muscle and urethral sphincter is not apparent (Fig. 9). The deep transverse perineal muscle of the urogenital diaphragm does not terminate sharply along a transverse line; a triangular prolongation passes backward, on either side of the rectum deep to the coccygeal extension of the sphincter ani (Fig. 9). The full extent of this prolongation of the urogenital diaphragm is revealed when the anal sphincter is removed (Fig. 10). The fascicles of the two sides converge, intermingle behind the anal canal and extend to a narrow coccygeal attachment, lying between the anal sphincter and the pelvic diaphragm, considering this hitherto undescribed element as an integral part of the urogenital diaphragm, the latter is, as previously stated, quadrangular not triangular. Many of the backward-directed fibers from the urogenital diaphragm penetrate the substance of the anal sphincter around its anterior three-fourths, interdigitating with these fibers and with the downward continuation of the levator ani (Figs. 10 and 11); other fibers continue around the anal canal to meet those of the opposite side, to become merged in the midline with an aponeurotic thickening. The latter continues to the coccyx, lying beneath the sphincter ani and conforming to its contour (Fig. 9 cf. Figs. 10 and 11).

In the posterior part of the diaphragm, the whole layer of urogenital musculature is laminated, partially separable into strata by incomplete fascial plates (Fig. 1). Transversely directed fibers of the part of the urogenital diaphragm between the anal and vaginal canals lie just beneath the superficial transverse perineal muscle (Fig. 10); those fibers which pass in exactly transverse course are elevated somewhat on the anterior wall of the anal canal (Fig. 1 level 1); they lie deep to the external anal sphincter and the superficial transverse perineal muscle. From a slightly deeper level appear fascicles which following a more oblique course ultimately reach the sides of the anal canal (Fig. 1 level 2). The coccygeal prolongation of the diaphragm arises from a still deeper level; the fibers, beginning near the tuberosity of the ischium, at first pass medially then, turning posteromedially as they skirt the anal canal, they course toward the coccyx (Fig. 11 level 3). The urethra, then, receives a considerable muscular support on the perineal aspect; sphincter fibers pass into and in front of the urethra (Figs. 9 to 12) downward upon it (Fig. 3, urethra retracted) and behind it (Figs. 1 and 3 at star, mucous membrane removed). The latter band is a reliable for surgical correction of urethrocele

(see Fig. 221 Curtis, 1938). On the pelvic aspect this support is augmented by similar contributions from the pelvic diaphragm, the anterior band of fibers (Fig. 6, at arrow) bounding the inconsiderable perineopelvic hiatus. In some specimens the musculature of the urogenital diaphragm seems to be developmentally defective; the deep compartment containing a venous plexus which is actually bulkier than is its muscular content. Our clinical observations, directed to this feature, indicate that many cases subjected to the rigors of childbearing are predisposed to urethral sagging because the urogenital support is congenitally weak.

The deep layer of the urogenital diaphragm is distinct from the levator ani against which it lies (Fig. 12); there is no intervening fascial stratum between the apposed layers of musculature of the two diaphragms. Although in the middle one-fourths of the width of the urogenital diaphragm in the anovaginal area the anal and urogenital diaphragms are in apposition, fibers are not exchanged between them to a noteworthy degree.

For a discussion of the musculofascial sheaths of the pelvic lacera, which are so important in the repair of cystocele and rectocele, the reader is referred to earlier articles in this series (Curtis, Anson and McVay 1939; Curtis, Anson and Benton, 1940). The current study has impressed the authors forcibly with the importance of the support afforded by the urogenital and pelvic diaphragms in the repair of cystocele and rectocele, reaffirming previous evidence that the musculofascial collars of the lacera are the chief support. Comparison of dissected material with corresponding tissues in patients subjected to cystocele and rectocele operations reveals the fact that there is commonly great hypertrophy of the supporting fascia in pathological cases, the degree of hypertrophy being in general proportional to the duration and extent of the lesion. The urogenital diaphragm and the pubococcygeal part of the pelvic diaphragm play a considerable rôle in the control of incontinence in cystocele cases; transverse mattress suture of the fibers lateral to the floor of the rethra (Fig. 2) is as valuable in all cystocele cases with urinary leakage. In those infrequent cases in which dribbling persists after an apparently successful operation, a satisfactory result may be obtained by bilateral snipping up of the fibers of the pubococcygeus which normally maintain the urethra in close attachment to the pubis (at arrow in Fig. 6 at star in Fig. 13).

In making a lateral or median episiotomy and in the tearing and retraction which accompanies labor the tissues of both diaphragms are involved

Fig 5 Female perineum, specimen II External anal sphincter, exposed by merely reflecting the skin The position of the coccyx is indicated by dotted line

(Figs 8 to 14) An anatomic feature of clinical importance merits emphasis in this connection, the pelvic and urogenital diaphragms are in close apposition in approximately the median two-fourths of the diameter of the outlet lateralward they diverge greatly, being separated by the anterior recess of the ischiorectal fossa. However, in the entire region subjected to perineal surgery the two diaphragms are in apposition, the urogenital diaphragm comprising perhaps four-fifths of the thickness, the levatores one-fifth. The urogenital diaphragm is more dense and firm, and thicker than the pubococcygeus of the levator ani with which it makes a surgical unit. Together they constitute the so called "levator ani" of clinical parlance.

IV PERINEUM ANAL MUSCULATURE

1 *External anal sphincter* In a perineal approach to the structures which close the pelvic outlet, the external anal sphincter is the first

muscle encountered, it is subcutaneous in position, broad but thin (Figs 5, 8 to 10).

The muscle is an orbicular sphincter, with a prominent coccygeal extension commonly called the anococcygeal ligament. Anteriorly it overlaps the conjoined bulbs of the vestibule, and into it are implanted the small superficial transverse perineal muscles. It is readily dissectable from neighboring structures (Figs 8 and 10). Owing to the proximity of the external anal sphincter to the cutaneous surface, the surgeon has difficulty identifying this structure at operation, further handicapped as he is by retraction of the injured tissues and by pathological changes.

Although a single partial division of the muscle incident to hemorrhoidectomy usually leaves a competent sphincter, a complete tear of the perineum does not, sphincteric incompetence results from retraction of the torn ends of the muscle, and from concurrent tearing of the urogenital diaphragm and the levator ani (Figs 9 to

Fig. 6. Female pelvis, specimen III, viewed from above and behind, looking into the lateral anterior portion of the pelvic bowl (see inset: arrow indicates direction of view). The musculature is exposed by complete removal of retroperitoneal and ligamentous structures, and of the fascial lining of the pelvis (including the endopelvic fascial continuations upon the sacra). The curved arrow indicates the direction of muscle-fibers in the urethral portion of the pubococcygeus. The urethra, vagina, and rectum have been transected near their points of passage through the pelvic diaphragm. Successive dissections of the same specimen follow (Figs 8 to 5).

2) In the procedure of repair the operative exposure of choice is a preliminary curvilinear incision around the anus, the vaginoperineal flap turned down over the anal aperture, followed by dissection of the retracted tissues, all proportionate to the extent of the lesion. Restoration of the injured sphincter urogenital diaphragm, and levator ani by sutures anterior to the rectum and anus is usually made without identifying the details of each anatomical component, although the circularly disposed firm fibers of the sphincter ani, hidden in the more superficial fibrous and fatty tissues, are in sharp contrast with the bundles of longitudinally directed levator ani at a deeper level closely applied to the rectal core.

V. PELVIS PERITONEUM AND SUPERITONEAL TISSUES

In an earlier article in this journal (Cruz, Anson and Beaton 1940) the anatomy of the

pelvic peritoneum and subserous tissues was fully described. It was therein stated that the general cellular tissue, the heavy ligamentous support of organs, and the fascial tubes covering the latter may be even more readily mobilized by gross dissection than they usually are in the course of pelvic surgery even by those who employ the technique of scissors dissection. Of these various tissues, contrary to Tandler's belief (in *Viel Stoetzel*) clinical evidence substantiated by anatomic dissection indicates that the peritoneum serves not merely as covering but that, with the contiguous areolar tissue attached thereto, it affords real support.

VI. PELVIS PART A. MUSCULATURE

1. *Endopelvic fascia*. That part of the endopelvic fascia which is reflected upward upon the rectum and vagina lies as the pelvic floor at the points at which these organs pass through the

Fig 7 The same specimen, viewed from the front, looking into the "parietal," or posterior, part of the pelvic bowl (see inset) Dissection as in preceding figure

diaphragmatic musculature (Curtis, Anson, and McVay, 1939, Figs 1 and 2) The covering for the bladder, however, is reflected away from the inferolateral walls of that organ in such a way that the urethra receives only a partial investment, being so covered only in front Since there are three tubes of fascia, in succession, encasing the urethra and bladder, the vagina and lower uterus, and the rectum, there is a double layer of fascia between adjacent organs In each instance the fascial sheath is in intimate relationship with the musculature of the corresponding viscus, receiving muscle fibers from it The fascial sheaths, each re-enforced by muscle fibers from the subjacent coat of smooth muscle, are utilized to furnish the major support in the repair of herniations of the tubular viscera, i.e., urethrocele, cystocele, and rectocele (Particularly in the case of rectocele, and in cystocele with incontinence, repair of the levator ani and the urogenital diaphragm are also important)

There has been prolonged controversy as to whether the supporting tissue utilized in plastic repair is muscle or connective tissue, likewise, it has been emphasized by anatomists that there is no fascial tissue in these regions sufficiently extensive or firm enough to be of service in repair A simple explanation suffices Wherever there is unusual mobility, also under pathological conditions, such as uterine prolapse or cystocele, there are always localized thickenings of the connective tissue This accounts for anatomists' failure to discover the thick vesicovaginal supportive tissues, an "anatomists' oversight" which aroused Halban's curiosity Blair Bell's academic insistence that the supportive tissue is muscle, not fascia, meets explanation in the fact that the fascial sheaths derive muscle fibers from the hollow viscera which they surround Here, too, we meet Tandler's requirement that connective tissue must be associated with muscle in order to be classified as "fascia" and in order to yield real

Fig. 6. In the anal triangle the external anal sphincter has been freed somewhat in order to show the coccygeal extension of the urogenital diaphragm. In the urogenital triangle the following superficial structures of the perineum have been removed: the integument and the subcutaneous tissue; the mucous membrane of the vestibular walls; the vestibular bulbs (no intermediate mass present); the inferior fascia of the urogenital diaphragm; some of the more superficial fibers of the urethral sphincter and deep transverse muscles which were attached to the inferior fascia. Shown are the following: the muscles of the urogenital diaphragm, roof of the vestibule, with the vaginal and urethral orifices; a portion of the transverse ligament of the pelvis; the body of the clitoris; the inferior perineal fascia as it invests the ischio-cavernosus muscles and covers the front of the pubis; the medial portion of the superficial transverse perineal muscles (stump on left elevated to demonstrate fusion at the central tendinous point of the perineum). The transverse ligament of the pelvis (i.e., the anteriorly fused fascial layers of the urogenital diaphragm) is concealed by the pubic symphysis.

has been removed, the musculature is brought into view (Figs 6 and 7). The muscles are disposed in two pairs, levatores ani and coccygei. The levatores occupy chiefly that part of the pelvic outlet anterior to coccyx, the coccygei that portion of the outlet behind (and above) the terminal elements in the vertebral column (Fig 7, cf Figs 14 and 15). Together they form a supporting floor upon which the pelvic viscera rest

and in which their terminal portions are firmly anchored (Fig 6), also a dorsal wall for the pelvic cavity (Fig 7). Each levator ani consists, in turn, of two parts, pubococcygeal and iliococcygeal, which, respectively, serve in the capacities just mentioned. These subdivisions will now be discussed separately, as will also the piriformis and obturator internus muscles which assist in forming the lateral and dorsal walls of the pelvis.

Fig. 1. In the anal triangle the external anal sphincter, now detached from the subjacent muscles of the urogenital and pelvic diaphragms and from the intrinsic musculature of the anal canal, has been drawn aside to reveal the back- and directed fibers of the urogenital triangle, the bulbocavernosus muscles have been rolled medialward by from the crura and the body of the clitoris; the superficial transverse perineal muscles have now been entirely removed to show the coarse fibers of the base of the urogenital diaphragm. It is evident that the so called sphincter of the urethra sends muscle fibers not only into the vagina, but also into the rectum, and in front of the urethra, i. e., but also into the vagina, & across the midline between the vagina and anus, but the all of the latter & and back and to the coccyx.

a. P. pubococcygeus muscle. The pubococcygeal muscle is, obstetrically and surgically the most important muscular element of the pelvic diaphragm, since it serves as a direct support for the bladder and urethra for the vagina and uterus and for the rectum. This fact is not made clear in the accounts presented in either surgical or anatomical textbooks on the contrary it is everywhere figured as sweeping backward around the organs to leave a very considerable opening in the anterior half of the pelvic diaphragm.

Viewed from within the abdomen (Fig. 6) the pubococcygeal portion of the levator ani is seen to be attached along the pubic bone and the

tendinous arch, the latter being the longer organ, the junction of the two forming a peak directed forward. Anteriorly there is merely a shallow hiatus, not a U-shaped cleft. In the midline the dorsal run of the clitoris passes through this opening into the pelvis, behind the pubic arch ligament and in front of the transverse ligament of the pelvis. The anterior fibers which cross transversely in front of the urethra are muscular and form a narrow but strong band; those nearest the urethra ascend upon the latter as do others from the lateral aspect. Some fibers also descend upon the urethra. The cleft is not seen in perineal view being concealed by the inferior por-

FIG. 11. In the anal part of the perineum the structures remain as in the preceding drawing. In the urogenital part of the perineum on the right the musculature is reflected as a single sheet to expose the superior fascia of the diaphragm, on the left its laminated character is demonstrated by making a similar elongate cut, but to depths which mark natural cleavage planes along which the strata are freed for a short distance to either side of the incision. The superficial lamina, 1, passes chiefly to the vagina, the intermediate one, 2, into and in front of the anal canal, the deep layer, 3, backward to the coccyx. The body of the clitoris and the anterior portions of the crura have been removed, the ischiocavernosus remain only at their proximal ends. The mucous membrane has been removed on the anterior wall of the vagina (at star) to show the muscular support derived from the urogenital diaphragm.

tion of the pubis (Figs 10 to 12). As may be seen from within the pelvis, the "visceral" sets of fibers of the pelvic diaphragm turn quite directly toward each organ, gaining implantation into their walls (Fig 6). The anterior cleft, then, is very shallow—not evident at all in perineal view (Fig 9). The urethra is firmly attached to the pubis—a fact of major clinical importance.

In the excavation between the vagina and rectum the narrow anteroposterior band of fibers fastens the organs closely together and ascends upon each tube. Behind the anal canal, many pubococcygeal fibers follow a semilunar course, but the majority pass posteriorly, in a thin sheet, to the coccyx, resting upon the iliococcygeus (Fig 6, concealed by the latter in pelvic view, Fig 12).

b Iliococcygeus muscle. The arciform aponeurotic origin of the iliococcygeus is shared with

that of the pubococcygeus (Fig 6, Figs 14 and 15, observer's left half of figure). The direction of the fibers is transverse (Fig 7), in contrast with the arrangement of fascicles in the pubococcygeus, whose fibers are directed somewhat sagittally (Fig 6).

c Coccygeus, piriformis and obturator muscles. The pelvic diaphragm is completed on each side posteriorly by a coccygeus muscle (Figs 7, 14, and 15). The plane of the flat surface of the coccygeus muscle lies at almost a right angle to that of the iliococcygeus. Narrower at the origin than at the insertion, in contrast with the iliococcygeus, the paired muscles fill the space between the iliococcygeus and the piriformis. The fibers of the coccygei do not unite in the midline in a muscular band but are inserted almost entirely into the coccyx by a firm thin aponeurosis.

Fig. 2. The urogenital diaphragm has been freed from the pelvic diaphragm, cut along the ischio-pubic ramus on each side and the coccygeal part behind (see arrows) then turned forward on the remaining pubic attachments. The space thus opened into is the anterior recess of the ischio-rectal fossa, from which all fatty tissue has been removed. The pubococcygeal part of the levator ani, exposed by removal of its thin investing fascia, is shown to constitute supporting muscle sheath for each of the lateral tubes.

The piriformis muscle partially closes the space of the greater sciatic foramen (Figs. 14 and 15) although belonging to the psoas-femoral group of muscles (like the obturator internus) it serves, to a degree, a diaphragmatic function, since it continues in the stratum of the coccygeus. In the standing position, the muscle is on the wall rather than on the floor of the pelvic cavity.

The importance of the obturator muscle as a parietal element is emphasized by examination of the space which it occupies (Fig. 4, cf. Figs. 6 and 15). The obturator internus fills the lesser sciatic foramen as it passes through the foramen.

3. *Pelvic diaphragm as a whole.* The three muscles which constitute the pelvic diaphragm proper and which represent the original tail muscles, *i. e.*, the pubococcygeus, the ischio-coccygeus, and the coccygeus, all take origin from the pelvic bones. The parts of the levator are either implanted into the walls of the tubular organs for

which they constitute a diaphragmatic support or—in the intervals between adjacent organs and in those between organ and bone—join the corresponding muscle of the opposite half of the pelvis. The coccygeus, being posteriorly situated, most insert into the sides of the coccyx. In the specimens illustrated a distinct cleft separates the adjacent muscles of the diaphragm, as is apparent when the investing fasciae are removed (Figs. 14 and 15).

The pubococcygeal portion of the levator ani constitutes what might be termed the "visceral" part of the pelvic diaphragm, since it is by this muscle that the terminal portions of the lateral tubes are firmly clasped (Fig. 6). There is no "hiatus of the levator ani" surrounding the visceral tubes at the site of their perforation of the pelvic diaphragm (Figs. 6, 14, and 15) the implantation of the medial fibers of the pubococcygeus firmly into the lacera constitutes a

Fig 13 The urogenital diaphragm has been removed except for a narrow strip of attachment along the ischiopubic ramus and at the transverse ligament of the pelvis. Here are exposed the components of the clinically important "perineal wedge"; the pelvic diaphragm has been incised in the middle line from the anal to the vaginal canal. The relation of these canals to the pelvic diaphragm and to fascial sheaths which intervene between pelvic diaphragmatic and intrinsic layers of musculature is shown. Like the vagina and the anal part of the rectum, the urethra receives special fibers from the levator ani (see star).

firm attachment. In perineal view it may be seen that the fibers which reach the sides of the anal canal descend upon it, as if interrupted in their course, as they descend, their direction is slightly backward as well as toward the surface (Figs 12 to 15). The fibers which reach the front of the canal likewise descend upon it, forming with the others a sleeve of definitely funnel-shaped character. More medially placed fibers, which, similarly, reach the vagina, terminate upon its sides, without, however, turning sharply inward (i.e., without changing course from sagittal to coronal plane), they fade away as they approach and interweave with the intrinsic muscle fibers of the vagina.

The intimate relationship of the pubococcygeus to the visceral tubes, and the direct support which this arrangement affords (Figs 6, 13, to 15), are of fundamental importance in a proper understanding of the mechanics of plastic repair. Yet the operator should be aware that this muscle is in relation only with the terminal portions of the viscera, the support at a higher level is contributed largely by the fascial collars and related ligamentous structures. The latter statement applies particularly to the operative relief of

cystocele and urethrocele, adequate rectocele repair requires not only the support of the rectovaginal fascial sheaths, but also restitution of the pubococcygeus together with the urogenital diaphragm.

Contrary to the usual gynecological concept, the chief part of the pelvic diaphragm is centered farther posteriorly than clinicians are accustomed to consider it. The bands of muscle fibers constituting the diaphragm are less massive anteriorly, in the urogenital region, becoming more dense and concentrated posteriorly where the fibers converge behind the rectum. The heavier nature of this so-called "levator plate" is ascribable to the fact that the fibers of the iliococcygeus course more transversely than do the fibers of the pubococcygeus, therefore, as the two subdivisions of the levator ani approach the coccyx, there is a double muscular banding where the iliococcygeus passes beneath the V-shaped vertebral extension of the pubococcygeus (Fig 6, cf Fig 14). Nor is this all, since beneath the former, in turn, is situated the conjoined muscular plate consisting of the external anal sphincter and the coccygeal prolongation of the urogenital musculature (Figs 9 to 11). The iliococcygeus is thus clasped be-

Fig 15 Pelvic diaphragmatic and associated musculature Lateral view By cutting parasagittally through the superior pubic ramus and through the body of the ischium in front of the spine, and by then removing the bone between the pubic and ischial attachments of the levator ani (see inset), the following additional anatomical features, important in gynecology, are demonstrated the arciform origin of the levator ani from the covering of the obturator internus (latter intact on specimen's left half), the uniformity in direction of the levator fibers the position of the anal part of the rectum at the "spout" of the diaphragmatic "funnel", the capaciousness of the foramina above and below the piriformis (at arrows), the relatively small size of the clefts between parts of the diaphragmatic musculature, the depth of the bony sciatic notch which is closed by the coccygeus and piriformis muscles

being the anal levator and sphincter, the bulbocavernosus and transverse perineal muscles (cf Figs 9 to 11). The collection is said to be a wedge-shaped mass, the edge of which is directed upward, the base downward toward the skin. It is a matter of surgical consequence that the apical part of the wedge consists of the pubococcygeus muscle (Fig 12), and, more deeply, of the fascial coverings of the anal and vaginal canals (Fig 13). If this succession were not appreciated, repair of rectocele could not be properly managed nor dangerous instrumentation within the pelvic cellular tissues fully avoided.

The iliococcygeus has no direct relation to the organs as they pass from the pelvis to the exterior, even its most anterior fibers are removed from the anal canal by an appreciable distance, in crossing the midline in front of the coccyx, the muscle merely forms part of the floor and wall upon and against which the terminal part of the rectum rests. Similarly, of course, the iliococcygeus offers indirect support to the sigmoid colon and the jejunoleum, especially when the body is in the standing position. The iliococcygeus is of obstetrical importance as a support, it is of lesser interest in gynecological plastic operations. As

part of the pelvic diaphragm it is a factor in uterine support, and it is also important clinically in relation to disturbances in function of the sigmoid-rectum, which it supports to varying degree in different individuals.

The coccygeus is of subsidiary diaphragmatic service in helping to support the organs as they lie within the pelvic cavity and in passing as a band-like barrier across the space between the coccyx and the ischial spine. It assists the levator ani (Figs. 7, 14 and 15). In pregnancy it furnishes a major support, but in labor although subject to considerable strain, it forms only the posterior wall of the parturient canal and therefore suffers material injury only in pathological cases.

The coccygeus, piriformis, and obturator internus muscles assist the associated ligaments in maintaining the integrity of the sacroiliac joints holding the posterior wall of the pelvis together. Important anatomically as part of the pelvic framework, they are of gynecologic importance chiefly in relation to backache and sacroiliac sprain.

As mentioned above the retropublic cleft transmits the dorsal vein of the clitoris (Fig. 6) and not infrequently an accessory clitoral artery. This transmission brings into vascular communication, by an anterior route, the pelvic and perineal tissues. The sciatic foramina transmit the internal pudendal vessels (cut in Figs. 8 and 9) serving a comparable function posteriorly. There are however intermediate vascular connections of lesser importance in specimen III passing from the deep surface of the vestibular bulbs, they are carried through minute openings in the urogenital (Figs. 10 and 11) and in the pelvic diaphragm (Fig. 13) they are grouped around the anal canal, and occur only in that median area where the two diaphragms are in contact; they are not situated in a lateral position where their route would involve passage through an ischio-rectal fossa. Whenever vessels are not confined to the two main pudendal routes (retropubic cleft and sciatic foramen) they are concentrated as accessories, in a median swath some two-fifths the width of the pelvic outlet. Curiously vessels do not employ in their perineopelvic passage the clefts which separate the three subdivisions of the pelvic diaphragm (pubococcygeus, iscococcygeus, and coccygeus muscles).

SUMMARY AND DEDUCTIONS

The subcutaneous tissue of the labium is not an indiscriminate mass of fatty tissue through which pass scattered fascicles of dartos muscle. It is a definitely lamellated stratum in which is lodged a

finger-shaped fatty diverticulum of the superficial inguinal fascia which is readily shelled out of its labial pocket. It is this process which produces the mound-like form of the greater lip. The posterior limit of the labial mound is coterminous with the bluntly pointed tip of the prolongation. The process rests upon the deep membranous layer of the superficial fascia. Within the tissue of its proximal portion, which begins at the subcutaneous orifice of the inguinal canal, not only is the round ligament dissectable but also is thinned form successively the labial extensions of the parietal layers of the abdomen.

Within the perineal compartment for which the deep membranous layer of fascia forms a firm floor, a much thinner but clearly defined layer the inferior perineal fascia covers the bulbocavernosus and ischioavernosus muscles, the former again invested with a firm musculofascial sheath. In addition to the very definite individuality of its layers, another feature of the perineal fascia merits clinical as well as anatomical emphasis: the firm musculofascial sheath which overlies the bulbocavernosus muscle assumedly is that utilized in the operation of Martius, a procedure for relief of incontinence of urine in cases with destruction of the floor of the urethra.

Inability to palpate the normal Bartholin gland is not ascribable solely to its small size (Fig. 4). It lies hidden behind the fatty process at a considerably lower level than the infected gland, which is limited posteriorly by firm musculofascial tissues and therefore must extend anteriorly as it enlarges.

The proximity of the external anal sphincter to the cutaneous surface merits emphasis, as do also its wide trigonal and coccygeal attachments. Is operative restitution of the sphincter the firm anal and coccygeal extensions of the rogenital diaphragm and the pubococcygeal part of the pelvic diaphragm are important factors in the repair.

At the central tendinous point of the perineum the anal sphincter blends with the superficial transverse perineal muscle. The transverse perineal muscle in turn, is blended with the underlying musculature of the urogenital diaphragm. The latter does not end at what is commonly considered the base of the urogenital diaphragm. Rather it is prolonged to coccygeal insertion, the urogenital diaphragm constituting totally a sling which utilizes not only pubis and ischium for fixation, but also the end of the vertebral column.

The musculature of the urogenital diaphragm is trilaminar. Strictly it is the deepest of the three

laminae of the urogenital diaphragm that end on the coccyx, the intermediate one surrounds the anal canal, the most superficial merges chiefly with the walls of the vagina and the urethra and the anterior portion of the external anal sphincter.

We have been taught, catechetically, that the urogenital musculature crosses the midline between urethra and vagina, and between vagina and rectum, but that the pelvic diaphragm is deficient in relation to the visceral tubes, fibers supposedly sweeping backward behind the anal canal, to leave an elongate U-shaped cleft, but such a concept is entirely incorrect, fibers of the pubococcygeal part of the levator ani reach each of the three tubes—anal, vaginal, and urethral, and descend upon each to blend with the intrinsic muscular coat. The visceral support is so complete that even the urethra receives a full investment, no cleft is visible from the perineal aspect, even when the urethra is drawn away from the pubic symphysis.

It is the anterior or pubococcygeal division of the levator ani that affords continuous support for the organs of the urogenital and pelvic parts of the perineum, the iliococcygeus completes the diaphragm at the sides and behind, but does not come into contact with the viscera. It underlies the coccygeal extension of the pubococcygeus. This reduplication of muscle layers gives added firmness to the so called levator plate, that heavy

portion of the levator ani situated behind the anus.

The preurethral cleft is small, oval in outline, little more than a retropubic hiatus for transmission of vessels and nerves from perineum to pelvis. Normally the urethra is close to the pubis—a fact of clinical importance in evaluating lesions associated with incontinence of urine. The urethra is displaced from the pubis by a traumatic labor, the pubococcygeal anchorage to the pubis being thereby disturbed. It is this preurethral cleft anteriorly and the sciatic foramina posteriorly that transmit almost all of the important blood vessels from one side of the pelvic diaphragm to the other.

Details are shown of technique by which excess skin and mucous membrane around cervical neck and urethra are excised, and then urethra formed, bladder closed after insertion of U shaped double which emerged below.

EXSTROPHY OF THE BLADDER

The First Case in Which a Normal Bladder and Urinary Control Have Been Obtained by Plastic Operations

HUGH H. YOUNG, M.D., F.A.C.S., Baltimore, Maryland

OF ALL genital abnormalities exstrophy of the bladder is certainly one of the most terrible. Until the recent present no operator has, I believe, ever obtained a complete cure in exstrophy. The great Iren delenburg spent his life trying to get a perfect result in these poor children and shortly before his death, in a very frank and pathetic article, he detailed the many variations of technique that he had employed without a single perfect result. He believed that it was necessary to disarticulate the pelvic bones at the sacroiliac synchondrosis so as to bring the widely separated pubic bones together in order to get a satisfactory urethra with sphincteric control but even though he carried out this osteoplastic technique and succeeded in turning in the exstrophic bladder he failed to get urinary control in a single case.

I too have been working on this subject many years and although on the verge of success several times, some complication has always occurred to prevent a complete cure of the exstrophy with perfect urinary control and interval urination. After a series of these heart-breaking failures I am glad to be able to report a complete success in a case of extensive exstrophy of the bladder in a girl of 6 years in whom, by a technique that I have gradually developed, I have finally succeeded in obtaining the cure of this awful affliction that

From the James Buchanan Brady Urological Institute, Johns Hopkins Hospital.

has been sought for by surgeons the world over for many, many years.

CASE REPORT

Extensive exstrophy of the bladder with 4 inch separation of the pubic bones. Cure of exstrophy at first operation, urinary control obtained by urethral and muscle plastic at second operation.

I. T., a girl aged 4 years, was admitted to the Brady Urological Institute on June 15, 1939 with congenital exstrophy of the bladder. Her faithful mother, by dint of great care and cleanliness, prevented inflammatory complications but the large extruded mass and the constant escape of urine into the child's clothes made life unbearable. Otherwise the child had developed well and enjoyed excellent health. The condition present is shown in Figure 1. On the surface of the exstrophied bladder two cone-like projections were present and from them urine spurted on each side. A roentgenogram showed wide separation of the

Fig. 1 Photograph of patient at age of 4½ years. Exstrophied bladder is 2 inches in diameter.

Fig. 4. Plastic to form urethra, replace bladder within abdomen, and close it after supplying U shaped catheter drainage.

pubic bones with a ligament connecting them. On this lay the wide open urethra. The mother, as instructed, to reduce her efforts to prevent inflammatory changes in the extrophied masses and to return with the child in a year for operation.

On July 2, 1940, the patient returned. With the child standing the extrophy presented large almost globular masses which had increased in size and projected inches from the surrounding abdomen. The extrophied bladder measured inches in diameter. The ureters were seen as bulging prominences on each side

of the lower third. The upper half of the extrophied mass was covered by epidermis. The covering of the rest of the bladder looked like normal mucous membrane. The line of demarcation between the skin and the mucosa was sharp. The urethra was wide open and contained a central rib. The orifice of duct, probably Bartholin's, was visible on the left side. The clitoris was divided and presented rounded areas on each side (Fig. 5). The orifice of the vagina as small transverse slit. The perineum and anus appeared normal. The extrophied mass was easily pushed with finger back through an opening in the abdominal

Fig. 5. Technique employed in obtaining fascial transplants from abdomen

wall which had solid firm edges. External to these the widely separated recti muscles ran downward and outward to join the separated pubes. With the exception of the central defect the abdominal musculature appeared normal. Streams of urine escaped intermittently from the ureters. Urine collected from both sides was pale of low specific gravity and free from infection. General physical examination was negative.

A plain x-ray negative (Fig. 6) showed a 10 centimeter separation of the two halves of the pubes. The globular exstrophied mass was plainly shown.

Mr. Ditsch's drawings depict the condition and the operative technique accurately.

In Figure 3, 1, the skin which covers the upper half of the exstrophy is shown and below it the orifices of the ureters, the wide open urethra, the separated halves of the clitoris, and the orifice of the vagina. In Figure 3, 2, clips placed on the skin at its juncture with the vesical mucosa demonstrate, by traction, that this skin can be used to cover the wound at operation. The incision crossed at the junction of the skin and mucosa and then continued around the exstro-

phed bladder and down below to form new urethra (Fig. 3, 3). In Figure 3, 4, the skin flap is being dissected from the bladder muscle. Figure 4, 1 shows the excision of mucosa on each side of the urethral flap thus disclosing muscle to be used in forming a sphincter. In Figure 4, 2 the edges of the mucosa are approximated with a continuous No. 0000 chromic catgut suture thread of 10 in being left in the new made urethra as

subsequent conductor. In Figure 4, 3, the bladder is pushed through the abdominal defect preparatory to approximating the sides of the bladder wall (Fig. 4, 4). Drainage is provided with a rubber tube which in the form of a U emerges from the bladder on each side (Fig. 4, 5). In Figure 4, 6 the bladder closure has been completed, and the nylon is brought out through puncture of the skin flap. Having closed the urethra and bladder

Fig 7 Suture of fascial transplants completed (insets 1, 2) after which U shaped tubes had been drawn out along side of thigh for vesical drainage Inset 3, Muscle drawn over new made urethra

the next step provides fascia to close the defect between the recti muscles. This technique is shown in Figure 5. In 1 the incisions are made on each side to expose the abdominal fascia. On the left side the wound has been retracted, thus exposing abdominal fascia which is freed from superimposed skin and subcutaneous tissues along the side of the exstrophy. A tunnel is made here and is enlarged by spreading a clamp, as shown

The incision is made through the fascia as shown in Figure 5, 2. By blunt and sharp dissection the fascia is separated from the overlying abdominal muscles (Fig. 5, 3) up to the edge of the abdominal defect. In Figure 6, 1, this strip of fascia has been drawn through the opening over the inverted bladder. On examination it seemed that this strip of fascia was hardly large enough in itself, and it was decided to obtain another similar

Fig. 8. Closing of deep plastic procedure upon bladder and urethra with an oval flap of skin which previously, as dissected from upper half of bladder.

Fig. 9. Appearance on return of patient 6 months later. Ectropion cured. Patient voiding through urethra but urinary control imperfect, partial incontinence.

strip from the right side as shown in Figure 6, 2, in which the fascia has been drawn across and sutured to the edges of the abdominal defect, thus completely covering the bladder. Before the lower stitches are placed the U shaped catheter which has been inserted into the bladder for drainage, is carried beneath the pubic ligament and skin, on each side of the vagina, so as to emerge through the skin of the upper part of the thigh, as shown in Figure 6, 3. In Figure 7, 1 suturing of the abdominal fascia from the right side is completed. The left is held ready to be pulled over it, as shown in Figure 7, 2. The next step is to cover the new made urethra with muscle drawn from each side. The technique is shown in Figure 7, 3. The orifice of the urethra with the fascia above it and the two rubber drains emerging from the wounds of the thighs are depicted. The oval skin flap which has been dissected from

Fig 10 Technique employed to resect urethra previously made and cure in continence. A U shaped suprapubic catheter tube drainage was provided. Urethra was opened and a strip removed on each side, thus leaving very narrow tract from which to form a new urethra (3).

the bladder, is held upward on a clamp. The thread of nylon is seen where it enters the under surface of this flap. In Figure 8, the completion of the operation is shown. In Figure 8, 1, the placing of a subcutaneous stitch of fine catgut to anchor the oval skin flap is shown. In Figure 8, 2, the interrupted sutures of silver wire have been placed to close the wounds.

The patient stood the operation well, the anesthesia was perfect. Convalescence was satisfactory.

August 15, 1940. It is now 6 weeks since operation. The two ends of the U shaped vesical drainage tube emerge

from the openings on each side of the vagina. The wounds have healed *per primam*. A No. 6 F children's sound passes through the new made urethra into the bladder to a distance of about 6 centimeters. A small child's cystoscope also passes without difficulty. The tubes are removed.

August 17. The patient was discharged today. The urine escaped through the openings made for drainage. No urine escaped through the urethra.

The patient returned December 10, 1940. The conditions present are shown in Figure 9. As seen here the exstrophy had not recurred. The abdominal wounds presented a slight keloid effect. The two halves of the clitoris had separated. The urethra was small but incontinent. Examination seemed to indicate that not enough muscle

Fig. Urethral closure completed and muscle flaps drawn from each side to cover it, after back skin edges are approximated with silver wire leaving strand of nylon in urethra.

It is given sphincteric control. It is decided to upon the patient again to obtain more and better with which it surrounded the urethra.

On December 20 the second operation was performed. The contracted orifice of the vagina was enlarged by an incision on each side. A goose-neck clamp was introduced through the urethra and brought up against the anterior wall of the bladder for a distance of about 7 centimeters from

the urethra. An incision was made through the tissues, skin, and bladder which were held up on its beak, which was then pushed out through the wound. A No. 6 rubber catheter was then drawn into the bladder and out through the urethra. A goose-neck clamp was introduced by the side of the catheter and directed against the left antero-lateral wall of the bladder. An incision was made on it at a distance of about 3 centimeters from the

opening which contained the catheter on the opposite side. A clamp passed in the opposite direction through this opening was made to emerge from the urethra where the tube was grasped and drawn back through the opening, as shown in Figure 10, 1 and 2. In this way good drainage was provided for at a distance from the region to be operated upon. In Figure 10, 2, is shown the incision which was made just above the orifice of the previously made urethra. This was enlarged (Fig 10, 3) and after the urethra was opened it was found that too much skin had been used to form the urethra at the previous operation. A strip was excised from each side (Fig 10, 3), thus leaving a very narrow strip of skin (only 3 or 4 mm in width), in the median line posteriorly, and exposing muscle on each side. The technique of closure is shown in Figure 11. In first inset, the greatly resected urethra has been turned in with a continuous subcuticular No 0000 chromic catgut suture on a Dulox needle. This line of suture was continued upward so as to close the bladder opening (Fig 11, 2). It was decided to go at a distance of the median line to free muscle which could be drawn over the new made tight urethra on each side. In Figure 11, 2, the muscle flap, which was obtained on the left side is shown and in Figure 11, 3, the sutures, which were inserted to draw this flap over the new made urethra, are shown. Here also is shown a muscle flap which has been freed by an incision preparatory to covering the first muscle layer. Suture of this layer of muscle is shown in Figure 11, 4. No 0000 chromic catgut was again employed. As seen here, the newly made tight urethra was covered by two layers of muscle, one drawn from the left, the other from the right. After this it was necessary only to draw down from above the skin flap, which was quite loose and redundant, and to suture the skin and subcutaneous tissue to the adjacent wounds below with fine silver wire. Thus the muscle plastic was completely covered around the very tight urethra which contained only a strand of nylon to be used subsequently as a conductor for the passage of instruments.

Sulfathiazole, 15 grams, three times a day, was given the patient, beginning 2 days before operation and continued. Three days after operation the patient had a skin rash which was diagnosed scarlet fever. The patient was transferred to the isolation ward for 3 weeks. (It seems probable now that this was a sulfathiazole rash and not scarlet fever.)

The catheter, which emerged from the two cystotomy wounds in the upper part of the bladder, worked well, and

Fig 12 Motion picture camera obtained picture of the patient voiding. This is one of the frames. She was able to start and stop the outflow of urine on command and had complete control. Interval between voidings $2\frac{1}{2}$ hours.

no urine escaped through the newly tightened urethra. The sutured wounds healed *per primam* and the double drainage tube was removed on January 12. Two days later filiforms and a No. 14 children's sound were passed through the newly made urethra into the bladder, and a No. 12 urethral catheter was inserted for drainage to facilitate closure of the two suprapubic wounds.

On January 31 the suprapubic wounds having healed, the urethral catheter was removed. The patient voided at intervals through the urethra and with almost perfect control when she left for home on February 6.

For a time leakage occurred from a pin point fistula high up in the skin flap where the strand of nylon emerged. This now has healed, and the patient is voiding naturally through the new made urethra. Urinary control is perfect, the interval from 1 to 2 hours. On July 8 the patient voided about 35 cubic centimeters of urine at a time. She has good control. A motion picture was taken of the child urinating. One of these frames has been enlarged to show this (Fig 12).

July 28. By waking the child at 2 hour intervals at night, voluntary voiding was obtained and bed wetting avoided. The bladder gradually is increasing in size, and the patient is learning to hold urine longer. There is every prospect of a perfect result. She already has good urinary control, voids freely in a small but forcible stream, can stop and start the outflow on order when told to do so. The exstrophy was cured by the first operation, the incontinence by the second.

January 11, 1942 (letter). The patient voids urine at intervals of 3 hours with good control.

This is the story of apparently the first case of exstrophy of the bladder and incontinence that has been cured (B U I 28229). After struggling with these cases for many years, this successful result tempts one to cry, "eureka."

Fig. Urethral closure completed and muscle flaps drawn from each side to cover it, after each skin edges are approximated with silver wire, leaving strand of nylon in urethra.

overs it to give sphincteric control. It was decided to operate upon the patient again to obtain more and better muscle flaps which surrounded the urethra.

On December 20 the second operation was carried out. The contracted orifice of the vagina was enlarged by an incision on each side. A goose neck clamp was introduced through the urethra and brought up against the anterior wall of the bladder for a distance of about 7 centimeters from

the urethra. An incision was made through the tissues, skin, and bladder which were held up on its beak, which was then pushed out through the wound. A No. 6 rubber catheter was then drawn into the bladder and out through the urethra. A goose neck clamp was introduced by the side of the catheter and directed against the left antero-lateral wall of the bladder. An incision was made on it at a distance of about 1 centimeter from the

opening which contained the catheter on the opposite side. A clamp passed in the opposite direction through this opening was made to emerge from the urethra where the tube was grasped and drawn back through the opening, as shown in Figure 10, 1 and 2. In this way good drainage was provided for at a distance from the region to be operated upon. In Figure 10, 2, is shown the incision which was made just above the orifice of the previously made urethra. This was enlarged (Fig 10, 3) and after the urethra was opened it was found that too much skin had been used to form the urethra at the previous operation. A strip was excised from each side (Fig 10, 3), thus leaving a very narrow strip of skin (only 3 or 4 mm in width), in the median line posteriorly, and exposing muscle on each side. The technique of closure is shown in Figure 11. In first inset, the greatly resected urethra has been turned in with a continuous subcuticular No 0000 chromic catgut suture on a Dulox needle. This line of suture was continued upward so as to close the bladder opening (Fig 11, 2). It was decided to go at a distance of the median line to free muscle which could be drawn over the new made tight urethra on each side. In Figure 11, 2, the muscle flap, which was obtained on the left side is shown and in Figure 11, 3, the sutures, which were inserted to draw this flap over the new made urethra, are shown. Here also is shown a muscle flap which has been freed by an incision preparatory to covering the first muscle layer. Suturing of this layer of muscle is shown in Figure 11, 4. No 0000 chromic catgut was again employed. As seen here, the newly made tight urethra was covered by two layers of muscle, one drawn from the left, the other from the right. After this it was necessary only to draw down from above the skin flap, which was quite loose and redundant, and to suture the skin and subcutaneous tissue to the adjacent wounds below with fine silver wire. Thus the muscle plastic was completely covered around the very tight urethra which contained only a strand of nylon to be used subsequently as a conductor for the passage of instruments.

Sulfathiazole, 15 grams, three times a day, was given the patient, beginning 2 days before operation and continued. Three days after operation the patient had a skin rash which was diagnosed scarlet fever. The patient was transferred to the isolation ward for 3 weeks. (It seems probable now that this was a sulfathiazole rash and not scarlet fever.)

The catheter, which emerged from the two cystotomy wounds in the upper part of the bladder, worked well, and

SURGICAL AND POSTOPERATIVE TREATMENT OF LARGE VESICOVAGINAL AND RECTOVAGINAL FISTULAS

VIRGIL S. COUNSELLER, M.D. F.A.C.S., Rochester, Minnesota

IT is now nearly 100 years since the classic work of Marion Sims on vesicovaginal fistulas. He contributed more to this subject and brought about greater success in the treatment of the condition than any other person had done prior to 1852. Since then there have been numerous modifications and suggestions as to surgical technique and methods of approach to the fistula. The same is true of fistulas from the bowel to the vagina. The problems involved in the treatment of these fistulas are as difficult as, and are often greater than, the problem of treatment of vesical fistulas. When both vesicovaginal and rectovaginal fistulas exist simultaneously the problems involved in the surgical and postoperative treatment are considerably increased.

It is not my intention to review the various causes of these fistulas, with which all are so familiar. Instead, I wish to point out some of the pitfalls in surgical management which frequently predispose to recurrence of the condition. I also wish to emphasize the importance of meticulous postoperative care for both vesical and rectal fistulas into the vagina, especially those of the larger and more complicated types.

VESICOVAGINAL FISTULA

It is the experience of most surgeons that in about 85 per cent of cases most small vesicovaginal fistulas can be closed at one surgical procedure, especially if previous repeated attempts at closure have not been made. Small vesical fistulas do not often constitute a difficult problem. However, I feel that it should be emphasized seriously that small fistulas such as these occasionally can resist all the skill of an expert surgeon, principally because enough attention has not been given, first, to the situation of the fistula and, second, to residual infection which may be present in the bladder. The importance of the situation of a vesical fistula cannot be too greatly stressed. For example, a small fistula which involves the posterior margin of the internal vesical sphincter is one of the most difficult to close of all fistulas within my experience and it should not be considered

lightly. Since the fistula involves the sphincter the sphincter is, therefore, torn and partially incontinent, resulting from contraction and formation of scar tissue within the circular muscle fibers. It is most difficult to avoid superimposing the vaginal and vesical suture lines at this point without producing distortion of the sphincter and urethra. Apposition of these suture lines predisposes to recurrence. Furthermore, when a catheter is placed through the urethra into the bladder it is almost sure to be in contact with the region of repair and such contact is a very potent factor in recurrence. The catheter always produces irritation and also incites infection which induces breakdown of the suture lines. This factor is one of the chief difficulties in closure of urethral and urethrovaginal fistulas. Urologists who now have become familiar with this fact do not leave a catheter in the male urethra subsequent to surgical repair of urethral fistula or after performance of plastic procedures for hypospadias. The patient is encouraged to arise and micturate in the normal manner or if the surgical procedure has been too extensive a perineal opening is made in the posterior urethra to divert the urinary stream. I am beginning to believe, however, that if a patient can void, the passage of urine over a small repair in the urethra or sphincter is more beneficial than detrimental, since by such a flow all sediment and exudate periodically are lavaged from the suture line. This belief, however, does not apply to fistulas situated entirely within the base or vault of the bladder where they are constantly bathed in urine.

The second factor of residual infection within the bladder in the failure of these small vesicovaginal fistulas to heal is one which is even more serious when large fistulas are encountered, and must be evaluated carefully before operation. A bladder that becomes totally incontinent becomes contracted and infected. Infection in such instances does not produce subjective symptoms, since the irritation cannot induce the desire to void, and the situation becomes annoying to the patient only if the upper part of the urinary tract becomes involved. Irritation and incontinence within the vagina constitute sufficient evidence that the same processes probably prevail within the blad-

der, and the conditions usually are induced by urea-splitting organisms, primarily those of the Proteus group, which are the most common and unfortunately the most difficult to eradicate. The formation of incrustations on the mucosa in the region of repair is an extremely potent factor in predisposition of the fistula to recurrence. The factors which are operative in the healing of wounds are exactly the same in this particular situation as they are elsewhere, namely, freedom from infection, proper hemostasis and lack of tension, so that interference with blood supply does not occur.

Large vesicovaginal fistulas of several months' duration constitute the greatest surgical problem from the standpoint of causation, infection and contraction of the bladder, retraction and scarred vaginal and vesical mucosa, involvement of the trigon, ureters, and sphincter. Destruction of the vesical neck, sphincter, and a portion of the urethra often brings about what approaches a hopeless situation in the matter of restoration of vesical function (Fig 1). Such a situation usually is directly attributable to difficult and perhaps faultily performed obstetrical procedures and to the results of radiation therapy for carcinoma of the cervix. In the first instance the earlier surgical repair is undertaken, the greater will be the chances for cure. A patient who has this type of lesion is always entitled to one or two serious attempts at repair, but any further effort is not likely to be successful. The principal effort must be directed, first, toward complete excision of all scar tissue and, second, toward complete mobilization of that portion of the bladder which is involved. This may be a difficult task, since the bladder often appears to be "frozen" against the pubic rami from which it must be entirely separated. The lacerated vesical sphincter retracts exactly as the lacerated rectal sphincter retracts and, therefore, it becomes essential for the surgeon to loosen the fixed residual portion to enable him to reapproximate the circular fibers of the sphincter. Since the trigon usually is almost wholly destroyed, it becomes necessary to narrow the trigon by bringing the ureteral orifices toward the midline. In extensive repairs of this type sufficient vaginal mucosa may not be available for the purpose of complete coverage of the denuded region. If the wall of the bladder will remain closed, the vaginal mucosa will eventually epithelize over the region. Absence of the urethra is not particularly important. If the sphincter can be made to function, so that complete continence results, a urethra can be constructed at a later date, if necessary. Several of my patients have

Fig 1 Destruction of the bladder neck, sphincter and portion of the urethra (after Stephenson, G. W., and Mason, J. C. *Surg., Gynec. & Obst.*, 1934, 58: 1036-1039)

complete urinary control and yet have a very short urethra, they do not have an external urethral sphincter. When reconstruction of the vesical neck is deemed a surgical impossibility, or if failure ensues subsequent to repeated attempts at repair, I think that diversion of the urine to the bowel is the procedure of choice.

A large vesicovaginal fistula which occurs after extensive radium therapy for carcinoma of the cervix is still less likely to be successfully repaired, by virtue of the fact that the tissue at a considerable distance from the edge of the fistula usually is too devitalized to be suitable for repair, and it is often impossible to mobilize this tissue. Any attempt at surgical repair necessarily must be delayed a sufficient length of time to preclude the possibility of local recurrence of the malignant process. Later, when there is no evidence of a residual malignant process, I believe that the patient is best treated by bilateral ureterosigmoidostomy.

Methods of approach. A well planned procedure should be outlined for each patient who has a vesicovaginal fistula. The fistula may be approached vaginally, transvesically, or transperitoneally. Ureterosigmoidostomy also will be considered herein.

Vaginal approach. The result from each of the aforementioned methods may be highly successful, but it is generally agreed now that the method of vaginal approach has many advantages over the others and that the operative risk which accompanies this method is practically nil. During the year 1939, 32 vesicovaginal fistulas were repaired surgically at the clinic, and all were re-

Fig. 2. Illustration of vesicovaginal and rectovaginal fistula, both as situated high in the vagina (after S. B. Lovelady and J. C. Mason, *Proceedings of the Staff Meetings of the Mayo Clinic*, 1935, 49-53).

Fig. 3. Performance of hysterectomy and closure of both fistulas from the abdominal side. Portion of the bowel is excised and end to end anastomosis is done. Gauze draining the cul-de-sac is in position (after Lovelady and Mason, *loc. cit.*).

paired by the vaginal approach. At the clinic we prefer to have the patient in a modified Kraske position with the thighs well separated and the terminal portion of the operating table removed. A Sims speculum is held firmly against the perineum and posterior vaginal wall, which permits easy exposure of the entire wall of the bladder and urethra except perhaps in the nullipara in whom a fistula has occurred subsequent to total hysterectomy. In such an event a Schuchardt's incision is made which converts the vaginal canal into a wide open cavity. The advantages of this approach are obvious. It permits the surgeon to dissect directly on the lesion rather than through dependent cavity as is necessary in the transvaginal approach. The ureters can be catheterized with ease, if it is advisable to do so when a laceration has extended laterally to the ureteral orifice. The ramifications of the tear in the wall of the bladder can be more nearly accurately identified. Fistulas that arise after total hysterectomy are most favorably approached in this manner since they are practically always situated high in the vaginal vault and result from passage of a suture through the wall of the bladder during closure of the vaginal vault. It is a relatively simple procedure to open the cul-de-sac above the fistulous opening and by placing a finger into the perito-

neal cavity the bladder can be separated from the scar tissue and drawn forward into the vagina.

Transvesical approach. A transvesical approach is desired by many surgeons, perhaps because of a lack of familiarity with the pelvic anatomy, familiarity which is essential. When this method is selected it must be predetermined that the result will be entirely successful otherwise the patient will have both a vesicovaginal fistula and a suprapubic fistula, with a contracted bladder. The problem then, of course, is greater than that which previously existed.

Transperitoneal approach. The transperitoneal approach entails much higher risk than any other method and should be undertaken only in very select cases. A fistula that is situated high in the vaginal vault in an extensively scarred and fixed region (the scarification and fixation usually resulting from postoperative cellulitis) may be more adequately treated by this method. After exposure and closure of the fistula, it is advisable to interpose some fat obtained either from the omentum or from the rectum between the wall of the bladder and the vaginal mucosa. The real danger which may arise when this method is employed is necrosis and leakage of urine, which is always infected, into the peritoneal cavity. It is wise to be prepared for this sequela by splitting

As long as suture material of any type exists within the vagina, there will be a constant flow of exudate, which, if it is not removed daily, will macerate the tissues, an occurrence which will predispose to premature separation of the suture line. For this reason, the vagina is cleansed daily by the careful introduction of a Sims speculum along the rectal wall, to expose the suture line. All mucus, exudate, or blood is removed with a dry cotton sponge and the suture line is painted with a germicidal agent (tincture of merthiolate). This routine also permits the surgeon to observe the healing process.

Specimens of the urine for culture are taken daily directly from the catheter, the bacterial count is estimated, and the acidity is determined. The administration of sulfathiazole is continued during convalescence of the patient. If strict attention is given to this detail, incrustation will not occur on or within the catheter. Prior to institution of this routine at the clinic it was not uncommon for the catheter to become occluded with sediment.

Proper selection of an indwelling catheter contributes much to the comfort of the patient. The catheter employed should be one that does not rest on the trigon or produce pressure against the internal vesical sphincter muscle. To obviate these possibilities, I devised one which consists of a French catheter (male), size 18 or 20, which is introduced through a larger segment of soft rubber tubing about 4 to 6 inches (10 to 15 cm) in length. Approximately 3 to 4 inches (8 to 10 cm) of the soft rubber tube which forms the outer sheath is sectioned to produce four strips of rubber equal in length (Fig 6). The French catheter is held firmly by the remaining segment of the outer soft rubber tube. The catheter is inserted through the urethra for the proper distance and the four strips of rubber are secured to sections of adhesive tape placed toward the pubes and also lateral to the rectum. The patient may move in any position, yet the catheter will remain in the original position, and the exertion of tension on the catheter is prevented.

The patient lies on the Bradford frame for a minimum of 2 weeks, depending on the character of the fistula which she had. After being removed from the frame, the patient remains in bed 2 to 3 days longer. The catheter is then removed and she is instructed to micturate every hour during the next 24 hours, then to micturate every 2 hours for 2 to 3 days, so as gradually to increase vesical function. At the time of dismissal, either the urine should be sterile or bacteriuria should be reduced to grade 1.

Fig 6 A new method for retention of a nonirritating catheter in the female bladder

RECTOVAGINAL FISTULA

There are three types of rectovaginal fistula which I wish briefly to discuss, namely, (1) that which occurs simultaneously with vesicovaginal fistula, (2) that which develops subsequent to repair of complete laceration of the perineum and (3) that which arises insidiously and in conjunction with an abscess in an anal crypt.

Rectovaginal fistula which develops with vesicovaginal fistula. As a general rule, this type of fistula is situated high in the vaginal wall, as exemplified by the fistula encountered subsequent to radium therapy for cancer of the cervix. This type of fistula occasionally is seen after precipitate labor in a previously nulliparous patient, and, in such instances, complete laceration of the perineum also is likely to have occurred.

Although it may be possible to repair both lesions (that is, vesicovaginal fistula and rectovaginal fistula) simultaneously, the risk of recurrence of either one or the other condition is most certainly considerably greater if such a procedure is carried out. When the vagina has been converted

Fig. 5. Bilateral transplantation of the ureters to the sigmoid for carcinoma of the cervix: a, left, 5 minute roentgenogram, in which fairly good concentration is seen on right side and fair concentration is seen on the left side; b, 30

minute roentgenogram, in which good concentration is seen on both sides, ureterectasis, pyelectasis, and calculous grade 2, on the right side and grade 1 on the left side, are present.

monium mandelate in doses of 3 drachms (17 gm). The intake of fluid is restricted to 1000 cubic centimeters in 24 hours. With the gradual decline in numbers of the organisms mentioned, and if the inflammation of the vagina and bladder is receding, surgical repair may be instituted safely, but medication and the making of cultures of the urine must be continued during convalescence of the patient. The advantages of sterile urine in wound healing, in particular during the postoperative course cannot be overestimated.

The appearance of calculi in the upper part of the urinary tract or within the folds of the mucosa of the bladder is a potent cause of continued pyuria while medication is being continued. Surgical repair of large vesicovaginal fistulas is not advisable until all calculi are removed. The advantages of the making of an excretory urogram as a preoperative measure are obvious, for the urogram not only will disclose calculi but will also provide fair index to renal function and will reveal evidence of previous infection in the upper portion of the urinary tract which might become serious complicating factor during convalescence.

Postoperative care. There is no surgical procedure which requires more constant and special postoperative care than repair of a large vesicovaginal fistula. Attention must be directed toward the insuring of continuous flow of urine through the catheter especially after the eighth postoperative day when suture material begins to show evidence of absorption. Should the catheter become occluded or partially extruded, sufficient pressure may accumulate to produce leakage. At the clinic we have attempted to fortify ourselves against occurrence of this accident by adoption of a routine in which every patient is placed on Bradford frame in the prone position, about 18 inches or more (45 cm. or more) from the surface of the bed. A two-way irrigating system is provided and the bladder is gently irrigated with few cubic centimeters of solution (boric acid) each hour during each 24-hour period. The urine is allowed to drop continually in a basin placed on top of the bed, where it can be observed by both patient and nurse. An effort is made to isolate such patients on one floor where student and special nurses are particularly instructed about nursing care.

nodule will develop on the vaginal wall just behind the perineum, and will remain extremely tender and will finally periodically subside. Subsidence is considered to be due to evacuation of the contents of the abscess into the bowel. The patient appears to be entirely comfortable and free from disease for several weeks, then the nodule recurs on the vaginal side of the wall, with extreme tenderness and discomfort. Finally, the contents of the abscess rupture into the vagina, and fecal material and gas periodically will be discharged through the fistulous opening into the vagina. My reason for drawing attention to this lesion is the fact that attempted closure of this fistula before all the inflammatory process in the rectal wall has subsided will result in surgical failure in 100 per cent of cases. Furthermore, the small focus of infection in the anal crypt usually is only one part of the infectious process and there are ramifications in the form of fistulous tracts in the bowel wall that must be completely excised.

The proper form of attack on such a fistula, then, is a two stage procedure. The first procedure is the problem of the proctologist, and it is usually necessary to cut both sphincter muscles and to destroy completely the perineum. However, this is not true in every instance. When there is evidence that the inflammatory process has subsided and that complete or partial loss of control of the bowel has occurred, the problem becomes that of the gynecological surgeon to reconstruct the anterior rectal wall and the perineum. In other words, the lesion is essentially the same at this particular stage as the lesion which is present at repair for complete laceration of the perineum, after all scar tissue has been completely excised.

Postoperative care Postoperative care of patients who have undergone repair of rectovaginal fistulas is of importance equal to that of postoperative care for patients who have undergone repair of vesicovaginal fistulas. The operative incision must be inspected daily from the vaginal side and from the rectal side. For from 1 to 2 weeks the bowel should be prevented from moving. Exposure of the suture line within the rectum is accomplished by means of a small anoscope. All mucous secretions and flecks of feces should be removed daily through the anoscope, and the suture line within the bowel should be painted with a germicidal agent (merthiolate). A small Sims speculum is placed in the vagina and the anterior vesical and vaginal walls are held firmly to expose

the suture line on the posterior wall. The vagina is cleansed with dry cotton sponges and the suture line is painted with tincture of merthiolate. When the wounds on both the vaginal side and the rectal side of the wall are kept clean, primary union can be expected in approximately all instances. I believe the high incidence of failure in such cases has been due to a disregard of the value of the postoperative care of the wound. The perineum should be kept free of any dressing material whatever, and secretions should be removed from the vagina more frequently than once a day, if necessary. Dry heat should be applied by means of an electric lamp during the day and removed at night.

SUMMARY AND CONCLUSIONS

Attention has been directed to the difficulty of closure of small vesicovaginal fistulas in certain situations with particular regard to the vesical sphincter and ureters.

Sulfanilamide and its derivatives have enhanced the treatment of vesicovaginal fistula in that the drug and its derivatives are able to destroy organisms within the urine in a much shorter period than had been possible formerly and are able thus to maintain the urine in a nearly sterile state during convalescence of the patient. This has been a very great asset in the improvement of end results. Meticulous care must be devoted to the patient during convalescence, to maintain the urine free from infection, to avoid incrustation in the bladder and occlusion of the catheter. The vagina should be cleaned of secretions daily.

Ureterosigmoidostomy has a definite place in the treatment of huge vesicovaginal fistulas in cases in which the bladder has been rendered incapable of again retaining urine.

Rectovaginal fistulas are best treated by complete excision of all scar tissue and re-establishment of the normal character of the rectal tube. Particular attention is directed toward those small fistulas which originate in an anal crypt, a circumstance in which it is essential that the surgeon understand the etiology of the condition and the clinical course of the patient. Postoperative care is similar to that for patients who have undergone repair of vesicovaginal fistulas in that suture lines in both the rectum and vagina must be kept clean daily. This can be done by the use of a Sims speculum, a small anoscope and dry cotton swabs. Attention to these details will greatly improve the number of instances of primary healing.

A FUNDAMENTAL ERROR IN CURRENT METHODS OF INGUINAL HERNIORRHAPHY

CHESTER B. McVAY M.D. Ph.D. Ann Arbor Michigan

BARRY J. ANSON A.M. Ph.D. (Med.Sc.) Chicago, Illinois

COMMONLY in the experience of the dissector and of the surgeon, structural features are encountered in surgically important areas of the body which are inadequately described in the textbooks upon which they have been dependent. In recent studies (McVay and Anson, 1940) the authors have found, for example, that the available accounts of the aponeurotic and fascial continuities from the lower abdomen into the thigh are highly conventionalized and scarcely satisfactory for the guidance of the critical surgeon. Certain of the features encountered in the study explain the frequency of recurrence, while others suggest the desirability for modification of the usual methods employed in inguinal herniorrhaphy.

The current brief report will review the salient features of inguino-femoral anatomy and describe an operation based upon this morphological study. Although brief it is hoped that this preliminary report will, by stimulating others, accelerate the accumulation of statistical data on similar cases, and will be of aid to those who have requested detailed information on the technique involved.

ANATOMY

External oblique. In the inguinal part of the abdominal wall, the external oblique is an aponeurotic plate covered on each surface by an investing fascial layer. It is, however, not a complete aponeurotic plate since it is defective at the triangular hiatus (loosely termed the *subcutaneous inguinal ring*) and in an area, lenticular in outline, caudal to the inguinal ligament (Fig. 1). In

From the Department of Surgery, University Hospital, Ann Arbor, Michigan, and the Department of Anatomy, Northwestern University Medical School, Chicago, Illinois (contribution no. 345 from the latter). The anatomical aspect of the present report represents a brief consideration of earlier observations by the same authors (1938, 1942, 1943).

The anatomical investigation, as presented at Northwestern University Medical School by the authors, in collaboration with the technical procedure as devised by Dr. C. B. McVay, during the progress of his laboratory study and post-mortem service at the University of Michigan, with the assistance and co-operation of Dr. F. A. Collier, professor of surgery in the latter institution (1943).

Figures are reproduced with the permission of the Williams & Wilkins Press, Baltimore, of pp. 202 and 227.

these areas, which are largely devoid of aponeurotic fibers, anatomical closure is effected by the fasciae which fuse back to-back as they stretch across each opening. Between the crura of the 'ring' they are carried downward into the scrotum as the external spermatic fascia; below the inguinal ligament they are continued inferiorly as a superficial component of the fascia lata.

Therefore, so far as the outermost of the three abdominal layers is concerned, it may be said that the barrier to herniation is incomplete in the presence of a patent processus vaginalis; the descending intestine or omentum need only enlarge the hiatus between aponeurotic crura and dilate the surrounding fascial envelope. Since the fasciae serve to bind together adjacent aponeurotic bands so that totally they form a plate under stretching in herniorrhaphy, may so weaken the covering fibrous layers that the way is paved for a recurrence when adjacent aponeurotic bands are drawn apart, shortened by suturing, a new hernia may occur through a cleft artificially produced either in the aponeurosis itself or distal thereto in the area of weakness between inguinal and femoral regions.

Internal oblique. Whereas the external oblique is chiefly aponeurotic in the inguinal region, the corresponding part of the internal oblique usually contains some muscle fibers, especially in its lateral portion (Fig. 2). In the inferomedial portion of the greater number of specimens, however, aponeurotic fibers diminish in size and number and muscle fascicles become sparse. The investing fascial layers then remain as the sole representatives of the internal oblique. On the spermatic cord, too, fascicles are few so that this intermediate one of the funicular coats is very similar to that derived from the conjoined muscle fasciae of the external oblique.

The lower portion of the internal oblique—that is, its cremasteric portion—arises from the ilio-psoas fascia as the latter leaves the pelvis for the lower extremity; its attachment to the inguinal ligament is by means of a rather delicate tissue. It is unlike the other funicular coats in that the proximal (abdominal) orifice of the tube which it

Fig 1 The external oblique aponeurosis freed of its external layer of fascia, showing that the inguinal ligament itself is a marginal structure, separate from the fascia lata of the thigh and independent of cremasteric part of internal oblique. Inset shows fascial continuities, opposite side

Fig 2 The internal oblique is exposed by removal of all of the external oblique except its lowermost aponeurotic fibers (inguinal ligament), the former layer, in its cremasteric (funicular) part is partially fascial, it arises from the ilio-psoas fascia, not from the inguinal ligament

forms is an elongate oval in outline, not a circle (opened in Fig 3), it does not completely surround the cord until that structure emerges through the subcutaneous inguinal ring. It is, therefore, a poor barricade, being capacious at its beginning and chiefly fascial through the greater part of its length.

Transversus abdominis The inguinal portion of the transversus abdominis muscle is more aponeurotic than it is muscular (Figs 3 and 4), its lowermost part arises from the ilio-psoas fascial tube as does the cremasteric portion of the internal oblique. The insertion of this lowermost portion of the transversus is not to the inguinal ligament as one might conclude from present methods of herniorrhaphy but to Cooper's ligament on the superior pubic ramus.

Almost without exception that part which is carried downward upon the cord is purely fascial (as its name, internal spermatic fascia, would indicate). Similar to the funicular sheath is the femoral sheath, for this, the fascial layers of the transversus fuse to form the anterior component of a tubular prolongation (Fig 4 and inset), the ilio-psoas fascia forms the posterior component. The inner fascial contribution from the transversus layer is the transversalis fascia but the outer bears no special name. The femoral differs from the funicular sheath in transmitting vessels

chiefly, in hernial cases it resembles the aforementioned sheath in containing (in its medial compartment) a peritoneal diverticulum.

SURGERY

All the recognized methods of inguinal herniorrhaphy which have been devised since the publication of the works of Bassini and Halsted, are alike in one respect: in each of them the various inguinal layers are sutured to the inguinal ligament. Although minor variations are legion, they seem to possess this feature in common.

The current article is entirely in agreement with those stating that simple excision of the hernial sac is adequate in a small indirect inguinal hernia when the abdominal inguinal ring is not markedly dilated, in this type of hernia, if no weakness of the posterior wall is demonstrable, passing sutures through the so called conjoint tendon and fastening it to the inguinal ligament will serve only to weaken layers and to reduce the defenses against a direct inguinal hernia. A large indirect hernia and a direct inguinal hernia present the same problems for repair. In the former, the medial extension of the dilated abdominal inguinal ring may lie next to the rectus muscle, with the result that the entire posterior wall of the inguinal canal (including the area of Hesselbach's triangle) is attenuated and the bulk of its tissue displaced medialward.

Fig. 3 The parietal part of the internal oblique has been cut and partially removed, the fascicular part turned downward from the spermatic cord. By this means it is demonstrated that the lower part of the trans. crura abdominis is aponeuroticofascial, not muscular, and that the muscle does not form an arching roof for the inguinal canal.

Although it is true that in the large indirect variety the inferior epigastric vessels still lie medial to the sac, the posterior wall itself must be reconstructed in a basically similar manner.

Zimmerman, in a recent article, has given an excellent presentation of the many problems encountered in the treatment of inguinal hernias. The surgical modification which he suggests—that of using a flap of external oblique aponeurosis to buttress the transversus abdominis aponeurosis in the region of Hesselbach's triangle—also employs the inguinal ligament to anchor the inguinal layers. In closure of an abdominal incision corresponding layers are sutured together in an effort to return the musculofascial anatomy to normal, and certainly in an inguinal herniorrhaphy this concept should be followed. In the more common types of inguinal herniorrhaphy the transversalis fascia and, variously, the transversus abdominis and internal oblique layers are sutured to the inguinal ligament, providing a poor substitute for their normal insertion. The inguinal ligament is not the insertion of the transversalis fascia, the transversus abdominis aponeurosis, or the internal oblique aponeurosis; its relationship to these structures is simply one of contiguity. From an anatomical standpoint this is reason enough for endeavoring to find some other structure for anchorage. Moreover, from a surgical point of

Fig. 4 The distal continuation of the transversus layer forming the femoral sheath, has been exposed by the removal of the inguinal ligament and cremasteric muscle and fascia, and the turning aside of the fascia lata. It is demonstrated that the femoral sheath is entirely fascial, as is also the internal covering of the spermatic cord. At the asterisk the layer is thickened by an aponeurotic expansion of the rectus tendon (lab. inguinale). In the area just below this marker the transversus is inserted into the superior pubic (Cooper's) ligament. Inset shows the femoral sheath, transected.

view the inguinal ligament does not make a suitable substitute for their regular insertion because of its character. The inguinal ligament, contrary to the usual conception, is loosely held in its convex position by the surrounding fasciae; it is easily shelled out of its fascial bed by the finger or a blunt instrument, it becomes merely the free margin of an aponeurosis which extends between the anterior superior iliac spine and the pubic tubercle (Fig. 2). Its attachment is broadened laterally by fibers of insertion passing into the iliopectineous fascia and medially by the expansion known as the lacunar ligament between these points it is relatively pliant (Figs. 1 and 2).

When traction is applied in cephalad direction simulating the pull of the muscles which might be sutured to it, it is displaced superiorly far enough to leave the lower inguinal region completely exposed beneath it (Fig. 3). In recurrent hernia occasionally the mass seems femoral in position, hernia having elevated the inguinal ligament.

If the insertion of the lower inguinal portions of the transversalis fascia and the transversus ab-

Fig 5 Dissection demonstrating the stage in a direct inguinal herniorrhaphy in which the hernial sac has been excised. The relationship of the inguinal ligament, Cooper's ligament, and the margins of the transversus and internal oblique aponeurosis is demonstrated. The margins of the latter are sharp because the attenuated portions have been excised.

Fig 6 Herniorrhaphy, showing the aponeurotic lower margins of the transversus and internal oblique sutured to Cooper's ligament.

dominis aponeurosis were not readily available, then there might be some reason for using the inguinal ligament, but, actually, the layers themselves and the heavy band into which they insert medially are conveniently situated for surgical use, the latter band, termed the superior pubic, or Cooper's ligament is a dense fibrous structure lying on the anterosuperior aspect of the superior pubic ramus from the pubic tubercle medially to the vicinity of the femoral vein laterally (Fig 5). It is composed of fibers from the transversus aponeurosis and attached transversalis fascia, a lateral expansion of the rectus tendon of insertion and the pectineus fascia. Cooper's ligament is used rather consistently in the repair of femoral hernias, usually, however, the inguinal ligament as well as the transversus aponeurosis and internal oblique aponeurosis are sutured to it, as described by Moschowitz. Dickson, however, advocated merely suturing the transversalis fascia to Cooper's ligament in the repair of a femoral hernia, ignoring the inguinal ligament. The first inguinal herniorrhaphy method known to these authors that utilized Cooper's ligament, is that described by Babcock. This method, however, uses only the medial portion of Cooper's ligament in the immediate vicinity of the pubic tubercle. Robins has subsequently advocated suturing to Cooper's ligament after the method of Babcock, and J. R. Veal and D. D. Baker utilize the superior pubic ramus in their periosteal graft.

The operation suggested is in essence a restoration of the normal inguinal anatomy. The incision

of the skin and method of ligating the hernial sac are in no way different from those in general use, the principle of high ligation and of utilizing fascial or aponeurotic structures is adhered to, the suggested method differs from others in that it ignores the inguinal ligament. After the sac is removed or imbricated, as the case may be, the superior pubic (Cooper's) ligament is isolated, and freed of adjacent preperitoneal connective tissue (Fig 5). If anomalous obturator vessels are to be ligated and severed, the small artery to the pyramidalis muscle, sometimes encountered, should also be ligated. The inferior margin of the transversus abdominis aponeurosis and attached transversalis fascia is clarified by excising any attenuated portion secondary to the hernia and freeing it from the underlying preperitoneal connective tissue (Fig 5). This aponeurosis is then sutured to Cooper's ligament from pubic tubercle to the femoral vein by a series of interrupted silk sutures (Fig 6). If the lower border of the internal oblique is aponeurotic, its substance is to be included in the sutures. If closure cannot be accomplished without undue tension, relaxation is accomplished after the method of Fallis. This type of closure leaves a small defect between the abdominal inguinal ring and femoral vein (Fig 6), normal anatomy is here restored by suturing the transversalis fascia to the anterior surface of the femoral sheath. It is worthy of special comment that, if the transversus abdominis aponeurosis is sutured to Cooper's ligament as far laterally as the femoral vein, the femoral ring is obliterated, by this means the possibility of a femoral hernia is obviated.¹

It will be noted that after the suturing of the transversus aponeurosis to the ligament of Cooper

¹The important relationships of the lacunar ligament, Cooper's ligament, femoral ring, transversus abdominis aponeurosis and falx inguinalis have been discussed in the earlier article by the present authors (McVay and Anson, 1940). Suffice it to say that the standard descriptions of these structures and their mutual relationships are not accurate.

and the establishment of the continuity of the transversalis fascia to the anterior femoral sheath that a pyramidal space is produced. The cord is dropped into this and the external oblique aponeurosis is closed over it so that the spermatic cord emerges at the site of the subcutaneous inguinal ring. The obliquity of the inguinal canal is simultaneously restored. It should be acknowledged that the suturing of the layers to Cooper's ligament is technically more difficult because of the latter's deep position. There is also danger of injuring the femoral vein. A simple precaution forestalls such an accident by the use of a vein retractor or the index finger for protection of the femoral vein, and a small ribbon retractor to keep the preperitoneal connective tissue out of the field, adequate exposure is obtained.

SUMMARY

In the repair of large indirect and direct inguinal hernias, it is recommended that the inguinal layers be sutured to Cooper's ligament and not to the inguinal ligament. It is pointed out that the inguinal ligament is neither the normal insertion of the inguinal strata nor a suitable substitute for such attachment; on the contrary, the superior pubic ligament, Cooper's ligament, which is the normal insertion, is readily accessible, intrinsically strong and directly fixed to bone.

For those who would make critical use of anatomical illustrations the following additional descriptions may be of service. In Figure 1, the deep (subcutaneous) fascia on the outer surface of the external oblique aponeurosis, with its contained spermatic fibers, has been removed except in quadrangular area over the anterior superior iliac spine. The femoral layer and the proximal part of the fascia lata have been reflected inferiorly to demonstrate their continuity at the groin, and to expose the unattached central portion of the inguinal ligament. Beneath the latter the crumpled fascicles are exposed. They arise from the iliopectineal fascia and the lat-

ter medial crumpled line, the deep layer of the fascia lata. The medial ligament is attached to the deep fascia. In the inset in Figure 1, the deep fascia over the inguinal ligament has been split open; the layers are drawn aside to demonstrate the continuity of the fascia lata with the subcutaneous fascia (superficial half of body). The aponeurosis of the external oblique continues with the iliopectineal fascia (inferior half of body) and the inguinal ligament. The inguinal ligament remains in position. The external oblique aponeurosis. The external spermatic cord has been rolled downward on the spermatic cord, thus exposing the crumpled layer. The inguinal ligament, continued as the femoral ligament, has an attachment to the pubic tubercle. The external oblique muscle has been secured near the center of its muscle fibers from the iliopectineal fascia and the latter medial crumpled line. The crumpled layer is attached to deep musculofascial character. The external spermatic fascia, visible, the artificial cloth belt area consists of crumpled fibers (which the latter are freed of these crumpled fascicles). A retractor placed deep to the cord and the crumpled elevates the iliopectineal abdominal aponeurosis to expose

attachment to the pubic pecten, the continuity between the crumpled stratum and the femoral sheath demonstrated in Figure 1, the crumpled layer including the superior crumpled line has been divided along the cord to demonstrate that the medial portion is entirely femoral. The transversalis extends inferiorly deep to the femoral ligament, so as to arise from the pecten, upon the spermatic cord. Clearly fascia. In Figure 2, the proximal stump of the spermatic cord has been elevated to show the external appearance of the abdominal inguinal ring, the external spermatic fascia has been rolled backward, leaving the crumpled line of the cord as their preperitoneal connective tissue (grasped by the finger). The crumpled muscle remains as two sets of fascicles arising from the superior fascia. The inguinal ligament remains as medial and lateral crumpled. The superior crumpled of the fascia lata has been cut, only the stump of its attachment remaining, the fascia lata has been turned inferiorly to show the transverse line muscle-aponeurosis (transverse abdominal fascia femoral femoral sheath). The appearance of the pecten tendon pecten: the pecten of the pecten (at 7). In inset in Figure 2, the femoral sheath, unattached, there is a mass of an entry femoral sheath and of an inferior preperitoneal of the preperitoneal connective tissue.

BASILAR INVAGINATION OF THE SKULL— SO CALLED PLATYBASIA

Report of Three Cases in Which Operation Was Done

WINCHELL MCK CRAIG, M.D., F.A.C.S., MAURICE N. WALSH, M.D., and
JOHN D. CAMP, M.D., Rochester, Minnesota

FREQUENTLY the stimulus of presentation of observations at one of our meetings results in subsequent reports of similar clinical observations. Three years ago when Chamberlain reported his cases of so called platybasia most of us realized that we had probably overlooked the surgical possibilities in this condition. Now that we are aware that "platybasia," or more nearly accurately, basilar invagination of the skull, is a deformity of the occipital bone, which narrows the foramen magnum, and of the upper cervical vertebrae, which flattens the spinal canal and that removal of the bone which is compressing the underlying brain and spinal cord usually will be followed by relief of symptoms, the syndrome is receiving more recognition.

The term "platybasia" in recent years unfortunately has been applied to a condition which is more properly described as 'basilar invagination of the skull,' or "basilar impression." According to anthropologists, true platybasia denotes an abnormal obtuseness of the sphenoid angle which results in a flattening of the basal, or as it is often termed, the sphenoid angle. The normal sphenoid angle is that angle which is situated between the line from the foremost point of the foramen magnum to the center of the sella turcica and from this point to the root of the nose. The angle varies normally from 115 to 150 degrees. The condition of basilar invagination of the skull has been known to anthropologists and pathologists for many years, and basically, the condition represents a developmental anomaly of the occipital bone and upper part of the cervical region of the spinal column.

According to Schueller, who described the roentgenographic features of the condition in 1905, basilar invagination is designated as an unusual change in the base of the skull, the most striking feature of which is the upward bulging of the posterior cranial fossa around the foramen

magnum. When viewed from inside the cranial cavity the base of the skull in cases in which the condition is typical exhibits an elevation of the edge of the foramen magnum lying between the pyramids of the temporal bones. The clivus in the presence of basilar invagination forms a convex bend, the vertex of which comes to lie at the level of the floor of the sella turcica so that the so called basal or sphenoid angle approaches a straight angle and not an obtuse angle, as in true platybasia, which is not associated with neurologic symptoms. The elevated portions of the occiput are considerably thinned, and the condyloid processes are more or less rudimentary. According to Schueller, in the classic case also are exhibited congenital variations of the upper cervical vertebrae. The first cervical vertebra is rudimentary in type and the posterior arch is usually fused to the lower surface of the occipital bone bounding the foramen magnum. The spinous process of the second cervical vertebra is fused with that of the third cervical vertebra.

In 1934 Ebenius described 4 cases of basilar impression (platybasia or basilar invagination) in which neurological changes were associated. Suboccipital decompression was carried out in 3 cases in an effort to relieve the symptoms. In 1938 Chamberlain described 4 cases of basilar impression (platybasia), in 2 of which suboccipital decompression had been carried out for the relief of symptoms. As a result of Chamberlain's report, interest in the condition was stimulated in this country. Although the abnormality is more properly designated as "basilar invagination," the term "platybasia" has become popular through Chamberlain's reference to it. Chamberlain has called attention to the fact that in lateral roentgenograms of the normal skull the shadows of the atlas and odontoid process will lie caudad to a line connecting the posterior edge of the hard palate and the posterior margin of the foramen magnum (Chamberlain's line).

Secondary basilar invagination may develop in the presence of any systemic skeletal disease in which the calvarium is softened, Paget's disease,

From the Sections on Neurosurgery, Neurology, and Roentgenology, The Mayo Clinic.

Presented before the tenth annual meeting of the Harvey Cushing Society in Rochester, New York, May 30, 1941.

Fig. Basilar invagination, showing the conditions found at operation before and after the bone was removed and the dura opened.

hyperparathyroidism, osteomalacia, and the like.

Gustafson and Oldberg reported several cases, with operative or necropsy confirmation, in which a syringomyelic picture of dissociated sensory loss was found on sensory examination of the patients. In our cases careful sensory examination failed to disclose any sensory changes except disturbance in the sense of pain occurring twice in the right side of the face. It is important to recall that the clinical picture may apparently vary somewhat from patient to patient. The stage of development at which the patient is seen may also prove confusing. We have recently seen at the clinic several patients who presented the classic roentgenologic picture of basilar invagination of the skull but who had, so far as could be found, no symptoms or signs indicative of disease of the nervous system. Whether or not these will occur at some later date remains to be seen.

It is an accepted fact that several skeletal anomalies may afflict a single patient who has basilar invagination of the skull, a fact which suggests that this condition usually rests on a congenital or developmental basis. List has comprehensively described anomalies of the occipital bone, atlas, and axis. Among the more prominent of these may be mentioned the Klippel-Feil deformity or fusion of two or more cervical vertebrae, the Arnold-Chiari deformity, or lengthening of the pons and medulla oblongata with herniation of the cerebellum into the spinal canal, spina bifida occulta, or failure of fusion of the laminae of one or more vertebrae and syringomyelia, or the existence of cavitation within the substance of the spinal cord, the cavity often being sur-

rounded by a zone of gliosis. Gustafson and Oldberg emphasized the almost invariable occurrence of adhesions about the brain stem and cerebellum in the portion that has herniated through the foramen magnum. They stated that operation which consists in enlargement of the foramen magnum without opening of the dura and freeing of these adhesions is not productive of relief and judging from our observations at operation, we concur in this opinion. It is possible that the late onset of symptoms among patients who have basilar invagination of the skull, although the skeletal deformities probably are present during most, if not all, of the patient's life, may be explained by the fact that symptoms might not occur until these adhesions form. The treatment of basilar invagination which produces symptoms is purely operative and in the reported cases has been productive of good results if the operation was not deferred too long.

REPORT OF CASES

CASE 1. The patient is a man aged 45 years, by occupation clerk. Except for renal colic from which he had suffered years prior to his coming to the clinic and the occasional feeling of abdominal fullness, no remarkable cause, the patient's history is not remarkable. About 22 months previous to the time of examination, malaise, occasional mild diplopia, and slight wastage of gas had developed. These symptoms had been completely relieved by ocular refraction and prescription of new lenses for his glasses. Eight months previous to the examination, as well as definite and persistent wastage of gas, which was worse in the dark, appeared and persisted. During the previous 5 months he had noted an occasional throbbing type of paresthesia of the right hand and arm. He had enough sometimes caused his legs, and occasionally his arms, to feel momentarily very weak. Frontal and occipital head

ache, which was worse on his arising in the morning, had become more frequent. For 2 months prior to his visit to the clinic slight difficulty in the swallowing of liquids had been noted.

The patient registered at the Mayo Clinic on November 9, 1940. Results of general medical and laboratory examinations were negative, as were results of careful examination of the ocular fundi. Neurological examinations disclosed coarse nystagmus on lateral gaze in either direction. The left side of the face, including the forehead, was slightly but definitely weak. Hypesthesia to pain was present on the right side of the nose and adjacent portions of the right part of the forehead, right cheek, and upper lip. The right corneal reflex was slightly diminished. The left side of the tongue was moderately weak and definitely atrophied. The gait was markedly ataxic, but inco-ordination of the arms or legs, and adiadokocinesis or the rebound phenomenon were not present. Thus, to recapitulate, there was evidence of involvement of the midline cerebellar structures (flocculonodular lobe) and of the right fifth cranial nerve nucleus (nucleus of the descending tract of the trigeminal nerve) and of the left seventh and twelfth cranial nerves. The differential diagnosis included tumor of the brain stem, or in the midline of the cerebellum, and a vascular or degenerative lesion of the brain stem and basilar invagination of the skull. The characteristic roentgenological observations consisted of true invagination of the base of the skull in the region of the posterior cranial fossa, plus anteroposterior narrowing of the foramen magnum with congenital variation of the first three cervical vertebrae. The posterior portion of the first cervical vertebra was fused to the inferior portion of the skull, and the second and third cervical vertebrae were fused both in the body and in the posterior portions.

The pressure on the pons and medulla oblongata, caused by a narrowed anteroposterior diameter of the foramen magnum and upper cervical vertebral canal, being responsible for the symptoms, the surgical procedure indicated was that of removal of the posterior arch of the foramen magnum and spinous processes and laminae of the upper cervical vertebra.

With the patient in the upright position and under the influence of intratracheal anesthesia, a midline incision was made over the suboccipital and upper cervical regions. This incision was carried down through the skin and muscles to the suboccipital bone and the spinous processes of the cervical vertebra. The muscle and periosteum were separated from the bone of the skull, and subperiosteal dissection was carried out about the spinous processes and laminae of the upper cervical vertebra. As the dissection proceeded we could see that the arch of the atlas was absent and that the second and third cervical vertebrae were fused, as was apparent in the roentgenogram. Laminectomy was done, and the fused spinous processes and laminae of the second and third cervical vertebrae were removed. We then were able to remove the posterior arch of the foramen magnum with double rongeurs, and a modified type of suboccipital craniotomy was done. After this the dura was opened and the inferior tonsil of the right cerebellar lobe was seen to have herniated through the foramen magnum to the level of the third cervical vertebra. Definite compression was present, indicative of a narrowed foramen magnum, and adhesions existed between the meninges, the pons and cerebellum. These adhesions were divided and the cerebellar lobe was gently dissected free from the underlying structures. Some definitely anomalous vessels situated around the cerebellar tonsil prevented amputation of the tonsil, which procedure has been suggested in cases in which the condition is extreme, as it was in this one. The entire region appeared to have been compressed, but after

the adhesions had been divided and the inferior cerebellar tonsil had been dissected free, much more room was provided, and definite decompression was accomplished (Fig. 1). The dura was then closed with interrupted silk sutures and the incision was closed with interrupted catgut in the muscle and silk in the skin.

In the preceding case the condition was so typical from the diagnostic and surgical standpoints that it really seemed that there was no question that surgical intervention was a safe and logical procedure. However, in the next case, compression was so great that respiratory difficulties were encountered throughout operation, and it was necessary to leave the dura open in order to obtain the maximal amount of relief.

CASE 2. A boy 16 years old was brought to the clinic on March 3, 1941, complaining of difficulty in swallowing liquids, a difficulty that had been present for $1\frac{1}{2}$ to 1 $\frac{3}{4}$ years prior to the time of his visit. Solid food could be taken without any difficulty. During the 2 years prior to the time of his visit he had suffered from some degree of weakness and loss of weight. He had always had some limitation of lateral motion of the neck, without pain.

Aside from osteomyelitis of the right femur, which had developed in 1934 and had taken a year to heal, the patient had remained in good health until about 1938, when he had begun to experience frequent attacks of stiffness and soreness in his neck. A violent cough or sneeze invariably would produce pain in nape of neck, more on the left than right, with extension of the pain up over occiput. Lying down would relieve this distress within a few minutes.

Nothing more of significance was noted until about March, 1939, when he had begun to experience difficulty in swallowing liquids. He would choke on liquids and had trouble with phlegm in his throat in the mornings. During latter half of 1939, he had begun to notice difficulty in walking and marked clumsiness developed in use of his hands. These symptoms had been progressive.

Shortly before the patient was admitted the father had noticed that while the boy was sleeping, he breathed in an unusual manner. Respirations which were shallow and frequent were followed by about three deep breaths taken slowly, followed in turn by a period of apnea which lasted for as long as 30 seconds. Then the process was repeated.

During the last 2 years prior to his visit, the patient had increased in height at least 12 inches (30 cm.).

The essential observations included a cerebellar type of ataxia, which was more marked on the left side, and elicitation of Romberg's sign. The patellar and achilles reflexes were increased and Babinski's, Chaddock's and Rossolimo's signs were elicited bilaterally. Rapid horizontal nystagmus was marked on the patient's looking toward either side, with slight nystagmus on his looking upward. Vibratory sense was moderately decreased at both external malleoli. The muscles of both upper extremities were definitely weak, but the strength in the lower extremities seemed normal.

Roentgenological examination of the cervical part of the spinal column and the skull revealed a congenital anomaly of the upper part of the cervical region of the spinal column, with a well defined basilar invagination deformity. There was an anomalous deviation of the body of the second cervical vertebra with resultant deformity of the odontoid process and anterior portion of the first cervical vertebra, there was also spina bifida occulta of the sixth and seventh cervical vertebrae. The lateral view of the skull and upper

part of the cervical region of the spinal column revealed deformity of the foramen magnum and first cervical vertebra, typical of basilar invagination.

The patient was operated on on March 8, 1941 at which time suboccipital decompression and laminectomy in the upper part of the cervical region was done. Because of the respiratory symptoms when the patient was asleep it was thought best to attempt to carry out the operation with the patient under the influence of intratracheal anesthesia. Induction of anesthesia was begun by the intravenous administration of pentothal sodium, when the patient's respiration ceased. Under artificial respiration he began to breathe normally and regional anesthesia was used thereafter throughout. With the patient in the upright position through a midline incision, the arches of the first, second, and third cervical vertebrae are removed. The second and third are fused and there is definite projection of the left side of the laminae which were compressing the medulla oblongata. Suboccipital craniotomy consisted of removal of the arch of the foramen magnum and the adjacent bone, for about 4 centimeters. At about this time the patient's breathing became very labored and he became comatose. We quickly opened the dura and found marked herniation of both cerebellar lobes to the level of the third cervical vertebra. Adhesions between the meninges, medulla oblongata, and the brain also are present; these were rapidly divided. When attempted to close the dura compression of the underlying part of the brain occurred. For this reason the dura was left open. Cargile membrane was used for closure of the opening, and the muscles are closed in the usual manner.

After this operation the patient recovered completely and was allowed to return to his home. There was marked absence of nocturnal dyspnea, and the patient's general condition was greatly improved. In letters months after the operation it was stated that he was greatly relieved of all symptoms, was awakening normally and was eating and sleeping without change in respiratory rate.

In the third case, the patient, although incapacitated for work, did not have a classical syndrome, although the roentgenograms of the head were typical. At operation the typical flat foramen magnum was found, with basilar invagination of the skull, but there were no anomalies of the cervical vertebrae and little herniation of the cerebellar lobes. The postoperative improvement, although it was subjective, indicated that operation was justified.

CASE 3. A man, aged 5 years, was admitted to the clinic on April 1941, complaining of numbness and weakness of the legs which had occurred intermittently during the previous 6 months. In October, 1940, the patient had noticed some numbness as he arose from the supine position. This had been associated with increased bilateral "tiredness" of his legs. A sensation described as "electric pins and needles" had seemed to affect the front of his feet and legs to his knees on his climbing the stairs. By November, 1940, this condition had progressed to such point that it was necessary for him to quit his work. His legs had continued to become weaker particularly about the knees. In February 1941 he had noted the same sensation in his arms as had been present in his legs, associated with sensation of numbness in the upper part of

the thoracic region of the spinal column. This had been intermittent. During the 3 months prior to his coming to the clinic he had noted paresthesia involving both lower extremities, but more on the right side. For 4 or 5 months he had experienced intermittent attacks of weakness that had involved the right side of his head.

On examination bilateral increase of patellar reflexes and static tremor on the left are found. Definite syndactylism was detected on lateral part. Roentgenological examination of the skull revealed flattening of the foramen magnum and typical basilar invagination of the skull. The spinal fluid was under normal pressure. Subarachnoid block was not present, and the content of protein was normal. There were, however, slow increase and rapid decrease in the pressure of the spinal fluid on and after performance of the Queckenstedt or jugular compression test.

On April 2, 1941 with the patient in the upright position and under intratracheal anesthesia, a midline incision was made over the occipital and upper cervical regions. Fusion of the upper cervical vertebrae was not present, and then the arch of the foramen magnum was removed, the dura was opened. Although herniation of the cerebellar lobes was not so marked as in previous cases, definite adhesions are situated between the meninges and the inferior poles of the cerebellar lobes. After an uneventful convalescence the patient returned to his home.

SUMMARY

Three patients with roentgenographic picture of basilar invagination of the skull are reported. In 2 of the cases associated anomalies of the upper cervical vertebrae also were present. Clinical symptoms suggested involvement of the spinal cord in the upper cervical region and the brain stem in all 3 cases, whereas neurological signs indicated a lesion of the cerebellum or its tracts in all cases, and in one case each, a lesion of the brain stem, and a lesion of the spinal cord in the upper cervical region. Marked respiratory difficulty occurred in one case.

Operation was carried out in each case, and adhesions between the meninges and inferior poles of the cerebellar lobes and brain stem were present and were freed in all cases. In 2 cases marked herniation of portions of the cerebellar lobes occurred. Relief from symptoms was striking in all cases.

The characteristic roentgenographic picture of basilar invagination of the skull has been encountered among several patients who had neither the clinical symptoms or signs of involvement of the nervous system.

AN EXTRA-ARTICULAR OPERATION FOR RECURRENT DISLOCATION OF THE SHOULDER JOINT

JACOB A GLASSMAN, M D, M S, Chicago, Illinois

FOR the treatment of habitual dislocation of the shoulder the writer introduces a simple and improved method which is accomplished by an attack that intends to be extra-articular throughout¹ The technique to be described was developed to replace the longer and more complicated procedures employed today, in which articular exposure, excessive manipulation and injury to synovial lining and capsule are objectionable features

Nicola, in considering the pathology underlying recurrent dislocation of the shoulder, listed three main groups (1) bony, (2) capsular, and (3) muscular

"1 In the bony group are included (a) Defects in the head of the humerus, either congenital or acquired after the first dislocation Atrophy of the head of the humerus, infantile paralysis, or congenital defects (b) Defects in the glenoid cavity, consisting of acquired fracture of the edge, or shallowness of a congenital type (c) Fracture of the greater or lesser tuberosities of the humerus

"2 In the capsular group are included (a) Detachment of the joint capsule from the anterior or inferior margins of the glenoid fossa (b) Enlargement of the joint capsule from relaxation following repeated tears

"3 In the muscular group are included (a) Weakness of the supraspinatus and infraspinatus muscles (b) Contracted pectoralis major, teres minor, and latissimus dorsi"

According to Steindler and others, the principal pathological feature in habitual dislocation of the shoulder is the relaxation of the antero-inferior capsular apparatus The original rent in the capsule is filled in by fibrous tissue and the resulting redundancy predisposes to subsequent dislocations, which occur on abduction and outward rotation of the arm, in many instances during epileptic seizures On the other hand, Bankart believes that the underlying pathology in traumatic dislocation of the shoulder joint occurs

¹The technique herein described was developed and perfected in the Department of Anatomy of the University of Illinois, College of Medicine, with the aid of Dr Otto F Kampmeier Professor of Anatomy and Head of the Department. The writer also wishes to thank Dr Jack Kirschbaum Pathologist of the Cook County Hospital for his invaluable assistance in furnishing fresh postmortem material to further the development of the technique

when the "head of the humerus shears off the fibrous capsule of the joint from its attachment to the fibrocartilaginous glenoid ligament"

For the purpose of contrast, we need to review briefly the essential steps employed today in the surgery devised to correct habitual dislocation of the shoulder joint Of the methods that depend upon muscular or tendinous slings for the stabilization of the joint, the Ehrlich-Clairmont myoplasty, and the Nicola tenoplasty are the most widely known The Ehrlich-Clairmont operation utilizes a flap of muscle taken from the posterior aspect of the deltoid muscle and passed anteriorly through the quadrilateral space to be sutured to the tendon of the subscapularis muscle as it inserts on the lesser tuberosity of the humerus Because of its extensive surgery and its frequent failures, this operation fell into disuse The Nicola operation utilizes the long tendon of the biceps muscle to keep the head of the humerus from dislocating from the glenoid fossa After adequate exposure of the shoulder joint, the capsule is opened, and the long tendon is divided below the level of the transverse humeral ligament A tunnel is then drilled from this point of division upward through the head of the humerus to the center of its articular surface The proximal end of the tendon is pulled through the osseous tunnel and reunited with its distal end by interrupted sutures Because of the excessive disruption and trauma to the joint capsule and to the articular surface of the head of the humerus, Berkheiser found it advisable to modify Nicola's operation by drilling vertically and in a downward direction through the lesser tuberosity of the humerus This departure from the original technique eliminates the undesirable step of having to drill through the center of the articular surface of the head of the humerus, but it does not do away with the necessity of laying the joint cavity wide open

Capsulorrhaphy or plication of the capsule has been attempted by many, but seldom found to be curative, and therefore, is never recommended alone Repair of the glenoid ligament alone or in combination with capsule plication and shortening of the subscapularis tendon is also seldom employed

Fig. 1. left. The arm is abducted to 45 degrees and the forearm is in complete supination. The dotted line represents an incision, beginning at the coracoid process and curved downward about 5 centimeters from the middle level of the shaft of the humerus.

Fig. 2. Some fibers of the anterior lamina of the tendon of the pectoralis major are cut along its insertion on the lateral aspect of the intertubercular groove.

Of the many procedures that resort to reconstruction of the bony part of the glenoid fossa, those described by Bankart and Oudard are most widely used. In Bankart's operation the coracoid process is divided and drawn downward with its muscle attachments. The subscapularis muscle is severed from its insertion on the lesser tuberosity and drawn inward. After the anterior aspect of the shoulder joint is exposed, the capsule is elevated and kept in position with a small bony wedge. The fibrous capsule is then fixed to the bone along the anterior margin of the glenoid and the subscapularis tendon and the detached coracoid process are reattached.

In the operation designed by Oudard a bony buttress is formed in front of the shoulder joint. He accomplishes this by splitting obliquely the coracoid process and lowering the lateral half on which the tendons of the coracobrachialis and the short head of the biceps are attached, to a point just in front of the glenoid lip of the shoulder joint. Originally Oudard employed a bone graft to increase the length of the coracoid process

when lowering it in front of the shoulder joint.

Of the operations employed today for recurrent dislocations of the shoulder joint, most surgeons believe that the operation devised by Nicola gives the highest percentage of good results. Although this may be true, we must admit that his approach gives less attention to anatomical and physiological considerations than is desirable. The Nicola operation requires the capsule to be held wide open, the transverse humeral ligament to be cut, and the entire tendon of the long head of the biceps brachii muscle to be displaced from its normal and important anatomical relationship

According to Gray's *Anatomy of the Human Body*, 2nd ed., vol. 1, "the posterior relations of the tendon of the long head of the biceps brachii to the shoulder joint appear to inspire no special purpose. In the first place by its connection with the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic support to all positions. It strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pushed up against the acromion, when the deltoidus contracts. Thus from the head of the humerus as the center of motion in the glenoid cavity. By its position along the articular border it arrests the swinging of the head of the humerus as the arm moves forward. It keeps the arm steady from the side. It arrests the supination and pronation, rotating the head of the humerus as the forearm moves, and prevents its slipping over its lesser tuberosity, or being displaced by the action of the acromion and pectoralis major, as is claimed, and being after such movements."

Fig 3

Fig 4

Fig 5

Fig 6

Fig 3 With arm still in abduction, the long tendon of the biceps is split lengthwise into ventral and dorsal halves, by first passing sharp point of scalpel through its central axis

Fig 4 Further splitting of the long tendon with the blunt end of the scalpel

Fig 5 The anterior or ventral half of the split tendon is cut across at its lower end, near the muscle belly

Fig 6 The arm is next adducted, and then it is raised forward and upward to an angle of 135 degrees or more. The intra-articular portion of the long tendon of the biceps is thus exteriorized thereby making it possible to proceed with the visible blunt division of the tendon in a direction toward its attachment on the supraglenoid tubercle.

Another highly undesirable feature of Nicola's procedure is the marked trauma to the articular surface of the humerus when the bit of the drill breaks through that surface, causing jagged edges. Wishing to retain the basic principle of Nicola, yet at the same time being guided more strictly by anatomical considerations in the treatment or stabilization of a shoulder joint subject to recurrent dislocations, the writer set out to devise a method which would reduce to a minimum the interference and trauma to its various components. The technique to be described herein was developed on embalmed and then on fresh autopsy cadavers. Experimentally, the shoulders of fresh cadavers were first dislocated, and then opened. Inspection revealed marked stretching and tearing of the shoulder capsule, especially at its anteroinferior aspect. The author's "extra-articular" operation was carried out, and found to be satisfactory in holding the head of the humerus securely in the glenoid fossa, even when an attempt was made to redislocate it.

THE METHOD

The proposed method of operation is as follows:

With the arm abducted to 45 degrees and the forearm in complete supination (Fig 1), an incision is made from the site of the coracoid process downward to about 5 centimeters from the middle level of the shaft of the humerus, and the deltoid muscle is exposed. The fibers of the deltoid are bluntly split as far down as possible and pulled aside to expose the shoulder joint and the upper one-third of the shaft of the humerus. In order

to uncover completely the long head of the biceps from where it leaves the joint capsule to as far as the muscle belly, some fibers of the anterior lamina of the tendon of the pectoralis major¹ are cut along its insertion on the lateral aspect of the intertubercular groove (Fig 2). Now by flexing the elbow, the long tendon of the biceps relaxes, and it can be easily freed from its loose investing areolar tissue with the blunt end of a scalpel. Once the tendon is lifted from its bed, further gentle stripping frees it along its entire course, from the lower border of the joint capsule to the beginning of the muscle belly. To illustrate the range of sliding of the tendon, the arm is adducted and raised to an angle of about 135 degrees (Fig 6). This maneuver permits the intracapsular portion of the long head of the biceps to emerge for a distance of approximately 5 centimeters or more, thereby making most of it extracapsular. Conversely, by allowing the arm to come down to the side of the trunk again, the originally intra-articular portion of the tendon is seen to glide back into the joint capsule. Proceeding with the operation, the arm is kept in abduction and the elbow is extended, and the forearm is placed in a position halfway between pronation and supination. While the extremity is held in that position,

¹In Cunningham's *Textbook of Anatomy* the description of the insertion of the pectoralis major muscle reads: "The tendon at its insertion forms a fascial expansion which extends upwards over the biceps tendon to the capsule of the shoulder joint. In this way, a bi-laminar tendon is produced united along its inferior border." While studying the relationship of the insertion to the pectoralis major to the long tendon of the biceps, the writer observed that this tendon, while sliding down through the tunnel provided by the split tendon, is kept closely applied to the surface of the humerus. The latter relationship, therefore, affords an efficient leverage for the long tendon when the biceps brachii contracts.

Fig. 7

Fig. 8

Fig. 9

Fig. 10

Fig. 7. The lower end of the anterior half of the split tendon is fastened with two silk sutures to the eyelet of flexible probe. The other end of the probe is passed through the synovial canal of the tendon almost as far as the supraglenoid tubercle. Here the tip of the probe is pressed upward against the roof of the capsule, and a stab wound is made with scalpel at the point of projection.

Fig. 8. The probe is pulled gently through the opening, bringing through the other end with attached tendon half. A. Represents sagittal section taken through the head and shaft of the humerus in plane that is longitudinal with the canal drilled through the lesser tuberosity.

Fig. 9. The tip of the flexible probe is passed into the newly formed osseous canal until it emerges from the lower opening. The probe is then pulled forcibly through the canal, carrying with it the attached end of the externalized tendon.

Fig. 10. An illustration of the ultimate relationship of the displaced tendon to the glenohumeral articulation and capsule of the shoulder joint. A. Further illustrates additional plication of lax capsule by several interrupted Lambert silk sutures. This step invaginates the externalized half of the long tendon within the external surface of the capsule.

the long tendon of the biceps is split lengthwise into ventral and dorsal halves (Fig. 3, 4). To accomplish this the operator should gently compress the tendon with an anatomical forceps which flattens it lateromedially permitting the scalpel to pass more easily and accurately through its central axis (Fig. 3). The initial passage of the scalpel's point through the tendon is made preferably close to the tendon's exit from the joint capsule. Further splitting of the tendon is continued with the blunt end of the scalpel as far downward as the belly of the biceps muscle and the anterior or ventral half of the split tendon is then severed transversely at its lower end, that is, near the muscle belly (Fig. 5). Additional splitting of the tendon in the upward direction is not attempted until the elbow is flexed, and the arm adducted and then brought forward and upward to more than 135 degrees. This movement exteriorizes the greater portion of the intra-articular portion of the long tendon of the biceps, thereby making it possible to continue the visible blunt division of the tendon, as much as the intact transverse humeral ligament will permit, in the direction proximal, that is, toward the attachment of the tendon on the supraglenoid tubercle (Fig. 6). Then lowering the extremity to the side of the trunk and extending the elbow joint both halves of the split long tendon are seen to slide

back into their intracapsular relationship. Next, the lower end of the anterior half of the split tendon is fastened with 3 silk sutures to the eyelet of a flexible probe and the other end of the probe passed upward through the synovial canal of the tendon almost as far as the supraglenoid tubercle. Here the tip of the probe is pressed upward against the roof of the capsule and a stab wound made with the scalpel at the point of projection (Fig. 7). Then the probe is pulled gently through the opening bringing through the other end with attached tendon half (Fig. 8).

By means of a 5 to 6 millimeter bit, a tunnel is formed in the lesser tuberosity by drilling from its apex vertically downward, that is parallel with the long axis of the humeral shaft for a distance of 3.5 centimeters. The bit is then withdrawn, placed on the outer surface of the tuberosity at an obtuse angle with the lower end of that vertical tunnel, and a second tunnel is drilled until it communicates with the vertical one (Fig. 9) so establishing a common canal through the lesser tuberosity. (To break down the crest of bone that might remain at the angle where the two bony tunnels join, as shown at a in Figure 8, the drill bit is moved appropriately to and fro before it is withdrawn.) The tip of the flexible probe is now passed into this newly formed osseous canal until it emerges from the lower opening, and the

probe then pulled forcibly through carrying with it the attached end of the exteriorized tendon (Fig 9)

Before proceeding with the final step, it is important to eliminate completely any wrinkling of the tendon which may have been imparted to it in the course of its handling. Such precaution is secured, when the arm is in adduction and the elbow flexed, by grasping the lower end of the tendon with a hemostat and forcibly pulling it, and at the same time, pushing the head of the humerus toward the glenoid fossa. Having acquired a maximum degree of tautness, the tendon is finally reattached to the intact dorsal half of the biceps tendon by several interrupted silk sutures. Figure 10 illustrates this ultimate relationship of the displaced tendon to the glenohumeral articulation and capsule of the shoulder joint. This figure should indicate also that closer apposition of the head of the humerus to the glenoid fossa is achieved, as well as the re-enforcement of the weakened anterior aspect of the capsule.

The surgical procedure, just described, is one which, in comparison with that of Nicola's, is practically extra-articular (except for the possible tearing of the synovial sheath surrounding the biceps tendon) and, therefore, neither lays open the joint to sepsis nor damages it with subsequent distorting processes. The joint capsule and the transverse humeral ligament are kept intact, and the transplantation of the entire long head of the

biceps muscle from its important relationship is made unnecessary. The time required to carry out the operation is considerably shorter than that for the other operations mentioned. Because of the apparent decrease in trauma one may expect less postoperative fibrosis and consequently a diminution in the number of cases with limitation of motion.

In cases in which a stretched articular capsule exists, the following additional step may be included with definite advantage. Several interrupted Lembert silk sutures are made to invaginate the exteriorized half of the long tendon within the external surface of the capsule, as shown in the insert of a, Figure 10. Such additional plication of the lax capsule not only diminishes the size of the stretched capsule, but also strengthens the displaced tendon in its course down to the upper opening of the osseous canal in the lesser tuberosity.

removed in quantities of 20 cubic centimeters and was immediately replaced by gas and the post-operative care of the patient was carefully standardized in order to provide as constant conditions as possible throughout the study.

Of the 82 patients studied, only 41 were considered reliable enough to report. Some were rejected because they were too young to give dependable answers and others because they were suffering from psychoses which made them unreliable. Patients who gave a history of frequent persistent headaches, vertigo or other symptoms before encephalography were eliminated, as were those whose postencephalographic symptoms disappeared during sleep and hence could not be classified accurately as to the exact time of disappearance.

The results obtained are shown in Figure 1.

From the figures in Table I it is apparent that helium encephalography followed by oxygen inhalation produced symptoms lasting less than half as long as those produced by oxygen encephalography plus oxygen inhalation and about one-fifth as long as the symptoms produced by encephalography as it is usually performed with air. It is also apparent from these figures that the effectiveness of postencephalographic oxygen inhalation depends upon concentration of oxygen inhaled, since inhalation of low concentrations had much less effect than inhalation of pure gas.

TABLE I

	Average duration of symptoms—hrs.
Air encephalography followed by	
No oxygen inhalation	58½
Low concentration oxygen	7½
Pure oxygen inhalation	1½
Oxygen encephalography followed by	
No oxygen inhalation	59½
Low concentration oxygen	22
Pure oxygen inhalation	9
Helium encephalography followed by	
No oxygen inhalation	8
Low concentration oxygen	6½
Pure oxygen inhalation	3½

Among the cases reported are 2 in which encephalography was performed by more than one method. One patient suffered for 24 hours after simple air encephalography and for 19 hours after air encephalography followed by inhalation of low concentrations of oxygen. Another patient who suffered for 34 hours after simple air encephalography was symptom-free 3 hours and 45 minutes after helium encephalography followed by inhalation of pure oxygen.

Since this paper was written, all cases in which patients were examined with encephalograms have

been reviewed. It has been noted that in approximately 75 per cent of the cases in which the encephalograms were made under pentothal sodium anesthesia, poor filling of the ventricular system resulted, whereas, in those cases in which encephalograms were performed under local anesthesia, unsatisfactory filling resulted in less than 20 per cent. In 14 cases in which poor filling of the ventricular system resulted under pentothal sodium anesthesia, further encephalographic studies were done under local anesthesia and, in only 1 case were we unable to obtain satisfactory results. As a further check on this, we deliberately used pentothal sodium in 1 case and then, at a later date, repeated the procedure under local anesthesia. In 4 of these cases, no filling of the ventricular system was obtained under pentothal sodium anesthesia, and in 2 others, there was unsatisfactory filling. When repeated under local anesthesia, satisfactory filling was obtained in 9 of the cases and unsatisfactory filling was seen in 1 of the 4 in which there was no air in the ventricles when pentothal sodium was used.

SUMMARY

When the cerebrospinal fluid was replaced by helium gas and the patient was then allowed to inhale pure oxygen until symptom-free, the average duration of symptoms was 3½ hours.

When oxygen was used to replace the cerebrospinal fluid and pure oxygen was then inhaled, the symptoms lasted 9 hours, or more than twice as long.

The symptoms following simple air encephalography as it is usually performed lasted 58½ hours, or almost ¾ days. This is about 3 times as long as the results obtained with helium.

The rationale of helium encephalography is discussed, and various methods of encephalography are compared on the basis of duration of postencephalographic symptoms which they produce.

Pentothal sodium anesthesia has proved unsatisfactory for encephalography. The best results are obtained when local anesthesia only is used preceding spinal puncture. The only advantage of pentothal sodium or general anesthesia is that the patient is not aware of the headache during the immediate procedure.

CANCER OF THE BREAST

Ten Year End-Results

CHANNING C. SIMMONS, M.D., F.A.C.S., Boston, Massachusetts

THE following is a report of the 10 year end-results of radical operation for cancer of the breast operated upon at the Massachusetts General Hospital during the 5 year period, 1927-1931 inclusive. The cases are the same as those previously reported on a 5 year basis in 1936 and 1939. Several papers on the results of radical operation for cancer of the breast have been published by the author or his associates in the Tumor Clinic on a 5 year basis. A detailed analysis of these cases will not be repeated here (2, 3, 4, 7, 8, 9). In previous reports the patients in the private wards were included with those operated upon in the general hospital. The results have constantly improved since the first study was made in 1907, and the percentage of 5 year cures in the last group studied (1930-1932) was 45 per cent. It was noted that in an appreciable number of cases the recurrence did not appear until after the fifth year, and this review is made to determine, if possible, the number of, and reason for, this late recurrence.

The cases of patients operated upon in the General Hospital only have been studied, for it was deemed too difficult to follow the private patients operated upon by many different surgeons, several of whom are now dead. The results of treatment of cancer have always been found to be better in the patients operated on in private wards, even when the two series are placed in comparable groups as regards duration, extent of disease, histological index of malignancy, age, etc. The reason for this is obscure, but the fact that the prognosis is better in patients who may be said to be in the higher social group has been pointed out by several observers (1, 5, 6, 10, 11, 12). The percentage of 5 year cures is therefore slightly less than that reported in the other communications.

The group studied consisted of 147 cases and with few exceptions these patients were operated upon by members of the tumor clinic staff. The 10 year end-result is known in every case. The usual radical operation was performed consisting of removal of the breast, both pectoral muscles, and the contents of the axilla. A large amount of subcutaneous tissue was removed from the mid-sternal line to the border of the scapula. Sufficient

skin was preserved to allow for primary closure of the wound in most instances, for, as the disease progresses along the deeper lymphatics and not in the skin proper, it is felt that preserving sufficient skin for primary closure is a safe procedure. This has been borne out by the fact that in the 104 cases in which the site of recurrence is known or who are living without disease, there were 6 local recurrences, or 6 per cent.

All patients were carefully studied for evidence of remote metastasis before operation and x-ray films were taken of the lungs and bones to rule out unexpected remote disease. Radical operation was performed only on those patients in whom disease was clinically limited to the breast or breast and axilla. In 5 cases, however, considering the size and extent of the disease, the operation might be considered as palliative.

That estimation of the extent of the disease is subject to considerable error is shown by the fact that 15 patients died within 1 year of remote metastases, the presence of which could not be demonstrated before operation, but without local recurrence. Axillary nodes were involved in all but 1 of these patients and in 3, although the disease was apparently local, it was advanced. Otherwise there was nothing to distinguish this group from certain other cases in which a cure was obtained.

Appraisal of axillary involvement is also subject to considerable error. In this group 84 patients presented axillary nodes clinically, in 72 of which cancer was proved to be present by pathological examination, while in 12 the nodes were inflammatory—an error of 14 per cent. On the other hand in the 63 cases in which no axillary nodes were palpable they were found diseased in 30, representing a 48 per cent error in the clinical appraisal of the extent of the disease. It is felt that the situation of the involved axillary nodes and the number have a distinct bearing on the prognosis, but, unfortunately, these facts could not be determined from the pathological reports.

There were 4 operative deaths—an operative mortality of 2.7 per cent. Three patients died of pulmonary embolus on the 5th, 7th and 21st days respectively, and 1 (colored) of unknown cause on the way to the ward after operation.

Chart Ten year end results in cancer of breast — Total, 34 cases, 33 per cent cures — axilla involved, 25 cases, 8 per cent cures — axilla not involved, 30 cases, 70 per cent cures (Patients living with disease at end of 10 years considered dead)

The results of operation on a 5 and 1 year basis are shown in Table I. Operative deaths are considered as failures, while patients dying of other causes without evidence of recurrence are excluded as inconclusive.

As will be noted in Table I, 6 patients living at the end of 5 years died later of recurrence, in 9 of whom the nodes were involved. In other words, 9 per cent of the patients living at the end of 5 years will develop late recurrence, or 7 per cent of all patients operated upon considering the patients dying of other causes without disease as inconclusive. In studying the causes further only 1 patient in whom the axillary nodes were negative for cancer died after the 5th year and this patient showed evidence of metastases in the lung and other breast 3 years after operation thus no patient with negative nodes developed recurrence after 5 years. In the 9 patients in whom the axillary nodes showed involvement and who developed late recurrence, all were apparently free of disease at the end of 5 years. In this group there were 30 per cent 5 year cures and 18 per cent 10 year cures. Five lived for 1 year or more after operation and with known recurrence for 4 years.

The 5 year results are approximately the same in the groups previously at risk. The number of cases is small and the percentage would be influenced by the manner in which the patients

dying without disease between 5 and 10 years are reckoned.

Further analysis of the cases of late recurrence is not illuminating. The average and median age of the group was 53, the average and median duration of the tumor at the time of operation was 5 months. As to the histological index of malignancy, 7 were classified as of median and 3 of high. The chief sites of recurrence are known in 7 of these 9 cases. The bones were involved 5 times, the supraclavicular nodes 2 times, and the lungs 3 times. There was 1 case only of local recurrence which appeared at the end of the fifth year. Patients living with disease at the end of the tenth year 4 in number are charted as having died in that year (Chart 1).

In 75 per cent of those dying of disease, recurrence and death took place within 3 years of the date of operation.

Sites of recurrence. The site of recurrence is known in 60 of the 88 cases dying of disease, many obviously having multiple metastases. The bones and lungs were the most common sites of metastases, being involved in 29 and 26 instances, respectively. The cervical nodes were the next most common seat, 17 patients having recurrence in that region. Cancer of the other breast, which has been considered as being metastatic, is noted in 5 instances. Six per cent only developed local recurrence.

Protoplast irradiation. Twenty-six patients in whom the nodes were involved received pre-

TABLE I — RESULTS OF OPERATION

	Five years	Ten years
Living	6 (40%)	44 (35%)
Dead		
of disease	75	80
operatively	4	4
Inconclusive		
dead of other cause without recurrence	6	5

TABLE II.

	Axilla not involved	Axilla involved
Year	Year	Year
Living	3 (15%)	27 (70%)
Dead	40	76
Inconclusive	3	7

operative x-ray treatment Five of these patients are living (19 per cent) while 21 are dead, 20 of whom died within 5 years while 1 lived 11 years It is only fair to state that the amount of irradiation given to these patients, as judged by today's standards, was totally insufficient seriously to affect tumor cells

SUMMARY

It would appear from this analysis that in cases of cancer of the breast in which the axillary nodes are not diseased, patients living without clinical evidence of cancer at the end of 5 years may be considered as permanent cures (70 per cent 10 year cures) But, in patients with positive nodes at the time of operation, 19 per cent living at the end of 5 years will eventually die of late recurrence, or 7 per cent of the cases operated upon These figures might be changed for better or worse if it were not necessary to exclude as inconclusive cases the 13 patients dying of some other

cause before the expiration of 10 years following operation The results of this study are shown graphically in Chart 1

THE PRESENT STATUS OF THE CANCER PROBLEM

SO much has been written on the subject of cancer in recent years that it is not an easy matter to sift out the facts from the near facts and obtain a true picture of progress and actual accomplishment.

As never before the medical profession is increasingly aware that cancer is one of the two greatest and most pressing problems of modern medicine. Heart disease and cancer are our two chief killers. Wilson, of the Harvard School of Public Health, recently found for the first time in the annals of American medicine, that more women during the twenty year span, from thirty five to fifty four years, die of cancer than of any other single disease.

It is obvious that the cancer patient must come to the doctor early in the course of his disease if a cure is to be effected but few realize however that over half of the patients suffering from cancer will not be cured no matter if they go to their physician at the

very first symptom manifestation. Hodgkin disease, leucemia, cancer of the pancreas and of the esophagus, as well as sarcomas of bone offer small chance of cure. And the first symptom of gastric, ovarian, testicular, lung, antrum, and even breast cancer is not infrequently that of metastasis or direct invasion into irremovable vital structures. On the other hand, so much is to be gained from an intensive campaign of cancer control for the other half that does have an opportunity for cure if diagnosis is made early and treatment given that in all probability cancer control which teaches the symptoms and signs of cancer to the laity is our most effective single step in the cure of those who have an opportunity for cure.

The annual physical examination not infrequently reveals cases of both early and late cancer however it has proved to be a disappointment as far as effectiveness goes in finding early cancer.

As a whole, the general public, particularly during the past few years, has learned much about the disease. Widespread fear persists but it is encouraging to note that the last Gallup poll on the subject revealed that 39 per cent of the population now believe that early cancer is curable. The previous Gallup poll had shown that 48 per cent of the population believed early cancer to be curable. There are signs which make us realize that in certain quarters progress is unquestionably being made. It is only recently that McCarthy of the Mayo Clinic, reported that in their cases of operable breast cancer it is necessary to perform a biopsy in three times the number of cases it was fifteen years before. This demonstrates that the mammary cancers of today

are smaller, and therefore more difficult of diagnosis

Although delay from the time of the first symptom until the patient's entry into the hospital for treatment is still appalling, a recent study made at the Memorial Hospital in New York, revealed that twenty years ago, in these same operable breast cases, the average delay was eleven months, seven days, while in 1940 the average delay was four months, seven days—a reduction of 62 per cent in valuable time lost. There are several evidences which demonstrate that the education of the public is catching hold. It is interesting to note two entirely new, and what are proving to be effective, methods of teaching the subject of cancer to the lay public. Five years ago the American Society for the Control of Cancer organized the Women's Field Army Against Cancer. Its chief aim was to enroll women in a campaign, pledging themselves to become informed on the simple signs of cancer, and to take the responsibility for the teaching of this information to the members of their immediate families. This campaign met with signal success. Today there are 225,000 women enrolled in this educational effort, and it is very largely through their influence that much new legislation has been effected, looking to improved care of the indigent cancer patient in several states. It is also the result of their influence that President Roosevelt declared the month of April to be "Cancer Control Month."

The other new experiment is taking place in Westchester County, New York, where a small textbook of seventy-five pages, "Youth Looks at Cancer," is being taught in the biology department of all high schools, and the problem of abnormal growth is being rationally and normally approached.

The program of the Cancer Committee of the American College of Surgeons has been

broad and aggressive. The College gives its stamp of approval to the idea that cancer is such a comprehensive disease that special training in diagnosis, pathology, and treatment is desirable. The College has been effective in establishing 370 cancer clinics in the United States and Canada, representing 20 per cent of the total approved hospitals of 100 beds or over. It is a policy that at the annual Clinical Congress, the subject of cancer shall be presented to the Fellows by a series of papers, by symposia, and by the giving of cancer clinics. Aside from this, the College maintains a registry for cured cancer cases which is available for study. There are now over 36,000 such cases of cured cancer registered. Now that many of the cancer clinics have been established for a period of five years, it is anticipated that the registration of cured cases will proceed at a rapid rate and that the College will soon have 100,000 cases of cured cancer—a monument to the effectiveness of good surgery and sound irradiation.

From the professional point of view, another bright spot is that a comparison of medical school curricula of 1940 with those of 1920 reveals a real increase in the hours allocated to the medical student on the subject of cancer. The medical schools are now beginning to make greater use of their material of the cancer clinics for teaching purposes.

On the whole, sufficient new experience has now accumulated in the fields of surgical and irradiation therapy to make a more exact evaluation of them possible. We now hear less of those extravagant claims which a new and impressive agent inevitably brings out. From experience we now know that there is no place for inadequate or poor surgery in this field. In spite of voluminous literature to the contrary, largely produced by discouraged surgeons and overzealous radiologists, we now find there is no place for incomplete surgery.

being done with the idea that cure of the remaining disease will be effected by irradiation. Radiation is an exact and effective therapy which should be carried out by those familiar with its accomplishments as well as its limitations. In certain pathological states irradiation is more effective than surgery and the reverse also holds true. And there are situations in which a combination of good surgery and expert irradiation offers most.

It seems that at present lead therapy as well as freezing the latest widely heralded cure have been abandoned. The effects on cancerous tissue of the radioactive isotopes, phosphorus and strontium are undergoing critical study. Cancer research laboratories are working ceaselessly on these and other leads. It takes much time and experiment before a cure can be accepted. We must hold fast to those two agents which have proved to be most effective namely "cancer control" and the expert use of surgery, radium, and x rays.

FRANK E. ADAIR.

OBSTRUCTIVE JAUNDICE

THE treatment of obstructive jaundice has been shown recently to demand not only especial attention to the preoperative and postoperative care but in addition great care in the selection of the actual operative technique for the case involved. In 1878 J. Martin Sims performed the first premeditated operation on the gall bladder in a jaundiced patient. The patient died apparently from a biliary fistula due to failure to remove the stone from the common duct. The second jaundiced patient was operated upon by W. W. Keen of Philadelphia, and this patient died in 36 hours from hemorrhage, exhaustion, and shock.

The mortality of operations upon jaundiced patients remained high until the twentieth century at which period the emphasis in

surgical study and investigation was placed upon anatomy and pathology. The chief factor in the mortality from operations upon this type of patient was not the result of an insufficient knowledge of pathological anatomy but rather to a lack of knowledge of the fundamental pathological changes in the physiology occurring in the jaundiced state. The work of Rous and McMaster on the bile and extrahepatic bile ducts, and of Rosenfeld, Wells, and Ballman and Mann on the liver were among the first important investigations of this character. With the aid of the information obtained by such studies, certain principles have been formulated regarding the preoperative and postoperative treatment of jaundiced patients with a resulting markedly lowered surgical mortality. That the physiology of this condition is not yet completely understood need hardly be mentioned. Indeed it is but recently that the most important contribution in years has come to the surgeon's aid in the treatment of jaundice—namely vitamin K and bile salts.

Obstructive jaundice to be amenable to surgery must be within reach of the surgeon, either in the common hepatic or the common duct itself. Many of the problems involved in the treatment of such an obstruction are the same irrespective of the type of obstruction. There occurs an increase in the ductal pressure which may be greatly delayed when the gall bladder is normal as in cases of carcinoma of the pancreas. As the pressure approaches 330 millimeters of bile the hepatic secretion of normal bile stops. The bile pigment no longer is secreted into the common duct. The mucous secretion of the bile dilutes the bile already present and the pigment is absorbed. The ducts are thus filled with the "white bile" familiar to us all. It is common knowledge that the presence of "white bile" in the common duct is a bad sign and definitely in-

creases the surgical risk. This is true only because it is evidence of liver injury. The pre-operative evaluation of the degree of liver injury is difficult or impossible. A rough idea may be gained by the indirect van den Bergh reaction (degree of jaundice) and the duration of the jaundice. Of the various liver function tests, the hippuric acid test of Quick is probably the best method available at present for determining liver function. In the jaundiced patient, however, the liver damage is evident, but the degree may be questionable. In any event every effort must be directed toward the improvement of the liver function before operation.

For a number of years attention has been centered upon the carbohydrate metabolism in the liver when associated with jaundice. It has been shown that the glycogen stores in this organ are greatly decreased. Therefore, it has become the widespread practice to force the ingestion of carbohydrates in the preparation of these patients for operation. This has, undoubtedly, been very helpful. However, when biopsies were taken of the liver and a number of patients prepared in this manner, it was found that the liver contained a large amount of fat. It has also been shown in experimental animals that the liver glycogen may be increased only by a diligence in the forcing of carbohydrates far beyond that previously taken.

As a result of a series of experiments carried on in the Harrison Research Department of the University of Pennsylvania under the direction of Dr. Ravdin, we have come to believe that the amount of glycogen in the liver is not as important a factor as the amount of fat in the liver at the time of operation. It has been conclusively shown that the degree of liver injury following volatile anesthetics is dependent upon the amount of fat in the liver and not on the

glycogen content. The problem in the pre-operative preparation of the jaundiced patient, therefore, is to remove the fat from the liver as rapidly as possible. Our experimental evidence has demonstrated that this is most effectively done on a diet high both in protein and carbohydrates with no fat. It has been our practice to give a diet in which 14 per cent of the calories are supplied by protein. The rationale of this change from a pure carbohydrate diet to a protein-carbohydrate diet is well founded, for it now seems likely that a great portion of the value received from the carbohydrate regimen used in the past was its ability to spare the protein in the body.

The patients with common duct obstruction frequently have such a reduction in appetite as to constitute a major problem in their pre-operative preparation. Here the feeding of vitamin B and lyophilized bile is helpful at times. In the occasional patient with severe liver injury and a poor appetite, it may even be advisable to pass a tube into the stomach or even into the jejunum and give forced feeding of partly digested protein and carbohydrates.

The most alarming complication in the jaundiced patient is hemorrhage. Before Quick began his studies on the prothrombin in these patients the surgeons were at a total loss to explain why one patient bled and another just as deeply jaundiced did not bleed. Studies of the bleeding and clotting time were of no avail. Now for the first time we apparently have a reliable method of determining the prognosis of the patient regarding the bleeding tendency.

The discovery of vitamin K by Dam and also Amquist has added a new and much needed chapter to the treatment of jaundice. It is now common practice to study the prothrombin of every patient so affected. Vitamin K in some form is fed to the patient

with ample bile salts (sodium desoxycholate) Vitamin K is a lipid and is not absorbed adequately from the intestinal tract in the absence of bile salts. The prothrombin values may be determined day to day so as to follow the improvement, which usually occurs rapidly. It can be anticipated that the prothrombin will fail to rise after such therapy only in patients with jaundice due to severe damage to the liver cell such as probably seldom occurs as the result of common duct obstruction alone. Although vitamin K is a recent addition to the surgeon's armamentarium, its value in the preoperative treatment of these patients is rapidly being established. Certainly the surgeon is no longer justified in operating upon a deeply jaundiced patient without a knowledge of the prothrombin value and the use of vitamin K if it is low.

Before the use of vitamin K the incidence of hemorrhage following operation remained about the same year in and year out. The mortality following these hemorrhages was materially reduced by repeated blood transfusions. Doubtless we shall find patients with severe liver damage who fail to respond to this type of therapy. We believe that such patients will be few. It may be possible to predict and experience may show that a failure to respond to vitamin K therapy will suggest that the jaundice is due to injury to the liver cell rather than to simple common duct obstruction thus eliminating surgery.

The prothrombin may be increased rapidly by blood transfusions. This doubtless accounts for the benefit derived from the multiple small transfusions as used for some years in these cases. Studies by Dr. John Rhoads at the University of Pennsylvania have shown that fresh blood should be used in these transfusions, as "bank blood" loses its prothrombin rapidly. It goes without saying that if the

surgeon is forced into operation upon a patient whose prothrombin does not rise following vitamin K therapy multiple small transfusions of fresh blood, as in the past, continue to be the treatment of choice.

Volatile anesthetics which are toxic to the liver cell should be avoided in the surgery of the jaundiced patient. Nitrous oxide and the barbiturates are also bad because of the anoxemia which frequently accompanies their administration. Ethylene and cyclopropane gases which may be given with a high percentage of oxygen are probably less objectionable although accurate control studies have not been made of these agents in the experimental laboratory. Local anesthesia is undoubtedly the anesthesia of choice from the standpoint of the liver. However it seldom affords sufficient relaxation to carry on the operation required. Its usefulness is definitely limited by the temperament and build of the patient and the temperament and skill of the surgeon. Spinal anesthesia conducted by a physician anesthetist should be considered the anesthesia of choice. It is indubitably an excellent anesthesia, its chief drawback, however being the anoxemia that is associated with the occasional drop in blood pressure. For the same reason surgical shock is to be avoided in these cases.

The postoperative care of the jaundiced patient is a continuation of the preoperative care plus the additional attention to the wound and biliary fistula if established.

It is highly important to continue the patient's nutrition in a usable form. The most acceptable method has been a continuous venoclysis of glucose solution until the patient can retain an adequate intake by mouth. Recent investigations in the experimental animal in the laboratory suggest that the amount of glucose that is usually given by venoclysis is not great enough to give the best

EDITORIALS

results. These experiments have attested to the value of passing a tube into the jejunum before operation so that forced feeding of a high carbohydrate protein may be administered for a few days before and after operation.

The continuation of the antihemorrhage therapy is imperative. Vitamin K should be given and bile salts must be given also since bile salts do not reappear in the bile for a considerable period of time after the release of common duct obstruction. Small transfusions of fresh blood should be given every 8 hours in the most severely jaundiced cases for 2 or 3 days. Vitamins other than K are now being added.

The use of a decompression apparatus in the drainage of the biliary tract may be useful. When only a first stage operation—a cholecystostomy—is done, the pressure in the biliary tract may be reduced gradually in the same manner as in decompression of the urinary tract. This may reduce the possibility of bleeding. When the obstruction has been removed the pressure in the biliary tract will depend upon the duodenal pressure, as for example in the cholecystoduodenostomy. When a T tube has been placed in the common duct the decompression apparatus is helpful

in forcing the bile into the duodenum, rather than allowing it all to escape externally.

If the patient loses a sufficient amount of bile externally there may be a profound biochemical disturbance which is not entirely understood. Unless this bile or its equivalent is given back to the patient he may develop a marked listlessness and sudden attacks of a shock-like state with a low blood pressure and cold sweats. Refeeding the bile in its entirety by a slow drip through a tube in the stomach is useful. Lyophilized human bile collected from previous patients and lyophilized pig's bile have recently been used very successfully.

The length of time the T tube should be left in the common duct varies somewhat according to circumstances. In the ordinary case of common duct stone we usually remove it on about the 14th day. The tube is clamped entirely for several days before its removal. In the case of a stricture for which a plastic operation has been done, the tube is left in place for months in an endeavor to minimize further scar contracture.

Space does not permit discussion of surgical procedures incident to the correction of the various types of obstruction which are producing the jaundice.

ELDRIDGE L. ELIAS

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

MEDICAL men of today surgeons in particular, have long been familiar with the saga of the Mayos—father and sons. To them it has always been an inspiring and stimulating story and they have recognized almost without exception the forceful impetus the Mayo Clinic has given to medical and surgical progress, and what a far-reaching and helpful part it has played in American life for the past 50 years. Even those who know the story best will be grateful for the opportunity to read the complete and well authenticated account of Alva Clapenette.

The most forceful appeal of this volume to the reviewer, is in the stimulus it affords and the example it upholds for the medical student of today. Combining Osher McCallum's *Halsted Watson's Life of Sir Robert Jones The Hero and Buggy Doctor*, Flexner's *William Henry Welch and Now The Doctors* if you are all comparatively recent volumes. They should be in the library of every medical school and hospital. The man with the divine spark burning brightly may not need to know what others before him have achieved, but most of us are not provided with self starters, and a few turns of the crank at the right time can sometimes accomplish wonders.

As to the story itself, it is well told and with not too much flourish and fancy writing. The opening chapters are a little tedious and the account of his toric facts, diligently sought out and verified, are too often elaborated with descriptive passages and generalizations that detract from the directness of the story. With the beginning of the Rochester period the story comes to life and from that moment almost every page except for the elucidation of surgical procedures, is interesting. Gradually one character emerges as the dominating personality that of Will Mayo and though the picture of Dr. Charlie, the lovable and understanding surgeon, the skillful technician, the much sought after "trouble shooter" is skillfully portrayed, it is Dr. Will who finally holds the center of the stage.

"Stress the tim and the opportunity said Dr. Will to his biographer. We were reared in medicine. There were three of us. All well and good but at the center of every effective effort in this world of ours, whether for good or evil, there is one individual who provides the divine fire that kindles and burns and, sometimes, tests a co-flagration. Such an individual was Dr. Will Mayo and in reading *The Doctors* if you cannot help but conclude that the outcome would have been the same whether his lot had fallen in Rochester in

Boston, or in London. His debt to others freely acknowledged, was great, but so is that of any other leader of men.

The most arresting incident of the volume is that briefly told on page 605, "I've just done my last operation." Take off the mantle, worn so long, voluntarily and gracefully to pass it on to younger men, and to bid them Godspeed and to do it without a sign of self-pity—in that act are all the elements of drama—heroism, renunciation, forgetfulness of self. Of men with the ideals and force of character of Dr. Will and Dr. Charlie the medical profession has every right to be proud.

The review in more detail of a book so interesting and stimulating is needless. Every medical student and every doctor will find in it interest, humor and inspiration and the young man in particular can recall Napoleon's words. Every French soldier carries in his knapsack the baton of the Marshal of France.

SCIENCE L. KOCK.

TOBIAS has turned out an excellent volume giving the essentials of dermatology. The material is up-to-date, is authentic for the day and is presented in a clear, succinct manner. The book pretends to no more than brief treatise so that it does not contain references to pertinent literature, etiological notes, or statistical facts. The volume is sparsely illustrated, but the illustrations that are shown are well chosen and are all in black and white. The basic principles of diagnosis and treatment are adequately considered and there is included even definitions of the more rare dermatoses. The book should prove to be very useful to the student and the practitioner as all of the common cutaneous diseases are treated quite adequately although the text is brief. The one criticism that I would make is the paucity of photographs. Those that are included are excellent but I believe the book would have a great deal more merit with a few more photographs of the commoner skin diseases. This criticism is negligible in relation to the book as a whole. It deserves fine reception for it is one of the best of the smaller introductions.

EDWARD A. CURTIS

THE lectures of Lawson Brown on the history of tuberculosis are an important part of the courses in the Trudeau School of Tuberculosis. They have been perpetuated in a volume entitled *The Story of Consumptive Pulmonary Tuberculosis*, which contains the lectures posthumously edited by Mrs. Maryville of Des Moines. By Marjorie Taylor, M.D. Philadelphia, London, Montreal: Lippincott Co., 1941. 272 pages. Price \$2.50. The volume is a valuable contribution to the history of tuberculosis. It is a well written and interesting book. It is a must for every student of tuberculosis. It is a must for every student of the history of medicine. It is a must for every student of the history of the human mind.

(THE DOCTORS MAYO. By Alva Clapenette. Minneapolis: The University of Minnesota Press, 1941.

Brown With the exception of the chapter on x-ray by Homer L. Sampson and that on chest surgery by Edward W. Archibald, the material is essentially in the inimitable manner of Dr. Brown. The 381 pages present an intensely interesting parade of the historical background of the refinements in chest examination and the study of tuberculosis.

The delightful narrative style makes the book a pleasure to read. It is a source book of early history in which the author has gleaned the facts from a lifetime of reading. The bibliography is quite complete and representative. The volume is well indexed both by subject and author titles. This is a good practical volume and should be in the library of anyone interested in clinical tuberculosis or the history of medicine.

E. L. WALSH

IT is with great satisfaction that the reviewer studies a new text on endocrinology. Grollman's *Essentials of Endocrinology*¹ is a moderate sized single volume compilation written for the medical student or anyone wishing to get a general scientific grasp of the endocrine field. Other works on this subject have suffered from specialization upon one gland or, on the contrary, because the author has presented a diffuse clinical picture with excessive therapeutic claims. The present volume is a complete scientific epitome of present endocrine knowledge. There are some passages and some conditions in the work that can be criticized, there are occasions when contradictions seem to be presented, for instance, in the discussion of "dwarfism due to pituitary insufficiency" it is emphasized that the appearance is one of "precocious senility," but in the illustration of a typical case of pituitary dwarfism the "juvenile appearance" is pointed out. On the whole, the discussion is brief and precise, description of syndromes is necessarily abbreviated, physiology and pathology are accurately stated and therapy is presented in a conservative manner but with encouragement when warranted.

PAUL STARR

THE monograph on *Orbital Tumors*² by Dandy consists principally of a review of the histories of 25 patients with operable and 7 with nonoperable tumors of the orbit, all verified microscopically. These tumors included fibromas, osteomas, meningiomas, sarcomas, carcinomas, gliomas, osteomatous cysts, Schueller Christians's disease, and inflammatory masses. Hyperostosing meningiomas were present in greatest number (9), and Schueller Christians's disease was second in numerical prominence (5). An account of the patient's complaints and neurological signs, the operative note, and a brief histological discussion accompany the presentation of each case history.

The operative approach was in most instances a modification of that used by most neurological surgeons in their attack upon orbital tumors. Dandy

uses a "concealed skin incision" to effect a trans-frontal osteoplastic flap, placed somewhat laterally in the frontal region. The advantages of the transcranial approach over the Kroenlein and other external orbital approaches is pointed out, and the accessibility of the orbital contents and the possibility for complete removal of the tumor without incidental damage to orbital nerves, vessels, and muscles is attested to by the improvement in the patients and the nonrecurrence of the tumors after the patients had been followed for many years by the author.

The outstanding feature of the book is unquestionably its fine illustrations. They alone could tell the story. The artist's sketches of the tumors *in situ* as well as the operative sketches are excellent. The photographs of the patients before and after operation, of the tumor specimens both gross and microscopic, and of the x-ray pictures of the skull indicate how long, carefully, and patiently the author collected his illustrative material. Several of the case histories are made spectacular by the illustrations alone.

JOHN MARTIN

A SYMPOSIUM delivered at Vanderbilt University in April, 1941 has been published as *Infantile Paralysis*³ by the National Foundation for Infantile Paralysis, Inc. The purpose of the meeting as set forth in the preface was to inform the medical profession and the public the "extent of advance and the limitations of the contributions of science to the solution of the manifold and intricate problems of poliomyelitis."

The book is written in sections by six contributors. "History of Poliomyelitis up to the Present Time" by Paul F. Clark, Ph.D., "The Etiology of Poliomyelitis" by Charles Armstrong, M.D., "Immunological and Serological Phenomena in Poliomyelitis" by Thomas M. Rivers, M.D., "The Pathology and Pathogenesis of Poliomyelitis" by Ernest W. Goodpasture, M.D., "The Epidemiology of Poliomyelitis" by John R. Paul, M.D., "The Treatment and Rehabilitation of the Poliomyelitis Patient" by Frank R. Ober, M.D.

The literature is comprehensively reviewed, but the authors do not clarify the issues so that one unversed in virus diseases can obtain a clear picture. The result is the impression that nearly all claims for progress in the study of poliomyelitis have been refuted. Such, of course, is not the fact. Here and there is an island of crystallized thought, but too often the few truths about poliomyelitis are lost in the discussion. The consensus of the authors is that the research has reached a plateau, that, despite much effort, nothing new has been discovered for some time, and that we must develop new methods of investigation.

As a review intended for the general practitioner, the book does not fulfill its purpose. There is too

¹ESSENTIALS OF ENDOCRINOLOGY. By Arthur Grollman. Ph.D., M.D. Philadelphia: London: Montreal: J. B. Lippincott Co. 1941.
²ORBITAL TUMORS, RESULTS FOLLOWING THE TRANSCRANIAL OPERATIVE ATTACK. By Walter E. Dandy. New York: Oskar Pfister. 1941.

³INFANTILE PARALYSIS. A SYMPOSIUM DELIVERED AT VANDERBILT UNIVERSITY IN APRIL, 1941. New York: The National Foundation for Infantile Paralysis, Inc. 1941.

body mechanics in the treatment of chronic arthritis as well as in prophylaxis, particularly in the hypertrophic type, is emphasized. The treatment requires understanding of these chronic conditions, it requires patience and time, but it offers help to individuals who are otherwise neglected and permitted to suffer, with the consequent advancement of the illness and increased loss of function.

Nothing is said of the cause of poor posture. Poor posture is apparently assumed to be primary. The results obtained by the authors are in accord with the conception that poor posture is secondary to the functional decompensation, that the altered posture itself then is a factor in decreasing functional capacity. Correction of the deformity will improve functional capacity, and removal of strain as well as increase of strength will re-establish normal function with relief of symptoms. The value of vitamins and minerals is granted in certain cases, as well as the diet to diminish excess weight and thus decrease the load. The importance of good foot statics for body mechanics is stressed, but the authors advise the use of supports as a means of treatment instead of correction of the altered position and re-establishment by means of normal functional exercise, namely, correct gait.

The application of the concepts brought forth is practical as is demonstrated by the case reports which show what can be accomplished by the use of treatment for impaired body posture in chronic cases. The importance of good body mechanics in the maintenance of physical fitness and health is emphasized.

This is a basic book for the orthopedic surgeon and is recommended to physical therapists, physical education teachers, public health physicians and nurses, and to internists, especially those interested in chronic diseases.

EMIL D W HAUSER

THE development and experiences in England of the Health of Munition Workers Committee from its inception in 1915 through to the establishment of the Industrial Health Research Board is traced in Vernon's *The Health and Efficiency of Munition Workers*.¹ It depicts a prolonged, intensive study of the complexities of the human element in industry. As such, experiences in hours of work, rest periods, night shifts, sickness and absenteeism, accidents, fatigue, ventilation, heating, lighting, welfare problems, and their relationship to employee efficiency are related. These problems are considered in the light of data accumulated in World War I, peacetime in private industry, and the experiences of today.

The book is of great interest to those of industrial management interested in industrial relations, employee welfare and safety education. As a reference work in a library of industrial medicine it is of value,

¹THE HEALTH AND EFFICIENCY OF MUNITION WORKERS. By H M Vernon. M.A. M.D. London: Humphrey Milford (Oxford University Press) 1940.

to one, however, just casually interested in industrial practice, it is only of limited interest.

E L WALSH

THE contents of Bancroft's *Operative Surgery*² deal with the surgical treatment of abdominal diseases and, with the exception of the section on spleen, do not deal with etiology, pathology, or diagnosis. Comprising 20 sections by as many widely known contributors, the work represents a distinctive departure from previous similar works, because of the uniformly splendid character of each section and because a complete treatise on the operative surgery of the abdomen is contained within one volume.

Section I concerns anesthesia, preanesthesia, drugs, inhalation, rectal, spinal and regional anesthesia. Section II concerns preoperative and postoperative treatment and is an extraordinarily fine and complete exposition of fluid balance, chemistry, shock, vitamin therapy in abdominal surgery, and hypoproteinemia. Section III covers blood transfusion. Section IV about the general principles of surgical technique, skin preparation, sutures, hemostasis, etc., attracted the attention of the reviewer because it is fascinating reading. There follow sections on the mouth, including neck dissections, a section on abdominal incisions, in which there is an interesting exposition of and argument for the transverse as opposed to the longitudinal incision. The remaining sections are exclusively about abdominal conditions and in the following order include peritonitis, gastroscopy, stomach and duodenum, jejunal ulcer, small bowel, appendicitis, colon and rectum, anus, bile tracts, liver, pancreas, spleen, and diet in postoperative abdominal conditions.

Avoiding vague generalities of praise, certain specific comments should be made. Practically all operative procedures suggested throughout all sections conform to the generally accepted ideas thereon. The chapters relative to peritonitis, stomach, duodenum, appendicitis, small bowel obstruction, colon, bile tracts, and spleen are worthy of special mention in this respect. The once common practice in such volumes of including much obsolete material for completeness, often to the confusion of the younger surgeon, is lacking. The illustrations, for the most part line drawings, are excellent. The subject matter is presented in a most interesting fashion. The book represents a valuable contribution as a compact reference work on abdominal surgery.

J R BUCHRINDER

IN a well written monograph³ of 257 pages Spink presents in a clear, concise manner the use of the sulfonamides in the practice of medicine and surgery.

²OPERATIVE SURGERY INCLUDING ANESTHESIA, PRE AND POST-OPERATIVE TREATMENT, PRINCIPLES OF SURGICAL TECHNIQUE, BLOOD TRANSFUSION AND ABDOMINAL SURGERY. Edited by Frederick W Bancroft. A.B. M.D. F.A.C.S. New York and London: D Appleton Century Co. Inc. 1941.

³SULFANILAMIDE AND RELATED COMPOUNDS IN GENERAL PRACTICE. By Wesley W Spink. M.D. Chicago: The Year Book Publishers Inc. 1941.

an excellent chance of being labeled endothelioma, and in no case has the origin of a tumor from endothelium been proved.

Furthermore much confusion has arisen because of the uncertainty concerning what should be called endothelium. According to Maximow and Bloom, the term should be reserved for the single layer of squamous cells which line the inner surface of the walls of the blood and lymph vessels and of the heart. MacCallum believed that only the lining cells of the blood and lymph vessels can be accepted as endothelium and stated that a few true endothelial tumors have been described which appear to arise from endothelium of blood vessels. Borst, on the other hand interpreted the term very broadly and accepted the endothelial origin of a wide variety of tumors whose exact nature has not been determined. Ewing (16) while admitting deficiencies of our present knowledge stated that his own experience inclined him to pursue a similar course.

It is evident, however from an analysis of the recent literature that many pathologists today agree that the term endothelioma has had too wide an application. In their opinion the term should be restricted to tumors arising from blood and lymphatic vessels and having vasoformative characteristics. The basis for this interpretation can best be understood in the light of the modern embryological conception of the origin and development of endothelium and of the vascular system.

EMBRYOLOGY

Endothelium arises from embryonic connective tissue, the mesenchyme which is a derivative of mesoderm. Other derivatives of mesoderm similar to endothelium are *mesothelium* which forms the lining of serous surfaces (pleura, etc.) and *mesenchymal epithelium* which gives rise to the lining of the meninges (49). These tissues, while similar in structure have very different developmental potentialities. In the early embryonic development endothelium arises through the flattening of undifferentiated mesenchymal cells but in the adult it is a highly differentiated tissue which grows only through proliferation of its own elements. Blood vessels and blood cells arise from the primitive endothelial cells shortly

after the formation of the germ layer probably coincidentally and successively at many foci in the embryo (theory of local origin). Blood vessels form by liquefaction, vacuolation, and flattening of the primitive endothelial cells. The vessels grow by proliferation of the endothelial cells and a process of budding or sprouting takes place. The vascular endothelium loses its blood forming power early and is transformed into the highly differentiated vascular endothelium of the adult organism. Lymph vessels also are of endothelial origin probably arising from mesenchyme independently of blood vessels (51).

Maximow and Bloom make the significant statement that in the adult form it is often impossible to differentiate squamous cells of mesenchymal origin (endothelium) and those of ectodermal or entodermal origin. Adult cells similar in structure and arrangement may have a totally different embryonic origin and quite different developmental potentialities. For this reason attempts to identify and classify neoplasms of the so called endothelial group have proved difficult and controversial. Only by careful consideration of these embryological factors and by a thorough study of the histogenesis as well as the morphology is it possible to diagnose accurately these tumors of endothelial origin.

HISTOGENESIS

Since vascular tumors vary greatly in their growth and development, interpretation of their histogenesis is difficult and confusing. Many excellent reports on the histogenesis of vascular tumors are found in journals devoted to dermatology and pathology. The authors, while not entirely in accord in their interpretations and conclusions, give detailed discussions of the histological and developmental variations in these complex tumors, emphasizing the importance of origin and development in their classification.

An analysis of these studies indicates that, on the one hand there occurs a typical benign angioma of the cavernous or capillary type which is a highly differentiated structure composed of fully developed adult blood vessels. This tumor grows slowly with little evidence of cellular activity. On the other hand, there

is a rapidly growing, invasive, metastasizing tumor consisting of angioblastic tissue which is embryonic in type and very cellular. It has little structural differentiation and is definitely malignant. Between these two extremes there are tumors with varying degrees of cellular activity and differentiation, some of which may become malignant clinically, although they appear relatively benign histologically.

Simple benign angioma is a tumor composed essentially of blood vessels which grow independently and have no intimate anastomotic connection with the circulation of the part. It must be differentiated from hypertrophic granulation tissue which follows inflammation and from mere vascular dilatation seen in chronic varicosities. Benign angiomas are congenital tumors, tracing their origin to the first anlage of the vascular system in early embryonic life (63). Some writers include them in the class of congenital malformations due to developmental errors or fetal displacements without power of proliferation, such as the "hamartoma" of Albrecht. Jaffe stated, "This tumor is a hamartoma with a tendency to continuous growth." Reid in a report on arteriovenous communications expressed the opinion that many angiomas represent congenital abnormal communications between the smaller arteries and veins. However, most agree with Ribbert that angioma, though congenital in origin, is a true neoplasm which grows independently from its own vascular substance and may invade surrounding structures.

The origin and growth of benign angiomas have been studied and analyzed by many authors. Their growth resembles very closely the development of vascular tissue from primitive vasoformative cells (vascular endothelium) in the embryo. The lining cells of the tumor capillaries proliferate and extend as buds or processes, probably from multiple foci, into neighboring tissue. The tumor cells become vacuolated. The vacuoles of adjacent cells coalesce to form irregular spaces which later contain blood. In many tumors these spaces remain more or less irregular in shape (cavernous angioma), in others the lining cells become arranged as a definite endothelium and practically normal capillaries are formed (capillary angioma).

It is well known that benign angiomas often undergo spontaneous regression or healing. Thrombosis of the blood spaces occurs, followed by organization and even calcification, as indicated by the presence of phleboliths. Capillary angiomas that grow very slowly may contain vessels of adult character in which the endothelial spaces are surrounded by smooth muscle and fibrous tissue, an organoid variety of angioma (24). Such tumors offer little difficulty for recognition and classification. When the cellular activity, however, becomes such that the open spaces give way to solid masses of compact endothelium-like tissue, interpretation and classification become difficult and controversial. Invasion of adjacent tissue, local recurrence, and metastasis further complicate the picture.

A group of angiomas has been described which appears benign histologically but which behaves clinically in a manner suggestive of a malignant growth as indicated by local invasion and destruction, recurrence after surgical removal, and metastasis to distant organs. This tumor has been variously designated as benign metastasizing angioma (6), multiple mesenchymal hemendothelioma (61), malignant mesenchymal angioma (39). It presents a manifold histological appearance with transitional stages, varying between undifferentiated mesenchymal tissue and mature adult blood vessels.

There is considerable controversy in the literature concerning whether or not these apparently malignant growths can actually develop from the more benign forms, and whether the presence of multiple tumors actually represents metastases. Many authorities report cases in which metastasis occurred. Jaffe, on the other hand, doubts the existence of benign metastasizing angioma and believes that these cases of multiple tumors do not represent true metastases. It is his opinion that they arise coincidentally and independently of each other from multiple congenital foci.

There is much evidence to indicate that in the malignant angiomas there is a tendency for the undifferentiated mesenchyme to form other structures of mesenchymal origin, differing from true endothelium. It may form connective tissue with a structure suggesting

sarcoma, or an epithelium-like structure with alveolar formation suggesting carcinoma. Such a process offers a logical explanation for the development of the "angioendothelioma" of bone, described by Kolodny which is an epithelium-like tumor closely resembling metastatic carcinoma or hypernephroma, and which will be discussed in more detail.

To summarize vascular tumors are mesenchymal in origin probably growing from congenital rests by a process of endothelial proliferation and differentiation into blood vessels. They are usually benign and may undergo regression and healing. True malignant angiomas exist, however characterized by rapid growth, invasion of surrounding tissues, and metastasis. Such tumors in their histogenesis tend to revert to the original primitive mesenchymal tissue producing a varied histological picture differing greatly from that of the benign, well differentiated form. They may possess morphological characteristics of either epithelial tissue (carcinoma) or mesodermal tissue (sarcoma). There is one essential feature, however which persists throughout the process no matter how varied or bizarre it may be, the recognition of which is essential for the diagnosis and differentiation of tumors of vascular origin. *An angioblastic tendency as evidenced by a vasoformative process of endothelial proliferation and the formation of new blood vessels must be present.*

CLASSIFICATION

It is evident from the foregoing description that the complex and varied histogenic and morphological picture presented by these tumors makes their classification and terminology difficult, confusing, and controversial. It is well known that the classification and nomenclature of any neoplasm has been a difficult problem, and in no other group has this been more evident than with endotheliomas. As a result, many methods and systems of classification have been advocated some of them are inadequate and others too complex and confusing. Restricting the term endothelioma to tumors of vascular origin with a definite recognizable vasoformative tendency simplifies the problem to a considerable degree however

Most pathologists classify tumors according to the predominant cell, considering both its structure and its embryonic origin. Mallory stated that the type cell is the one important element in every tumor. Ewing (16) discussed the problem as follows: "The generally accepted plan of classification and terminology which is based on histology modified as much as possible by histogenesis, is a natural product which has become very firmly established and probably deserves to prevail against the varying prominence of embryology, chemistry and etiology."

MacCarty proposed a terminology based on a biological conception of neoplasm, which emphasizes structure, cellular differentiation, and the significance of the reserve cells. Pulford applied this conception to the differentiation of endothelioma, and suggested that the embryonic connective tissue cell (mesenchyme) is the reserve cell of the endothelium. He divided endothelial tumors into three distinct groups: angiomas, angioendotheliomas, and endotheliomas. He considered angioendotheliomas as a connecting link between the benign angiomas and the malignant endotheliomas, and reported a case in which the change from the benign to the malignant in different stages was shown. All three groups were characterized by differentiation into blood vessels.

Fraser classified vascular tumors into compact, capillary, and cavernous types, the compact representing the more cellular or malignant stage. Kettle and Roes suggested a somewhat similar division but pointed out that certain atypical forms occur in which the endothelial cell loses its characteristic features and reverts to an embryonic form, growing as a spindle cell (connective tissue) or it may develop into a flattened pavement cell with alveolar arrangement (epithelium). Busman noted a similar tendency and considered the term endothelioma to represent a compromise between what is histogenically a sarcoma but morphologically a carcinoma. Klinge divided vascular tumors into congenital hamartomas, and genuine vascular tumors which are true neoplasms derived from the mesenchyme. He further subdivided the second group into tumors still showing the mesenchymal tissue

characteristics, which he called malignant mesenchymal angioma, and tumors which arise from the products of the differentiation of the mesenchyme, namely, the true angiomas, and the angioendotheliomas. This problem of terminology and classification of vascular tumors has also been discussed by Geschickter and Keasbey, 24, Rintelen, Rabsom, and Watson and McCarthy.

There is considerable confusion and vagueness in the use of the terms angioendothelioma and angiosarcoma which have been loosely applied to various types of malignant tumors of extreme vascularity. The problem is complicated by the fact that in certain neoplasms there is an excessive development of blood vessels as a result of venous stasis or nutritional demands. These are not true vascular tumors, although their vascularity has been indicated by the term "angiomatous" (16). Many of the earlier reports of malignant angiomas are tumors of this type. Ribbert stated that malignant angioma (angiosarcoma) and angioendothelioma are difficult to differentiate, and that malignant angiomas may very well be called angioendothelioma because in both there is proliferating endothelium which produces vascular channels and invades surrounding structures. Winkler considered angiosarcoma, endothelioma, perithelioma, and angioendothelioma, and sarcoma of vascular tissue as synonymous terms. Borst suggested the term angioblastic sarcoma or malignant angioblastoma as indicating a malignant tumor in which the characteristics of the normal vascular tissue are more or less apparent, although distorted and atypical. Ewing (16) stated that the present tendency is to limit the term angiosarcoma to cellular angiomas in which the unit is the vessel and not the endothelial cell. He reserved the term angioendothelioma for vascular tumors in which the endothelial cell predominates. In discussing the malignancy of vascular tumors, Geschickter and Keasbey (24) stated, "The pathologic conception of malignant tumors of blood vessels (endotheliomas) has been constantly narrowed. Many of the lesions formerly described as hemangioendotheliomas, peritheliomas, cylindroma, and perithelial angiosarcoma may be reclassified as metastatic lesions

of the thyroid or kidney, or as secondary deposits from nonpigmented malignant melanomas."

It is suggested from this study that a simple and workable classification is one which considers vascular tumors as endotheliomas accompanied by a definite vasoformative tendency with endothelial proliferation and new blood vessel formation. These tumors may be classified as (1) benign angioma, a slow growing, highly differentiated tumor, congenital in origin, with definite well formed blood vessels and an innate tendency to regress and heal, and (2) malignant angioma, a more cellular and compact growth with active endothelial proliferation and invasiveness, showing a tendency to revert to its primitive mesenchymal structure. In certain cases of malignant angioma it is possible to differentiate two subdivisions, namely the *angioendothelioma* and the *angiosarcoma*. The angioendothelioma shows a rather marked cellular proliferation, and in its tendency to revert to a primitive mesenchymal structure the cells assume a cuboidal appearance and alveolar arrangement closely resembling epithelial tissue. Nevertheless, new blood vessel formation is evident. In angiosarcoma the vasoformative tendency is much more prominent. This new vessel formation is the predominant feature of the tumor, and enables it to be more easily identified as a true vascular tumor.

These terms are rather indefinite and ill defined, tending to merge one into the other. Structures suggesting both types may be found in different areas of the same tumor, and the terms are frequently used synonymously. Certain clinical features as well as the histogenesis and morphology must be considered in the final analysis. The special clinical and pathological features which apply in the identification and classification of vascular tumors occurring in bone will be considered later.

VASCULAR TUMORS OF BONE

Primary vascular tumors of bone are not common but probably occur more frequently than reported cases indicate. In the benign forms they are slow growing or regressive, and because they are symptomless, they may be unrecognized. In the more malignant types

they present such a varied clinical course and pathologic appearance that they are often incorrectly diagnosed. On the other hand many tumors of bone have previously been included in this group which in the light of further analysis do not belong there.

REVIEW OF LITERATURE

Very few thorough, comprehensive studies of the pathological and clinical features of vascular tumors occurring in bone have been reported in the literature. Most contributions have been case reports or have dealt only with certain special features of these tumors such as the roentgenographic considerations. Many of the older studies are of little value as the majority of the cases reported were highly vascular tumors of various types other than true angiomata.

Hitzrot in 1917 reported a case of cavernous hemangioma of the upper end of the humerus and included the first roentgenograms published on this tumor. He reviewed the literature to 1917. In 1930 Bucy and Capp (10) gave an excellent report on primary angioma of bone with special reference to roentgenographic diagnosis. They reviewed all reported cases to date and added 8 cases, 6 of which were from the Registry of Bone Sarcoma of the American College of Surgeons. Geschickter and Massenz (27) in 1938 again brought the literature up to date and included 4 additional cases.

Cases of angioma of vertebrae with clinical symptoms have been reported with increasing frequency in recent years. Many have been diagnosed before operation by the characteristic roentgenographic appearance. Topfer in 1928 found angioma of the vertebrae in 257 cases of 2,154 postmortem examinations of the vertebral column, 11.9 per cent. None of the lesions found at autopsy had apparently produced clinical symptoms.

Many cases of angioendothelioma are described in the literature, some of which are included under the term endothelioma. Endothelioma of bone was probably first described by Lucke in 1866. Marchwald in 1895 reported a rather remarkable case of multiple intravascular endothelioma in most of the bones of the skeleton. Howard and Crile in

1905 analyzed 19 previously reported cases and added 4 of their own. Many more cases of single and multiple endotheliomas of bone have been reported but no effort has been made to enumerate all of them here. Hirsch and Ryerson in 1926 gave a complete list of all reported cases. After a critical analysis of these cases they concluded that in many of them doubt exists regarding the thoroughness and completeness of the postmortem examination. In their opinion many of the tumors reported as endotheliomas were no doubt metastatic carcinoma from primary lesions not found at autopsy.

Kolodny in 1926 reported 2 cases from the Registry of Bone Sarcoma (Cases No. 154 and 291). He discussed the features in detail and defended the use of the term angioendothelioma of bone as a distinct clinical and pathological entity. Since Kolodny's contribution, cases have been reported by Pritchard (1931), Barry (1932), Warner and Slingleton (1933), Brailsford (1934) and Lutz and Pusch (1939). Some of these cases are registered with the Registry of Bone Sarcoma and are included in this study (B.S.R. Nos. 154, 291, 1040, 2156).

True angiosarcoma of bone is probably a rare tumor as only a few cases have been reported in the literature. There is much confusion concerning the use of the term, and many of the earlier cases were no doubt vascular sarcomas and not true malignant angiomata. Freilich and Coe in 1936 published a case of angiosarcoma of the scapula and reviewed all cases previously included in the literature. In addition to their own they listed 3 cases involving bone: one of the ribs (70), one of the femur (67) and one of the clavicle (48). Pulvertaft in 1938 reported a malignant vascular tumor of the sacrum which he called a hemangioblastoma, classifying it with Kolodny's angioendothelioma of bone. The photomicrographs accompanying the report show a degree of blood vessel proliferation more characteristic of angiosarcoma. Delitch in 1939 described a case of primary angioma of the tarsal and metatarsal bones with sarcomatous degeneration. The histological description and drawings strongly suggest that this case can be classified as an angiosarcoma. There is also a case of angiosarcoma of the os calcis reported

Clinical symptoms The clinical signs manifested by benign angioma of bone are variable and not pathognomonic. Many tumors are symptomless or produce symptoms secondarily by pressure and growth. In the vertebrae the tumor often produces pressure on the cord with neurological signs of varying degree. Vertebral angiomas associated with epidural angioma have been reported occasionally.

Roentgenographic appearance. Perman, Bucy and Capp (10) Geschickter (23, 27) and Nemenov have called attention to certain signs appearing in the roentgenograms that are more or less characteristic and aid in the diagnosis of benign angioma. In the vertebrae the picture is characteristic and even diagnostic. There is an irregular absorption of bony trabeculae and a thickening of the remaining vertical trabeculae with resulting parallel vertical striations and loss of the normal homogeneous structure. Not uncommonly these trabeculations extend into the vertebral arches (Fig 1 a).

Involvement of the flat bones often presents a characteristic sunburst appearance in the roentgenograms (plexiform angioma). Bony trabeculations radiate from a common center usually at right angles to the plane of the bone. Cases presenting this appearance have been reported by Anspach, and Kaplan and Kanzer. Four such cases are included in this series (Fig 2 a).

The roentgenographic appearance of angioma of long bones has been described as the unique soap bubble effect. There are coarsely multifoculated areas of rarefaction which expand the shell of bone to paper like thinness, giving a cystic appearance resembling giant cell tumor. In angioma, however the loculations are somewhat smaller and within them there is a fine fibrillary framework. The cortex usually is not expanded as in giant cell tumor or bone cyst (Fig 3 a).

These roentgenographic effects are determined largely by the bone involved and rapidity of the growth of the tumor. However the roentgenogram is not always characteristic or diagnostic.

Pathological findings Bucy (9) described the histological structure of benign angioma of bone in considerable detail. With the ex-

ception of one case in this series the tumors are cavernous in type composed of large endothelium lined spaces filled with blood (Figs. 1 b 2 b). The remaining case can be classified as a capillary angioma (Case No. 849). In none of the cases is there evidence of unusual endothelial proliferation, and mitotic figures are not found. The stroma is loose fibrous connective tissue and is variable in amount. Bone destruction takes place as the result of reaction to growth and not to invasion by the tumor mass. Calcification is present in one case (B.S.R. No. 1882).

Treatment and results The majority of cases in this series have been treated quite successfully by irradiation or operation or by both. Wherever possible, as in the cranium or bones of the extremities, resection or curettage and cauterization have proved satisfactory. The danger of severe hemorrhage from operation must be considered, especially in operations on the cranium and spine. In one case (B.S.R. No. 662) death occurred as a result of shock and hemorrhage following removal of the growth in the cranium.

Karshner and associates attributed the high mortality in laminectomy to overenthusiastic surgical efforts. They warned against opening the dura or attempting to remove more of the tumor mass than is necessary to relieve pressure. They also pointed out that although high voltage roentgen ray therapy is recommended as a postoperative measure, it would seem inadequate and hazardous to use it alone when there is compression myelitis. Irreparable damage to the cord may occur before any beneficial effect can be anticipated.

Meyerding found angioma of bone to be somewhat radiosensitive and under moderate dosage, repeated at regular intervals for a number of months, it gradually regresses until healed. In several of the cases reported by Geschickter and Copeland (23) cures were obtained by curettage followed by chemical or thermal cauterization. With these methods of treatment the prognosis is excellent, and amputation should rarely be necessary.

MALIGNANT ANGIOMA (TABLE II)

The histological variations evident in a study of malignant angiomas suggest that

Fig 1 a, Benign angioma of the second lumbar vertebra. The vertical striation is diagnostic. b, Cavernous

angioma of vertebra (B S R No 940). The blood filled channels between the bone trabeculae are very large.

they might be divided, as previously stated, into two groups, the angioendothelioma and the angiosarcoma. It must be appreciated that such a division cannot be too rigidly applied. It is very difficult or occasionally even impossible to determine into which of the two groups some of the cases should be placed. This difficulty is evidenced by the wide difference of opinions expressed by the pathologists who examined these cases for the Registry of Bone Sarcoma. Because of these difficulties in classification, all angioblastic tumors in this group are tabulated under the general heading of malignant angioma. Wherever possible, an attempt is made to indicate whether or not the tumor is considered an angioendothelioma or an angiosarcoma (Table II).

There are 15 cases in this group of malignant angioma. The sexes are almost equally represented, 7 females and 8 males. The age limits are younger than in the benign angiomas, ranging from 3 to 53 years, the majority being in the second and third decades. The long bones are the most frequently involved, although in 3 cases the tumor is primary in the bones of the hands and feet, and in 1 instance in the ileum. Multiple lesions are present in 6 cases, the multiplicity being a part of a widespread metastasis in 3. It is impossible, therefore, to ascertain accurately which is the primary lesion in some of these multiple cases.

Amputation was performed in 9 cases with apparent cure in 4, and 1 has been too recent to express an opinion. Exploration and cu-

Fig 2 a, Benign angioma of scapula (B S R No 941). The "sunburst" appearance is diagnostic. b, The large

endothelial lined venous sinuses lie between bone trabeculae. Amount of connective tissue framework is small.

retreatment were carried out in one case with no recurrence after 10 years. Ten patients were treated by radiation, death occurring in 6. In the 4 surviving patients treated by radiation amputation was done in all 4. In 1 case an apparent cure was brought about in the primary lesion but the tumor recurred in an adjoining bone 5 years later and amputation was necessary.

Death following metastases to viscera and other bones occurred in 8 cases. In 1 case death resulted from intercurrent disease 6 months after amputation.

Angioendothelioma Kolodny stated that most pathologists hesitate to admit that an angioendothelioma of bone is a pathological entity. He pointed out the reasons why this tumor should be considered an entity and

defined the term as "a malignant tumor of the vascular system of bone with a typical microscopic structure and a definite origin from the endothelial lining of the vessel wall. However, be stressed that in every case of suspected angioendothelioma, the possibility of a metastatic origin must be considered and eliminated."

The histological appearance of these tumors as described by Kolodny resembles an adenomatous growth with the tumor cells arranged in alveoli and tubules. The tumor cells are large polyhedral, or sometimes cylindrical in shape with well defined cell membrane and pale vascular nuclei and minute nucleoli. The alveoli have a lumen sometimes filled with blood.

Hirsch and Ryerson, in a study of bone metastases from primary carcinoma of the lung

reviewed the problem of so called multiple endotheliomas of bones. They were inclined to cast doubt on the correctness of many such reported cases. In their opinion the assumption of multiple primary foci in bone as an explanation of coincident tumors in various parts of the skeleton seems to be due to the failure of finding a small primary carcinoma on postmortem examination or to inability to distinguish the primary group from the secondary in the presence of many tumors in different tissues. As a solution to the problem, they urged careful and thorough postmortem examination supplemented by a thoughtful interpretation of the changes thereby demonstrated.

Geschickter and Copeland (23) did not mention angioendothelioma of bone as a clinical entity in their monograph of bone tumors. Furthermore Geschickter and Masseritz (26) in a study of Irving's tumor stated that in the

series they did not see a case of bone tumor in which the diagnosis of angioendothelioma was justified. They said it is readily understood how metastatic hypernephroma, anaplastic and mucoid forms of carcinoma, and angiosarcoma can possibly be diagnosed as angioendothelioma. Yet, in the discussion of a case of angioendothelioma reported by Lutz and Pusch in 1939, Geschickter (22) made this significant statement:

"A few years ago it would have been embarrassing to open this discussion because I was convinced there wasn't any such thing in bone as angioendothelioma, but today we have to admit that all forms of pathologic involvement of the bone of a neoplastic character have not been described. The only objection to the term endothelioma is that it is so widely misused. My conception is that these tumors arise from primitive mesoderm around joints and may be found in bone. They are not metastatic, they are moderately radiosensitive but not radio-curable and these patients should have the benefit of radical surgery."

Fig. 4. a, Angioendothelioma of humerus (B.S.R. No. 50). A large cyst-like expansion of the shaft with numerous thin lary trabeculations and thickening of the cortex is evident. b, Gross specimen split longitudinally.

The pale tissue composing the bulk of the tumor is necrotic. The large clear cells with eccentric nuclei are arranged in sheets, some of which are heavily filled with blood.

The loose manner in which the term angioendothelioma has been used by some authorities only adds to the confusion of identifying this controversial tumor. Some use it simply as a descriptive term indicating a certain histological structure, with others it designates a definite pathological and clinical entity. Connor for example employs the term to describe an unusually vascular type of diffuse endothelioma (Ewing's tumor). Kolodny on the other hand indicates a definite clinical entity quite different from Ewing's tumor. Many pathologists today do not accept Ewing's tumor as a true endothelioma of vascular origin but believe it to be a neoplasm originating from the reticulum or the lymphoid cells. Ewing (6, 7) on the other hand, recognizes a definite angio-blastic tendency in this tumor and considers it to be a form of capillary angiosarcoma or endothelioma arising from the blood vessels of bone marrow. He classifies Ewing's tumor therefore as a form of malignant angioma. He reserves the term angioendothelioma to designate a more vascular type of endothelioma, which he describes as a solitary cystic tumor usually developing in the ends or shafts of the long bones. The tumor presents large cuboidal or cylindrical cells arranged in

cords or pseudoalveoli and enclosing freely circulating blood. The cells are large with clear cytoplasm, sharp cell membrane and small nucleus. He further states that a similar structure may be seen in liposarcoma or in metastatic carcinoma of kidney or adrenal which tumors must be excluded before the diagnosis of angioendothelioma can be established.

Rost wrote at length on the histological differentiation between primary bone endothelioma and hypernephroma. He believed that the two can be distinguished by a purely morphological analysis, emphasizing the importance of the relationship of the tumor cells to the surrounding connective tissue stroma in differentiating the two. In endothelioma they are intimately related to the underlying struc-

Fig 5 a, Angiosarcoma of femur with metastasis (B S R No 1530) The primary lesion is a large rarefied area just above the condyles which has broken through the cortex anteriorly The small discrete, oval lesions in the midshaft are probably metastatic b, Metastatic lesions

in the ribs are seen c, The lesion is composed of irregularly arranged vascular spaces lined by large endothelial cells and surrounded by a fibrillar network containing large numbers of similar cells Mitotic figures are seen New blood vessels evident in the section are characteristic of this tumor

of bone exists as a pathological and clinical entity is still a controversial one, although the evidence suggests that such a tumor of bone does occur The problem of diagnosis is especially difficult when the skeletal lesions are multiple, since it is often difficult or impossible to ascertain which is the primary focus In such cases metastatic lesions from a primary carcinoma or hypernephroma cannot be ruled out absolutely without a complete and careful postmortem examination In single lesions the problem is not so difficult If the patient remains well for several years following amputation or excision, it is presumptive evidence that the lesion is primary in bone

Six cases in this group of malignant angiosarcomas have been designated angioendotheliomas, although the diagnosis in some of them might be open to question because of the difficulty in distinguishing them histologically from metastatic carcinoma or hypernephroma Postmortem examination was done in 3 of the cases, however, and no evidence of primary carcinoma was found Metastasis and death occurred in 4 of the 6 cases In the 2 cases

that were not fatal, the proximal half of the humeral shaft was involved in both One of these (B S R No 83) was treated by curettage and cauterization with no recurrence 10 years later In the other case (B S R No 2156) treatment consisted of radiation and finally amputation Death occurred 6 months later from coronary occlusion but without evidence of recurrence Postmortem examination was not made

Geschickter's (22) and Ewing's (16) statement that angioendotheliomas are usually found in the ends of the long bones is confirmed by this study Examination of the roentgenograms shows a varied appearance which cannot be called characteristic or diagnostic All show rarefaction and destruction, and rarely bone production Some reveal cystic expansion with well defined septa which Brailsford described as characteristic of angioendotheliomas Such an appearance, however, is not typical of the cases in this series (Fig 4, a)

An analysis of the clinical symptoms reveals nothing significant or diagnostic The symptoms vary according to the location of the le-

Fig 6f

Fig 6g

matin granules. Mitoses are frequently found. The cellular areas are traversed by a varying number of wide, thin walled blood spaces which are lined by flat endothelium. In places, the blood vessels are very numerous and may even excel the strands of cells. The vessels are now less sharply differentiated from the cells surrounding them and transitions can be found between the cells in solid strands and those lining the blood spaces. Since the undifferentiated neoplastic mesenchyme reveals distinct vasoformative tendencies, the microscopic diagnosis is angiosarcoma" (Jaffe).

Telangiectatic sarcoma has been designated by some as a form of angiosarcoma, as in a case reported by Hodges, et al. In the classification

of the Registry of Bone Sarcoma, however, this tumor is placed under the osteogenic sarcomas. Ewing (17) has recently discussed its classification as follows:

"Telangiectatic sarcoma, a form of malignant bone aneurysm, is a very characteristic bone tumor, but its exact origin and relation to other bone sarcomas has not been satisfactorily determined. There is considerable evidence suggesting that this process belongs with the tumors of blood vessels of bone and is a cavernous angiosarcoma. Further data seem necessary before the true nature and relations of the so called telangiectatic bone sarcoma can be determined, and these data should relate to the part played by blood vessels in the origin and growth of

ther osteogenic sarcomas. Their clinical connections with other malignant bone tumors seem to warrant their retention, for they present, in any complete group of bone sarcomas.

The term angiosarcoma is used in this study to indicate a malignant neoplasm showing proliferating vascular endothelium with new blood vessel formation in which the vasoformative tendency is the predominant feature (Fig. 5 a). Nine cases have been classified as angiosarcoma on the basis of this histological picture. Metastases and death occurred in 4. Amputation was performed in 5, 4 of which were alive without evidence of recurrence on last report. The author's case has been followed 13 years. Excision was done in 1 case in which the primary lesion was in the fibula, death with pulmonary metastases occurring 2 years later.

The clinical and roentgenographic signs are in no way distinctive, being of little value in differentiating angiosarcoma from other malignant bone tumors. Since the diagnosis is made entirely on pathological findings, biopsy is of great value.

The results in this series indicate that angiosarcoma and angioendothelioma are only moderately radiosensitive in contradistinction to Ewing's tumor. Early surgery, such as excision or amputation, supplemented by radiation offers the best possibilities for cure.

REPORT OF A CASE OF ANGIOSARCOMA OF TARSAL BONES

P. S. Whit, male, aged three years, was first seen on January 9, 1926, complaining of pain in the right heel. His father stated that he limped when he first began to walk. The symptoms gradually increased in severity until he was unable to bear any weight on the affected leg. There was no history of injury.

The patient was a rather frail boy who refused to bear any weight on the right foot. Examination of the right lower extremity revealed atrophy of the thigh and calf muscles. Any attempt to move the foot caused pain, localized in the medial side of the heel. There was fullness on the medial and plantar aspect of the heel. These areas were very tender to pressure, especially over the plantar surface of the heel posteriorly. The right knee was held in slight flexion, and an attempt to straighten the knee elicited pain in the foot. The physical examination was otherwise negative.

Roentgenograms (Fig. 6, a) of the right foot showed a cystic area involving the calcaneus. I

teriorly the process had broken through the cortex. T. Osburn. A tentative diagnosis of tuberculosis of the calcaneus was made, and the patient was hospitalized. The foot was immobilized in a plaster of Paris cast extending from the toes to midhigh thigh. He was kept in bed, and heliotherapy was started. Laboratory findings were essentially negative, including the tuberculin and Wassermann tests. Instead of improving, the pain increased. It was necessary to remove the cast 3 weeks later. Examination indicated that the infiltration and swelling beneath the heel had increased, and the foot was more tender. It was therefore decided to explore the lesion by operation.

On February 20, 1926, under ether anesthesia, an aspiration was attempted without success. The calcaneus was then exposed by posterolateral flap incision. The periosteum was intact, but there was an opening in the bone cortex on the plantar surface of the calcaneus extending into a large cystic cavity. The cavity was filled with purplish red, friable tissue, resembling granulation tissue. Several small pieces of bone were lying free in the cavity. The edges of the opening were irregular and overhanging. The lesion was very vascular, bleeding freely when touched. The cavity was thoroughly curetted and then cauterized with phenol. It was necessary to pack the wound to control hemorrhage. The skin wound was loosely closed with interrupted silk worm sutures.

Convalescence was uneventful. The gauze pack was removed under gas anesthesia on the 3d day without further hemorrhage. The sutures were removed on the 10th day, the wound being apparently healed.

Pathological report. A direct smear showed organisms, and the culture was negative. T. guinea pigs which were inoculated with tissue fragments yielded negative postmortem findings. The microscopic examination revealed erythrocytic, vascular growth suggestive of sarcoma (Fig. 6, b). In view of the diagnosis, sections were submitted to two other local pathologists, who confirmed the diagnosis. As the advisability of amputation had to be considered, slides and roentgenograms were submitted to the late Dr. Joseph C. Bloodgood, of Baltimore, who reported that he considered the microscopic appearance suggestive of angiosarcoma or angioendothelioma. He advised against amputation but urged continuation of the roentgen-ray treatment. Some months later photomicrographs of the tumor tissue were submitted to Dr. James E. King of New York City, who expressed the opinion that it was malignant neoplasm originating from vascular endothelium, but qualified this opinion by stating that it is hazardous to draw too sharp distinctions from photomicrographs.

Progress notes. Dr. Bloodgood advised as follows, and the boy was given heavy doses of roentgen ray over the foot and leg. He was discharged from the hospital on March 30, 1926. A roentgenogram taken at that time showed increase in the

destructive process, and the edges of the cavity appeared smoother with evidence of bone condensation. He was seen at intervals for a year and a half, roentgenograms being taken frequently with no evidence of recurrence. He continued to have pain, however, and was unable to bear full weight on the affected leg.

The patient then disappeared from treatment and was not seen until 3 years later (1930) when he was readmitted to the hospital. He was walking with a crutch, complaining of severe pain in the right foot. He stated that he had not been able to bear weight on the affected leg since he was discharged. Examination revealed marked atrophy of the right lower extremity with shortening of 6 inches. There was a severe equinovalgus and cavus deformity of the foot with contracture of the plantar fascia. A roentgenogram showed that the original cavity of the calcaneus was completely healed (Fig 6, b). An attempt was made to correct the deformity of the foot by means of a wedge osteotomy. After 2 or 3 months the cast was removed, and he was discharged from the hospital.

He returned in 1933 at which time he still complained of pain and inability to walk. Examination revealed that the deformity had recurred. The foot was especially tender in the midtarsal region. Roentgenograms revealed an area of destruction involving the midtarsal bones which had not been evident in the previous pictures (Fig 6, c). In view of the new lesion and the marked disability in the leg due to pain, shortening, and deformity, amputation was performed through the middle third of the leg in September, 1933. He made an uneventful recovery and was fitted with a prosthesis 3 months later. He was last seen in November, 1935, at which time he was apparently in excellent health. Verbal reports since then indicate that he is well.

Pathological report of the amputated specimen. The foot was cut through the sagittal plane, the calcaneus and midtarsal bones being split. A dark, chocolate brown, circumscribed tumor consisting of soft, friable, very vascular tissue was found involving the navicular, cuboid, and second cuneiform bones. The calcaneus was small and atrophic, but there was no evidence of tumor tissue (Fig 6, c). Microscopically the tumor was composed of many vascular spaces lined with endothelial cells. The true angiomatous character of the tumor was much more readily discernible than in the sections from the calcaneus made 7 years previously. The blood spaces were much larger, the tumor cells being less densely packed and apparently not as proliferative as in the previous sections. Connective tissue was less dense but more abundant. Red blood cells were seen in some of the vascular spaces. Granules of blood pigment were present. Endothelial proliferation and new blood vessel formation were a prominent part of the picture. In some areas the endothelial proliferation was marked, cells being so densely packed that obliteration of vascular spaces was noted (Fig 6, g).

This case is of unusual interest not only because of its rarity in regard to type, location, and age, but also because of the rather striking changes that were observed over a period of 7 years before amputation was done. At first the tumor showed many signs of malignancy, and there was some difference of opinion among the pathologists on this point. The original sections showed such marked endothelial proliferation that the vascular spaces were almost obscured and the histological, as well as the roentgenographic, appearance strongly suggested sarcoma. As time passed, however, the primary lesion eventually was obliterated, as indicated by the roentgenograms and the pathological examination of the amputated foot. The marked shortening of the leg with atrophy probably should be attributed to the effect of the roentgen-ray therapy on the epiphyseal cartilage.

The final roentgenograms taken 7 years after the first operation revealed a surprising condition in the presence of a large destructive lesion in the midtarsal region, which had not been evident in the previous pictures. Pathological examination revealed an angiomatous tumor in this area which histologically resembled more nearly a benign capillary angioma than an angiosarcoma, although there were areas which still showed marked endothelial proliferation. Nevertheless, the structural differences between the original lesion in the calcaneus and those of the tumor in the midtarsal region were quite evident. The question arises whether the latter tumor was the result of direct invasion from the original lesion, or whether it developed from a second congenital focus, independent of the primary lesion. The serial roentgenograms and the gross appearance of this tumor suggest that the latter mode of origin was quite possible.

Because of its angioblastic tendency and its recurrence after apparent cure, this tumor is classified as an angiosarcoma of low grade malignancy. Its varied histogenesis demonstrates the difficulties involved in the identification and classification of angioblastic tumors.

CONCLUSIONS

A review of current opinions on the pathology of vascular tumors indicates that they are

mesenchymal tumors arising from congenital rests by a process of endothelial proliferation and differentiation into new blood vessels. They occur in both benign and malignant forms. They are true endotheliomas.

The typical benign angioma is a highly differentiated structure composed of fully developed blood vessels which grows slowly and with little evidence of cellular activity.

Malignant angiomas, on the other hand are characterized by rapid growth, invasion of surrounding tissue, and sometimes metastasis. They consist of very cellular angioblastic tissue which in its histogenesis tends to revert to the original primitive mesenchymal structure, producing a varied histological picture differing greatly from the well differentiated benign forms. Often in these malignant forms the primitive mesenchymal structure will assume morphological characteristics resembling either connective tissue (sarcoma) or epithelial tissue (carcinoma) rendering their histological diagnosis extremely difficult. They all possess one feature in common, however essential for diagnosis. There is always present an angioblastic tendency evidenced by endothelial proliferation and the formation of new blood vessels.

Tumors arising from blood vessels in bones are rare but their inclusion in a special class of bone tumors is justified on the basis of certain distinctive pathological and clinical features which they possess. A clinical and pathological study of 27 angiomas of bone has been herein reported.

The benign forms possess certain roentgenographic and pathological features which are practically diagnostic. These features have been described in considerable detail.

The malignant forms on the other hand are most varied in their structure and growth and offer more difficult problems in diagnosis. It is suggested that on the basis of histogenesis the malignant angiomas of bone can be divided into two subdivisions, the angioendothelioma and the angiosarcoma. Angioendothelioma is an angioblastic tumor but with an epithelium-like structure difficult to distinguish from metastatic carcinoma. In angiosarcoma the vasoformative tendency is a more predominant feature the new blood vessel be-

ing the unit of the tumor rather than the proliferating endothelial cell. Examples of both of these types of malignant angiomas are included in the series. These two groups vary greatly in their growth and malignant tendencies and they possess few characteristic roentgenographic or clinical features distinguishing them from other malignant tumors of bone. Diagnosis is based largely on their histological appearance. They are only moderately radiosensitive and early diagnosis and radical surgical treatment are essential for cure.

SUMMARY

1. A pathological and clinical analysis of 27 cases of benign and malignant vascular tumors involving bone is reported.

2. A résumé of current opinions on the pathology of vascular tumors is included, special attention being directed to histogenesis and classification.

3. It is suggested that malignant angiomas of bone can be divided into angioendothelioma and angiosarcoma. The distinctive features of each are given.

4. Treatment of vascular tumors of bone is outlined emphasizing the importance of early diagnosis and radical surgery in the malignant types.

SUPPURATIVE JOINT DISEASE AND ITS RELATION TO PYOGENIC OSTEOMYELITIS

A Review of End Results of 67 Involved Joints in 57 Patients, Modern Chemotherapeutics

JACK BLAISDELL, M.D. and PAUL H. HARMON, Ph.D. M.D. Sayre, Pennsylvania

INTEREST in the outcome from major joint suppuration appears to have been stimulated by World War I coincident with an awakening of interest in the long term outcome from injuries and disease incurred in that conflict. During that period the revolutionary and heroic treatment of Willemss was inaugurated only to fall into later disrepute among his civilian surgical successors. A rational treatment of the condition appears not to have been devised until the late Russell Hibbs contended that pus within a joint played the major rôle in destroying its cartilage. To lessen this potential damage, surgical drainage of the joint was deemed necessary to provide an avenue of escape for purulent materials. Phemister later demonstrated a tryptic ferment in the products of pyogenic suppuration and showed that a pyogenic exudate will dissolve cartilage *in vitro*. He was unable to demonstrate a similar ferment in tuberculous pus. This same author also established the fact that pressure in the presence of a pyogenic exudate accelerated the erosion of cartilage. Traction on a joint, which separates its articular surfaces, together with arthrotomy or other drainage, became the accepted and logical treatment. It is the only effective means of treating suppurating joints, but its exact application varies with the joint. This regimen led to preservation of motion in the largest percentage of cases, but it has been only in later years that end results of a large number of cases have become available. The historical aspects of the changing surgical viewpoint concerning the therapy of suppurative joints will not be reviewed in this place because excellent historical sum-

maries have preceded this paper. They will be found in the writings of Garrison Bick, Inge and Liebolt, and Wilensky.

The exact differentiation between the causes of joint suppuration had to await the successful routine application of bacteriological methods to this disease. However many years prior to these applications of bacteriology Wiseman (17th century) was credited with differentiating the clinical features of suppurative joint disease from the "tumor albus" of tuberculous disease of the knee. However this differentiation was not made with ease and certainty until Phemister pointed out the roentgen characters of suppurative joint disease as compared with those of tuberculous infection of the joints. In the former destruction of the cartilage and then the joint space occurred first in the contacted or "weight bearing" portions of the joint, while tuberculous pannus destroyed the noncontacted portions of the articular cartilage by growing over the joint from the peripheral nonweight bearing portions. The surface spread of tuberculous tissue is inhibited by motion and contact. From a clinical point of view the acuteness of suppurative joint disease usually prevents confusion with tuberculous joint involvement. In civilian life, the frank association of acute and chronic pyogenic osteomyelitis with the production of suppuration within the joints further aids in clinical diagnosis. The frequency of joint complications from suppurative joint disease has varied in the statistics of different authors. These are given in Table I. In general, there has apparently been a closer association of suppurating joints with pyogenic bone involvement in recent years. This apparent greater association of bone infection as a point of origin of

joint suppuration is accounted for by the smaller incidence of penetrating injuries in civilian practice and by the greater frequency of roentgenographic study of bone and joint disorders

From the historical aspect, recommendations for treatment have varied. Early surgical writers recommended simple incision of the joint "to evacuate the matter," noting that the joint finally became immobile as a result. During the period when amputation of the extremities was a popular surgical procedure, suppuration in the major joints was considered an indication for amputation. The modern tendency, except for the introduction of the Willems treatment, which is no longer generally practiced, has been toward conservatism. Roentgen visualization of the involved part has allowed the surgeon to direct his treatment intelligently toward discovery and concomitant treatment of bone suppuration. There have been no contributions of major importance since those of Phemister until the recent application of specific chemotherapy. Notwithstanding, the grade of treatment has steadily improved and with it the end-results. It should be brought out, though, that regardless of the diligence and persistence in surgical care, many cases will suffer ankylosis and loss of extremity length because of the extent of initial bone disease, a factor not under control of the surgeon in cases in which the infection has occurred by the blood stream.

We have found 57 patients with suppurative joints in the records of the Guthrie Clinic

Fig 1 Involvement of various joints by suppurative joint disease. Cross hatch areas, no or minimal bone involvement, black areas, bone involvement

and the Robert Packer Hospital. While some of these patients presented multiple joint involvement, 67 separate joints were available for study. These cases represent all those seen in a period of 8 years, but our treatment, as described in a later section of this paper, was applied to only a few of them inasmuch as it has been evolved as a result of the relatively recent applications of chemotherapy.

In general, the application of chemotherapy, following prompt diagnosis and arthrotomy, probably would result in better general outcome than that presented by this whole group of cases (Table II). Figure 1 gives the distribution of cases according to joint involvement. During the same period of time, 488 cases of pyogenic osteomyelitis were seen in this institution. Those with joint involvement made up 11.7 per cent of the total. Males comprised 70.7 per cent of this latter number, a finding in agreement with the usual greater incidence of suppurative bone disease in this group. The age incidence was 0 to 10 years, 26.3 per cent, 11 to 20 years, 29.8 per cent, 21 to 30 years, 14.0 per cent, over 30 years, 23.0 per cent. The age incidence was unknown in 7.0 per cent of the cases. The purpose of this paper is to emphasize the need for early and prompt bacteriological diagnosis by joint aspiration and vigorous and meticulous therapy including the prolonged application of traction to the involved extremity and to describe the application of specific chemotherapy both during the acute stage and as

SUMMARY—57 cases

Died—7

Chronic or ankylosed or both with draining sinuses 25 improved (healed occasional minor discomfort) 5 cured (Included 2 cases cured by amputation) 20

used to heal the wound. The employment of traction results in a greater percentage of movable joints in the end-results (see section on treatment)

DIAGNOSTIC CONSIDERATIONS

The patient with suppurating joint disease presents himself with a painful, swollen, and immobile joint, splinted by spasm of neighboring muscles. This situation is the sequel of either pre-existing neighboring bone disease or a penetrating local injury. Occasionally, the initial bone disease has long been quiescent and has had a recent reactivation by trauma. The usual accompanying symptoms and findings of acute or subacute infection are present fever, a variable degree of "toxemia," prostration, and an increase in circulating polymorphonuclear neutrophilic leucocytes in the peripheral blood. The local findings should immediately direct the attention of the surgeon to the joint. The chief conditions to be considered in differential diagnosis are (a)

acute rheumatic fever, (b) sympathetic sterile joint effusion produced by trauma or neighboring infection, (c) intermittent hydroarthrosis, (d) joint tuberculosis, (e) hemophilia, (f) traumatic hemarthrosis, which may accompany marginal fractures and "sprains", (g) acute rheumatoid arthritis—in children, Still's disease, (h) acute bursitis, (i) periarticular cellulitis, (j) small fractures and sprains. (See Figure 2)

In the instance of the deep lying joints—hip, shoulder, intervertebral joints and temporomandibular joints—the local joint distention may be masked by pain and muscle spasm. The presence of pus within the joint can be confirmed only by aspiration, since periarticular suppuration will often closely simulate the findings of intra-articular involvement. Aspiration is further indicated at the earliest possible moment, in order to obtain material for smear and culture by the bacteriologist. From his report, specific chemotherapy is prescribed. Aspiration is the

first step in treatment since suppurative products should not be allowed to accumulate. In certain cases this is adequately prevented by one or more joint aspirations (see section on treatment).

The surgeon should not be content with positive findings in a single joint: all the joints and exposed and accessible bones should receive a meticulous physical examination since suppurative bone and joint disease is frequently multiple. The symptoms in a single joint may overshadow those in other joints and the unwary diagnostician may neglect or overlook an important part of the patient's disease. In our series, 9 patients, 15.8 per cent, presented multiple joint involvement.

The symptoms arising from the systemic phase of suppuration (septicemia) may also largely or completely mask the metastatic manifestations. In these instances, the most important consideration is the chemotherapeutic treatment of the general infection and the general care of the patient rather than local attention to the joint. Selection of the appropriate drug in these cases is essential. In addition, blood cultures should be made in every case of manifest joint disease as a control upon the adequacy of dosage of the sulfonamide series of drugs.

Roentgenograms should be made of the joint and neighboring bones when the patient is first seen. They will usually show no alterations unless the patient has had previous neighboring bone disease. The earliest finding is narrowing of the joint space (Fig. 3) which is often not detectable unless a roentgenogram of the contralateral corresponding joint is available. This narrowing is not pathognomonic of acute joint disease as it may be produced by pre-existing chronic joint disease. In the latter instance, characteristic bone markings will usually give a clue to the nature of pre-existing bone disease: for example, sclerosis, osteophytes with or without bone destruction. If suppuration in the area is of recent origin, no osseous alteration

weeks after onset. The importance of these facts in relation to treatment will be brought out later. There is seldom any confusion in interpreting acute, progressive demineralization of the bones as visualized by roentgenograms taken at weekly or fortnightly intervals, for in no other condition does this process advance so rapidly. Small osseous foci which are responsible for initiating joint suppuration may not be visualized for several weeks (3-8). These smaller foci have no bearing on treatment and are of scientific interest only. See Figure 4 for representative cases of slight to moderate osteomyelitic involvement which has resulted in suppurative arthritis. In the instance of primary joint suppuration, especially if purulent products are not removed by aspiration or arthrotomy, solution of the cartilage promptly occurs and a roentgenogram of the joint will subsequently show erosion of bony articular cortex or sequestration of this structure and solution of the underlying cancellous bone (Fig. 5). There is usually no need for these latter changes to occur if aspiration and prompt, adequate treatment is executed.

TREATMENT

Opinion is now fairly well crystallized upon the measures to be followed in treating acute and chronic suppuration within the peripheral joints. The basis for the procedures to be described has already been discussed: the indications are to preserve motion, if possible, and to relieve pain and minimize joint damage by removing suppurative products and by traction. Chemotherapy aids in controlling suppuration and in sterilizing the blood stream when involved. Some variation in treatment is needed when extensive osteomyelitis of the long bones is present, as it may not then be possible to allow joint motion to remain when appropriate treatment is being given for the extensive bone infection. The management of chronic cases differs from one in the acute stage and will be discussed

Fig 2 Roentgenograms of 5 cases illustrating different diagnosis from suppurative joint disease a, Tuberculosis of the hip in a juvenile patient. Note destruction on both sides of the joint predominating in the nonweight bearing portions of the joint b, Early tuberculosis of the knee in an adult. This case demonstrates the classical early findings in roentgenograms with marginal and intercondylar bone destruction (nonweight bearing portions of the joint) c, Hemophilic "arthritis" showing bone

atrophy, subchondral cysts, lamellation at the anterior and posterior portions of the distal femoral epiphysis and premature but symmetrical closure of epiphyseal lines d, Chondrosarcoma of the upper tibia protruding posteriorly. Bone destruction and spotty calcification in the tumor establishes the roentgen diagnosis e, Acute trauma to the knee without fracture followed by hemarthrosis. Occasionally this condition will be followed by infection when a penetrating wound is present

Fig. 3. Roentgenograms of septic arthritis involving 4 different joints in the same number of patients: a, hip; b, shoulder; c, knee; d, met. Note that in all these instances, there is certain amount of marginal bone demineralization adjacent and thick the joint. Note also the joint ankylosis of the capital femoral epiphysis in, a, b¹ and b² are taken before and after surgical removal of diseased bone adjacent to the glenoid.

Fig. 4. Roentgenograms of small jointarthritis in an infant. Septic arthritis of the scapula. a, Tip of scapulum in an infant which has localized suppurative focus. b, tip has broken into and caused joint infection.

Involved shoulder joint. Compare soft tissue swelling of involved shoulder with uninvolved contralateral joint. b, b¹, inferior portion of patella, ruptured into knee joint.

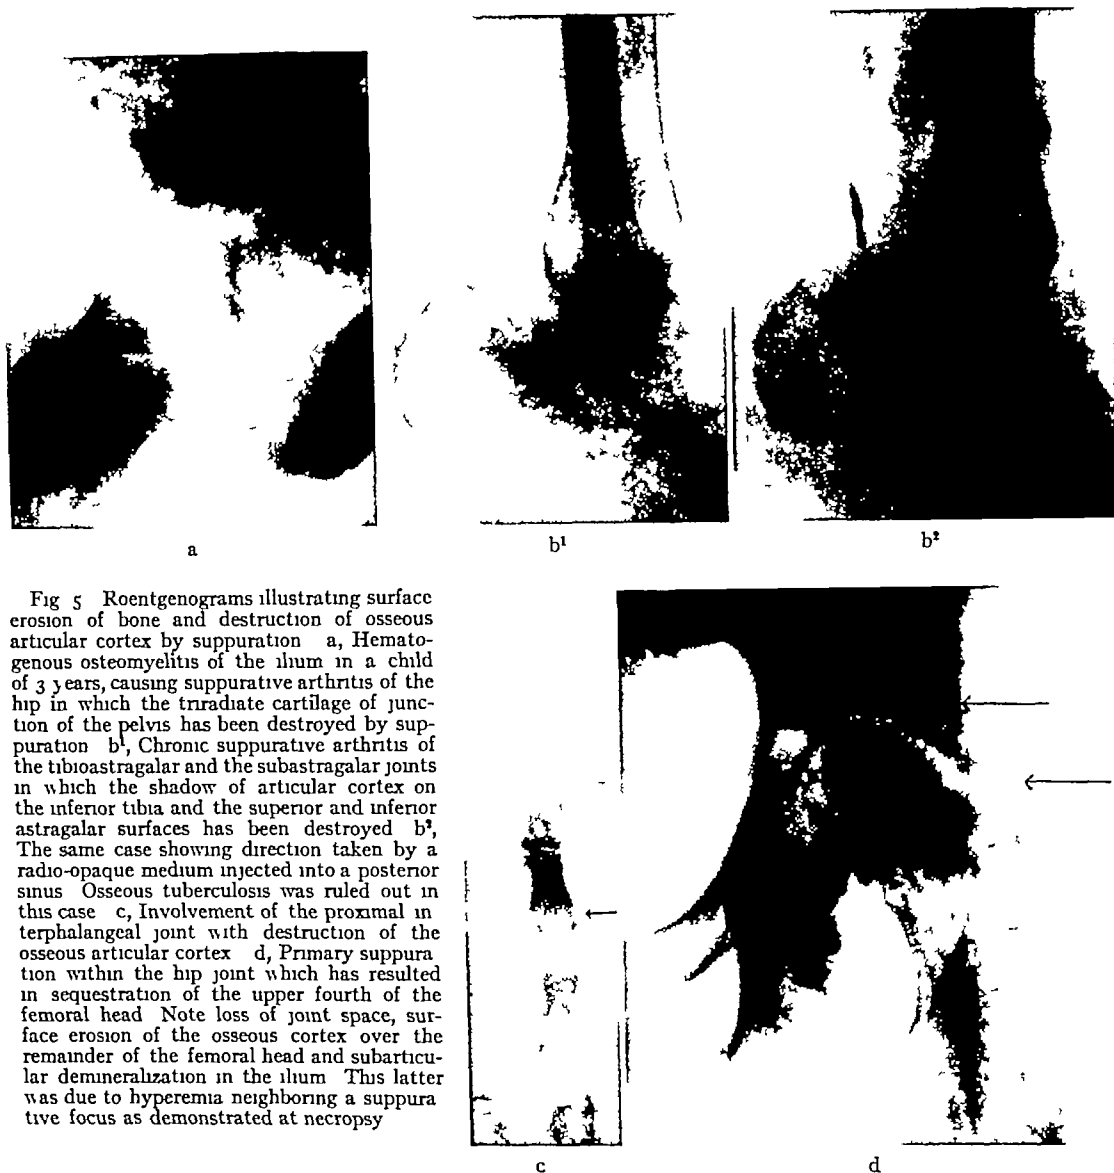

Fig 5 Roentgenograms illustrating surface erosion of bone and destruction of osseous articular cortex by suppuration a, Hematogenous osteomyelitis of the ilium in a child of 3 years, causing suppurative arthritis of the hip in which the triradiate cartilage of junction of the pelvis has been destroyed by suppuration b¹, Chronic suppurative arthritis of the tibioastragalar and the subastragalar joints in which the shadow of articular cortex on the inferior tibia and the superior and inferior astragalar surfaces has been destroyed b², The same case showing direction taken by a radio-opaque medium injected into a posterior sinus Osseous tuberculosis was ruled out in this case c, Involvement of the proximal interphalangeal joint with destruction of the osseous articular cortex d, Primary suppuration within the hip joint which has resulted in sequestration of the upper fourth of the femoral head Note loss of joint space, surface erosion of the osseous cortex over the remainder of the femoral head and subarticular demineralization in the ilium This latter was due to hyperemia neighboring a suppurative focus as demonstrated at necropsy

puncture wound, uncomplicated by osteomyelitis

CASE 1 C S, aged 4 years, was admitted to the Guthrie Clinic and the Robert Packer Hospital 8 days after a puncture wound occurred on the left foot The wound became infected and the infection ascended into the leg by the lymph channels A hypodermic needle was broken off near the patella by a local physician who first treated the patient This latter site soon became infected, the knee swelled, and walking was very painful for 2 days

just prior to admission On admission, the left knee was warm to touch, patellar ballotment associated with pain was present, and the patient was able to flex the knee but 15 degrees because of exquisite pain Roentgenograms upon admission showed the increased volume of soft tissues and the foreign body (needle) but were otherwise negative Laboratory studies were negative except for a leucocytosis—13,000—and an increased sedimentation rate—27 millimeters in 1 hour The patient was placed in bed on a Bradford frame, the left knee was extended by adhesive tape traction applied to the

gram of sulfathiazole placed in the wound when debridement and nature of compound fracture of patella was performed.

leg. Aspiration of the knee joint obtained 5 cubic centimeters of purulent fluid from which the *Staphylococcus aureus* as cultured. Sulf thiazole was given the patient in 0.5 gram doses every 4 hours. In the next 3 days the temperature rose to 6 degrees F and swelling of the knee returned. Four days after admission a parapatellar rhotomy was performed, and the small foreign body was removed. Synovium was stitched to the skin in each incision and two soft rubber drains were placed through the incision, with care that neither touched cartilage. Traction and sulfathiazole were continued. On the second postoperative day the temperature did not exceed 100 degrees F and the patient appeared to have improved. He was kept recumbent in traction for more days. The rubber drains were allowed to remain in place for only 3 days until satisfactory large bilateral parapatella sinuses were established. He was discharged from the hospital, draining but little on the twenty third postoperative day. Three days after discharge from the hospital all drainage ceased and the sinuses fully epithelialized during the following week. Six weeks after operation, almost normal range of motion was present, and the patient had no swelling or pain in the knee. On follow-up visit 7 months later the patient presented a normal appearing knee where there was a complete range of motion. Check-up roentgenograms at this time and previously failed to show an osseous focus of infection.

In this acute uncomplicated case prompt arthrotomy aided by traction throughout the period of recumbency resulted in a successful outcome. Previous aspiration alone did not check the accumulation of suppurative products although in 3 cases in our series repeated aspiration alone sufficed to control the infection. Sulfathiazole was used to control the hemolytic *Staphylococcus aureus* infection. In later cases healing of the sinuses has been

accelerated by the use of this drug and in some instances sulfadiazine used in a powder atomizer. This general procedure is probably applicable to the greater majority of cases of suppurative arthritis occurring in the lower extremity. Occasionally especially associated with seropurulent exudates due to infection with the α -hemolytic streptococcus, aspiration alone will relieve joint distention.

When massive acute osteomyelitis of the long bones complicates or causes joint suppuration, it is impossible to apply effective traction unless the localization of bone infection is in a site which will not interfere with its maintenance. These situations are not encountered with the frequency of uncomplicated joint suppuration and joint suppuration associated with minimal or moderate foci of osteomyelitis. The indication for cast treatment in preference to traction is the presence of pathological fracture or in the prevention of this condition. The following case of acute recrudescence of chronic osteomyelitis of the right femur with subsequent involvement of the right knee joint, is illustrative.

CASE. H. F., male, aged 26 years, was admitted to the Guthrie Clinic and Robert Packard Hospital with a history of chronic osteomyelitis of the distal right femur of 3 years duration. The past treatment included several typical attacks and one postoperative course with maggots. He had been asymptomatic until 4 months prior to admission when he had experienced an acute local spread of the infection. Treatment had been delayed until both femoral condyles were involved by direct extension. Even at that time, involvement of the joint was not recognized elsewhere. He had had continued pain on active and passive motion due to joint involvement, even though the femoral osteomyelitis was adequately drained. Roentgen study showed diminution of the right knee joint space and painful patellar ballooning was present.

Aspiration of the knee joint controlled his pain only partially and it was not until long leg plaster was applied that he was almost pain free. The roentgen demonstration of the extent of osteomyelitis in the distal femur as a further indication for use of plaster since pathological fracture is feared.

Results that may be obtained in the future in treating these disorders may be expected to be better than the outcome in this series of cases inasmuch as the majority of these were treated before the advent of the use of the

Fig 6 Cases demonstrating contraindications to radical surgical treatment. a, left, Roentgenograms of pelvis of a child, age 10, 4 months after onset of acute suppurative arthritis of the hip and 3 months after the sequestered femoral head was removed from the draining arthrotomy wound. During this time, the patient had been in a plaster hip spica. The roentgenogram shows a bone abscess in the proximal femur with numerous small sequestra adjacent to it. b, Roentgenogram of a chronic hip joint disorder of 3 years' standing, in an adult. This was proved by biopsy and culture to be a pyogenic joint. Operative fusion was contraindicated by the supra acetabular osseous abscess.

sulfonamide group of drugs. These drugs are excreted from the blood stream into the joint in the presence of fluid exudate within these structures.

Table III summarizes cases in which the concentration of sulfathiazole in joints was determined in the presence of known blood levels of this drug. We are not cognizant of any similar observations upon record in the literature. These observations show that average concentrations of sulfathiazole in the knee joint in instances of sterile effusion are about two-thirds that of the blood concentration. Although no direct observations were made on the concentration of this drug in the instances of suppurating joints, it is likely the same or greater. At present, it is believed that there are no definite critical levels for the action of the drug, but it is desired that the blood concentration be kept between 3 and 8 milligrams per 100 cubic centimeters. To be effective in joints, however, the blood level should be kept at an adequate level which will usually result from a 4 gram initial dose

followed by 4 daily doses of 1 to 1.5 grams each in adults. Sulfathiazole or sulfadiazine will be the drugs to be used in most instances inasmuch as most suppurative joint infections are produced by the staphylococcus. It should again be emphasized that the causative bacterial organism should be determined at the earliest possible moment in order to utilize chemotherapy most advantageously.

All gradations of severity of pyogenic joint infection are encountered. The chronic types with insidious onset are rare. Their symptoms and findings are the same as those of any chronic joint disorder except pain is likely to be severe and constant. Fever may or may not be an accompaniment. A certain number of these cases are confused with tuberculous joint involvement, as the roentgen picture is likely not to be characteristic of either. Aspiration with or without joint irrigation is the only means of diagnosis. Bacterial cultures of joint contents and frozen sections of synovia establish the diagnosis when arthrotomy has been performed under the mistaken diagnosis

Fig. 7. Roentgenograms of some terminal and advanced deformities produced by suppurative arthritis (and neighboring osteomyelitis in some instances). a, End-result of wrist involvement. The proximal carpal remnants are fused to the radius. b, End result of shoulder involvement of the same patient as in a. Note the ossification in the capsule superiorly and advanced destruction of the glenoid. c and d, Flexion deformity of the knee resulting from suppuration within that joint. These films were taken years apart. Note the improvement with passive stretching and weight bearing. d, End result from pan-

arthritis of the ankle joint in which all the joints about the astragalus have been destroyed by suppuration resulting in osseous ankylosis of all bones neighboring upon the astragalus. e, Roentgenogram of knee in an adult in which slight motion had been preserved following suppuration just before this plate was taken; the patient had suffered supracondylar fracture. f, End result of suppuration within the hip which had destroyed the femoral head, portion of the neck and resulted in pathological dislocation. g, End result of suppuration within the hip resulting in bone loss and severe flexion-adduction deformity

of tuberculosis of the joint. The infection may occasionally be sufficiently low in its virulence that bone grafts will survive when the unwary surgeon has performed an arthrodesis uncontrolled by synovial biopsy. Indications are that an increasing number of primary operations can be performed on chronic suppurating joints without the danger of sinuses developing when the sulfonamide drugs are used locally and by mouth following the operation.

The stationary case who presents himself with deformity is usually a problem involving the restoration of the weight bearing axis of the body. If the history has been that of an acute disease with rapid ankylosis with or

without drainage of the joint, the diagnosis was almost certainly that of suppurative joint disease. Before performing osteotomies for the restoration of the weight bearing axis, roentgenograms should be scrupulously inspected for the presence of small sequestra or bone abscesses (Fig. 6). In the presence of these operation should not be undertaken and should be deferred until neither are present, which may mean a period of years. There are at present, indications that the restrictions in operating upon bone formerly the seat of infection can be relaxed when local and systemic chemotherapy (sulfathiazole or sulfadiazine or both) is utilized. However the

Fig 8 Two patients with prepatellar bursitis. The patient with circumscribed bursitis in, a, would less likely be confused with suppuration within the joint than the patient in, b

Fig 9 Two patients with residual deformity from suppurative arthritis. a, Patient 6 months after onset of suppuration in the glenoid face of the scapula. Note the loss of normal contour in the left shoulder and the drop in position of the muscle belly of the biceps due to rupture or detachment of the origin of the tendinous long head. b, Patient 4 years after suppuration in the left knee. Note flexion deformity of 30 degrees. He had only 10 degrees of motion in the knee at this time. Same patient as shown in roentgenograms, Figures 7c¹ and 7c²

limitations associated with this new auxiliary are not as yet defined and are still under clinical investigation. The factors involved in prognosis will be presented following the results in our own series of cases. Table II gives these in summary.

A review of the deformities produced by joint and adjacent bone suppuration in this series demonstrates some advanced and appalling skeletal derangements. In the acute cases, deformity was prevented by fixation in the positions of maximum function. Table II

reveals that many cases did not come under care until long periods after the acute onset. These patients for the most part, presented deformities which under proper supervision could have been minimized or prevented entirely. Certain of these cases are illustrated in Figure 7. It is not within the scope of this paper to discuss the surgical treatment of deformities produced by suppuration within and near the joints as such a discussion would cover much of the field of reconstructive surgery.

SUMMARY AND CONCLUSIONS

1. The rationale of the treatment of acute joint suppuration by extension and arthrotomy is reviewed.

2. The outcome of 67 involved joints from 57 patients is tabulated and summarized. It is pointed out that these are poorer results than would be obtained under modern treatment with chemotherapeutic aid since the latter tends to minimize suppuration in the acute stage and to allow elective and reconstructive operations to be performed in cases in which secondary operations were contra-indicated.

3. Frequency of joint involvement by suppuration is in the following order: hip, knee, ankle, shoulder, elbow and wrist.

4. The necessity of early diagnosis by joint aspiration and bacterial culture and smear is

shown, since upon the results from bacterial culture and smear the proper chemotherapeutic agent is selected. When this information is lacking during the first few hours, the chemical agents that are active against the hemolytic *Staphylococcus aureus* (sulfathiazole or sulfadiazine) are to be used presumptively and change if any made as the result of the bacteriological findings. In children who have acute joint complications following upper respiratory and middle ear infections, sulfanilamide (a hemolytic streptococci) is to be used presumptively.

5. Comparative joint and blood concentration of sulfathiazole are presented, as determined in 6 cases.

SUPPLEMENTARY AND SYNERGISTIC ACTION OF STIMULATING DRUGS ON THE MOTILITY OF THE HUMAN COLON

HARRY F ADLER, Ph D, A J ATKINSON, M D, and A C IVY, Ph D, M D,
Chicago, Illinois

THE most uniform criticism of the drugs used to stimulate the motility of the human colon is their relative ineffectiveness in doses unaccompanied by undesirable side reactions such as nausea, vomiting, salivation, headache, and cardiovascular changes

This investigation was undertaken with the idea that a combination of drugs might be found the dose of each of which would not cause side reactions, but in combination would effectively stimulate the colon. For example, Kerr Cross found that physostigmine and pituitrin in combination had a more powerful effect on the motility of the human appendix than either drug alone, and that the use of the two drugs in combination in the treatment of postoperative distention was more effective than either drug alone

LITERATURE

Brief reference is made to some of the more recent studies regarding the action of the drugs to be used

Pituitrin A review of the literature reveals a rather wide difference of opinion in regard to the effect of pituitrin on the colon. Ochsner, Gage, and Cutting, basing their views principally on their review of the literature and observations on the dog, believe pituitrin to be ineffective. Frazier, basing his views principally on a review of the literature and on observations in man, believes that the drug is valuable in the management of adynamic ileus. He recommends that from 0.5 to 1 cubic centimeter of pitressin be given every

4 hours. According to our interpretation of the literature, pituitrin usually inhibits colon motility in the dog and usually stimulates colon motility in man. Our own experimental results confirm this interpretation.

Physostigmine The literature clearly demonstrates that this drug stimulates the motility of the canine (13, 21, 24, 29) and human (6, 9, 10, 11, 23, 24) colon. Sometimes, however, effective doses produce undesirable side reactions.

Prostigmine The use of this drug for the prevention and management of postoperative distention has been reported upon favorably by a number of authors (7, 8, 16, 17, 20, 31). Carmichael et al. observed the action of prostigmine in 41 patients. They showed that prostigmine methylsulphate in 0.5 milligram doses produces in normal subjects active movements of the colon, but there was no evidence that colon contents were moved. X-ray and barium studies revealed that considerable variation occurred in the response of different individuals to the drug. However, in the doses used, there were no side reactions and the drug was of value in gaseous distention if accompanied by an enema. The authors suggest that prostigmine followed by pituitrin and then an enema is an effective measure for stimulating peristalsis in postoperative distention. Levis and Axelman administered prostigmine methylsulphate (1 cc 1:4000 or 0.25 mgm) as a prophylactic measure against ileus, at the time of operation and every 4 or 6 hours thereafter for 24 to 48 hours. The last injection was followed by a soapsuds enema. Prostigmine was found to be better than pituitrin. No side reactions as with eserine (physostigmine) were noted.

Ergotamine Ergotamine in large doses, apparently acts directly on the receptor mechanism

TABLE I.—QUANTITATIVE DATA PERTAINING TO PROPULSIVE AND TOTAL MOTILITY IN THE COLON OF 4 DOGS AFTER INJECTION OF PITUITRIN, PHYSGOSTIGMINE AND PROSTIGMINE

No. of experiments	Control and drug experiments	Total motility		Propulsive motility	
		30 minute periods		30 minute periods	
10	Controls (4 dogs)	37	83	44	73
6	small pituitrin	3	2.79	2.34	8
6	small physostigmine	30	2.56	2.39	5
17	small prostigmine	30	2.5	2.3	6.7
15	s.c. large physostigmine	66	89	73	89
16	s.c. large prostigmine	69	177	67.3	136
8	s.c. large physostigmine	8	87	88	126
8	s.c. large prostigmine	68	76	7	75
8	s.c. large physostigmine	73	75	9.3	4.77

Total motility is time in per cent that the colon is active per 30 minute period of experimental time. Propulsive motility calculated as per cent of total motility.

nism of muscle cells so as to prevent the cells from responding to the substance (sympathin) liberated by sympathetic or adrenergic nerve endings. In small or moderate doses the drug stimulates smooth muscle to contract for example the uterus and arterioles. Such doses are employed clinically. On this basis it was assumed that small doses of the drug might augment the activity of other stimulating drugs on the colon.

The effect of ergotamine on the motility of the intact gastrointestinal tract of man has received little attention. In doses of 1 or 2 milligrams given subcutaneously it sometimes causes nausea and vomiting (15). It delays gastric evacuation (33). Only one report (19) indicates that it may be of benefit in the management of postoperative distention.

METHODS AND PROCEDURE

Preliminary experiments were performed on dogs with an appendicostomy for the purpose of studying some of the drugs which were to be used on man. In the dog, considerable evidence is available regarding the effect of some of the drugs on *nonpropulsive* motility but none is available with direct evidence regarding their effect on *propulsive* motility.

These are the two functional types of motility found in the alimentary tract.

Experiments on the dog. Four trained dogs with appendicostomy and weighing from 19 to 36 kilograms were used. The basal colonic motor activity of each was well known as a result of previous experimentation. The colon motility was recorded by the tandem balloon technique of Templeton and Lawson. One system of two balloons was placed in the proximal colon by way of the appendicostomy. A second two balloon system, recording motility from the distal colon, was inserted through the anus to such a distance that the most caudal balloon was located approximately 6 centimeters oral to the internal anal sphincter. The balloons were connected to individual water manometers by way of T tubes and inflated according to a standard procedure (4). Since the position of the balloons is fixed, the tandem balloon method does not differentiate between propulsive and nonpropulsive motility. To differentiate such motility the propulsive force technique (4) was used. All drugs were injected intramuscularly.

Experiments on human subjects. Four ambulatory adult males with colostomy were studied by means of the balloon technique. These patients had the lower sigmoid and rectum resected from 6 to 18 months previously for carcinoma of the rectum. They were in excellent condition with no signs of metastases. The descending colon had been brought to the surface as a fistula. The subjects were under experimental observation morning and afternoon for at least 150 minutes at each session. The colon was lavaged once a day (before breakfast) and usually no material was evacuated until the next morning when lavage was again performed. During the day only slight leakage through the colostomy and normally (for them) no gastrocolic reflex which led to expulsion of material occurred.

A one or two balloon system was introduced through the fistula to such a distance that the proximal portion of the descending colon was always studied. Our observations have been made chiefly from the region near the splenic flexure. After they were inserted, the balloons were inflated according to a standard procedure (4).

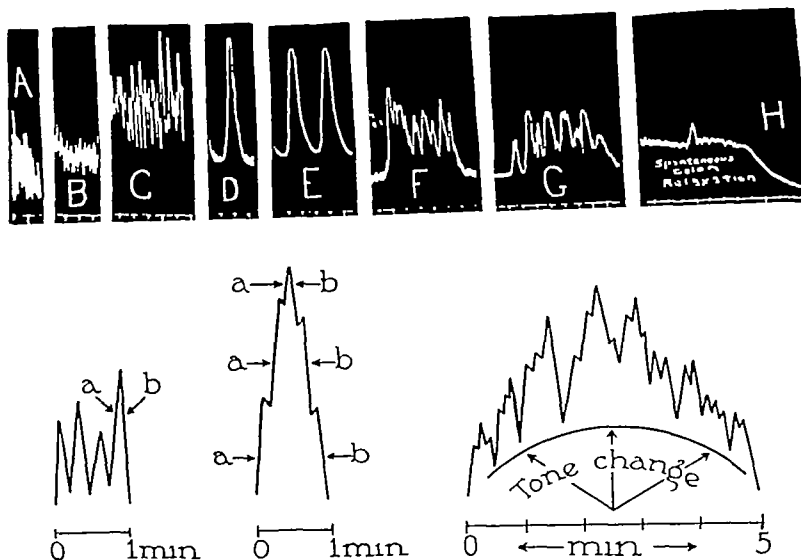

Fig 1 A to H, Excerpts of tracings from the colon of man A, B, C, type I contractions at various tonus levels, D, E, type II contractions, F, G, type III contractions, H, spontaneous relaxation of a balloon containing segment

The types of contractions are diagrammatically represented showing the manner in which complex contraction patterns are built up from more simple contractions

RESULTS

The normal or control motility *Functional types of motility* Two functional types of motility occur in the alimentary tract, one is *nonpropulsive* and the other *propulsive* in nature (28) Since drugs may affect these two types differently we have studied the effect of the drugs on each type

Types of contractions in the human colon Templeton and Lawson described three different types of contractions in the colon of the dog We have found and reported the same types of contractions in the human colon (1) and have correlated the three types with propulsion of contents Similar observations have again been made in this work and will be briefly reported at this time The types of contractions as obtained by the balloon method are illustrated in Figure 1

Type I contractions of various amplitudes, at a rate of 3 to 8 per minute occur on either high or low tone, usually on low tone They are nonpropulsive Type II contractions constitute the most frequent type of motility observed They are propulsive only when they are of large amplitude and co-ordinated with the activity of adjacent colon segments A

low amplitude type II wave may be propulsive if the contents are liquid Type III contractions consist of type II movements of variable amplitude superimposed on definite tonus waves The type III wave is a change in tonus upon which are superimposed type II contractions which may be propulsive

The quantity and functional quality of colon motility Seventy control periods of at least 150 minutes in duration were obtained from the 4 human subjects Forty similar control periods were conducted on the 4 dogs Individual variations were noted, the expulsion of colon contents was recorded as well as the nonpropulsive and propulsive motility The tracings were analyzed by adding the periods of time during which the colon was active, this gave the "total motility" The same was done for the "propulsive motility"

Referring to Table II, under the section "Experiments 2 hours after the last meal," it is to be noted that the colon of the 4 human subjects was active 53 per cent of the 50 minute period or it was active on the average 26 out of the 50 minutes of experimental time Thirteen per cent of the activity was propulsive in type, or the colon manifested pro-

propulsive motility during 6.5 minutes of the 26 minutes. When the average is taken for the 70 periods of 150 minutes each on the 4 human subjects, it is seen that motility is present 80 minutes or about 50 per cent of the time and the propulsive motility constitutes about 10 per cent of the total. In individual experiments there is sometimes considerable deviation from this average ratio. However the averages are significant because the most important analysis which can be made of the effects of drug administration on the colon is the extent to which each drug or drug combination affects the ratio of total motility to propulsive motility which normally is about 10:1. Of course the quantity and quality of motility is subject to variation in the same and different human and canine subjects. During the course of an experimental period sudden changes in tonus and motility may occur which cannot be predicted. This emphasizes the necessity of obtaining numerous control studies when drug effects are to be evaluated. The averages of a number of tests minimize the error due to such spontaneous changes. In the human colon, periods of quiescence in a given segment may endure for as long as 60 minutes. On the other hand, periods of activity 180 minutes long have been observed in a segment of distal colon. Further the activity of one segment is not an index of the type or the presence or absence of activity in a segment 3 to 4 inches proximal or distal. As in the dog at times the motility of two adjacent segments appears to be integrated or co-ordinated at other periods inco-ordinated.

The averages for the 30 control periods on the 4 dogs (Table I) and are similar to those for the human (Table II). The action of the drugs on the dog's colon will be presented first.

The action of pituitrin. Dog. In 27 experiments of 150 minutes duration (Table I) surgical pituitrin injected intravenously at a rate of 0.1 cubic centimeter per 10 seconds for 5 units or intramuscularly in 5 unit doses (0.15 to 0.25 units per kgm.) invariably inhibited motility almost immediately and often definitely decreased the tonus. This effect lasted for from 30 minutes to several hours. In 30 of the experiments (intramuscular injection) de-

pression of the motility took place in 5 to 10 minutes regardless of whether the drug was injected at a time when the colon was showing strong spontaneous motility or was in a state of quiescence. The distal colon was more profoundly depressed than the proximal, often remaining quiet for an hour after the motility in the proximal colon had returned to normal. In 2 instances it was observed that at least one balloon containing segment in the proximal colon was active whereas the remaining balloon containing segments in the proximal and distal colon were quiet.

In 12 experiments (Table I) smaller doses of pituitrin ranging from 1 to 2 units also inhibited motility but for a shorter time. Larger doses of pituitrin (10 to 15 units) sometimes had a side effect causing apprehension on the part of the animals, but the effect on the colon was the same. At no time was any stimulation of the colon motility in the unanesthetized dog seen after doses of pituitrin ranging from 1 to 15 units were injected. As one would expect, administration of pituitrin caused inhibition of balloon bolus propulsion and decreased propulsive force measurements when those techniques were employed (Table I). The results on the human colon were quite opposite (*vide infra*).

Physostigmine sulphate Dog. By trial it was determined with the 4 balloon tandem technique that 1 milligram (0.015 to 0.025 mgm. per kilogram) of physostigmine given intramuscularly to 4 dogs was effective in producing propulsive motility. Two milligrams was too powerful, causing repeated defecation in all dogs, while 0.5 milligram stimulated the colon in only 12 or 16 experiments. One milligram in 14 experiments gave no untoward side effects, and the tandem balloon system showed that the whole colon participated in the reaction. However tonus was increased and maintained at a high level in only 3 instances. Most frequently rapid tone changes appeared in the form of propulsive type II contractions which were propagated distally from the proximal to the distal colon.

Eight experiments conducted on 4 dogs using the balloon bolus technique (3, 5) showed that the bolus moved rapidly from proximal

TABLE II—QUANTITATIVE DATA PERTAINING TO PROPULSIVE AND NONPROPULSIVE MOTILITY IN THE HUMAN COLON AFTER DRUG ADMINISTRATION

Experiment	Drug and dose (mgm)	Experiments 1 hr. after last meal						Experiments 30 min. after last meal

‡Physostigmine—Eli Lilly and Co. (Eli Lilly and Co., Inc.).

colon to distal colon after administration of 1 milligram of physostigmine. Single integrated type II contractions were capable of moving the bolus 10 to 15 centimeters in a few seconds. In only 1 case did a wave initially propel the bolus orally (reversed movement) for about 4 centimeters after which a second wave shifted it distally. Light additional experiments conducted upon the 4 dogs with the propulsive force measuring apparatus (4) showed that the colon motility following the injection of 1 milligram physostigmine intramuscularly was highly propulsive. Tracings were obtained in which the individual type II contractions registered a propulsive force equivalent to 120 grams. Such waves of propulsion were recorded for 1 to 2 hours after the initial reaction of the colon to the physostigmine occurred from 15 to 25 minutes after intramuscular injection, and endured for several hours (Table I).

Prostigmine methylsulphate. Dog. Lighten experiments conducted on 4 dogs with the use of the tandem balloon technique and the techniques used to measure propulsive motility revealed that prostigmine in doses of 1 cubic centimeter of a 1:4000 solution (0.25 mgm) gave about the same results as 0.5 milligram of physostigmine. Doses of 1 cubic centimeter of a 1:2000 solution (0.5 mgm) were much more effective and were equivalent in action to 1 milligram physostigmine. The propulsive waves were coordinated so that they were propagated to adjacent distal segments of the colon. No side effects other than increased salivation were noted with even 2 cubic centimeters of 1:2000 prostigmine methylsulphate, but motility initiated in 8 such experiments on 4 dogs resulted in defecation (Table I).

Drug actions on the colon of man. In the experiments on the human subject the blood pressure and heart rate were recorded at 5 and

then 10 minute intervals during the first hour after injection of the drugs.

Pituitrin. Man. In 31 experiments surgical pituitrin in doses of 1 to 2 units was injected intramuscularly into the 4 subjects. Within 3 minutes after injection (Figure 2 A) and in 28 instances strong co-ordinated type II contractions resulted, which were sensed by the subjects and culminated in the expulsion of material and flatus from the colostomy. The action of pituitrin in this dosage usually persisted for 15 to 20 minutes. In 2 experiments the response was slight, in 1 instance the pituitrin had no discernible effect.

As indicated in Table II the total motility during the first 50 minute period was slightly below the control level, but there was a decided increase in propulsive motility. With these small doses the blood pressure and heart rate were not changed and the subjects had no sensations other than those associated with propulsion of colon contents.

Physostigmine sulphate. Man. Twenty experiments were conducted in which physostigmine in doses of 1 or 3 milligrams were injected intramuscularly. Expulsion of colon material and flatus occurred in from 20 to 40 minutes after injection due to an increase in total and propulsive motility (Table II). With 1 milligram the results were variable in the different subjects. One patient was nauseated on 3 occasions, and vomited during one period 2 hours after injection. The colon of a second patient showed no reaction to the injection of 1 milligram of physostigmine and he manifested no side effects. On other occasions he was given 1 to 3 milligram injections and both the propulsive and nonpropulsive motilities were decidedly increased. Heart rate and blood pressure were not changed with these doses nor did he have sensations other than those resulting from increased colon motility.

If the dose of physostigmine is sufficient to initiate colon motility the stimulation may persist for several hours after injection (Table II). When the doses were graded for each subject, physostigmine acted on the colon without producing side reactions. However no correlation was found between the weight of the patient and his tolerance to physostigmine. Furthermore the reaction of the colon

to 1 milligram of the drug varied in the same individual on different occasions. Therefore, an accurate correlation between these dosages and effect on colon motility was not evident.

Simultaneous injection of pituitrin and physostigmine sulphate. Man. In 22 experiments, 1.25 units of surgical pituitrin plus 0.7 to 1 milligram of physostigmine were injected simultaneously. Pituitrin action appeared within a few minutes and endured for about 20 minutes. Following the action the physostigmine effect became manifest and lasted for several hours. It seems significant that whereas 1 milligram of physostigmine used alone failed to produce a good motor effect in this one patient referred to previously on 3 of 6 occasions a good motor reaction resulted from the physostigmine when combined with pituitrin. The second patient who was nauseated by 1 milligram of physostigmine manifested a good motor response without nausea to 0.7 milligram plus 1.25 units of pituitrin. In the 2 remaining patients no definite evidence of synergistic action of the 2 drugs was obtained but there was no doubt regarding the supplementary effects of the 2 drugs.

With physostigmine alone in adequate dosage, especially with the combination of pituitrin and physostigmine, facilitation of the gastrocolic reflex to a meal ingested 2.5 hours after injection was almost uniformly observed.

Prostigmine methylsulphate. Man. Prostigmine methylsulphate in doses of 1 cubic centimeter of a 1:4000 solution (0.25 mgm.) and 1 cubic centimeter of a 1:2000 solution (0.5 mgm.) was given intramuscularly in 30 experiments of 150 minutes duration (Table II). Twelve of these experiments on 4 subjects using the 0.25 milligram dose resulted in augmented motility in 7 instances. There was an increase in both the total and propulsive motility. With this dose, however the time of onset of action was variable. The shortest latent period was 20 minutes and the longest 1.0 hours. Tonus during the period of observation was sometimes, but not uniformly, increased. In 3 instances the increase in total and propulsive motility was slight, and in 2 there was no apparent effect. The latter 2 and 1 of the former 3 occurred in same patient who was not affected by 1 milligram physostigmine.

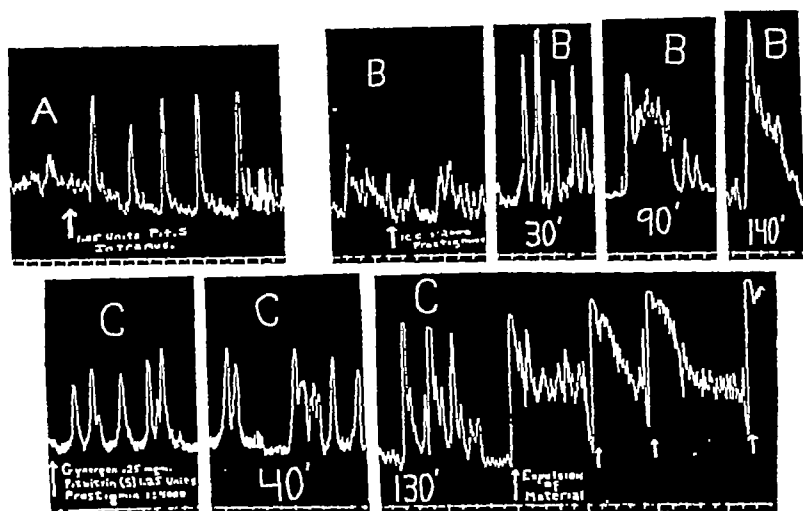

Fig 2 A, Propulsive motility in the colon of man initiated by 1.25 units surgical pituitrin injected intramuscularly, B, propulsive and nonpropulsive motility in the colon of man after intramuscular injection of 1 cubic centimeter of prostigmine 1:2000 (0.5 mgm), C, motility after simultaneous intramuscular injection of gynergen (ergotamine tartrate 0.25 mgm), surgical pituitrin (1.25 units), and 1 cubic centimeter prostigmine 1:4000 (0.25 mgm). The last 4 arrows indicate expulsion of material from the colon.

Eighteen injections of prostigmine methylsulphate (0.5 mgm) were made in the 4 subjects. In all cases there was a definite increase in propulsive and total motility (Figure 2, B) for several hours (Table II). However, as with the smaller dose there was variation in the time of onset of motility. The shortest latent period was 12 minutes and the longest 80 minutes. Facilitation of the gastrocolic reflex was definite in 14 of the experiments. There were no side reactions or definite changes in heart rate and blood pressure encountered in any experiment with prostigmine methylsulphate in these dosages. One cubic centimeter of prostigmine 1:4000 (0.25 mgm) was found to be about as effective in activating the colon segments as 0.5 milligram of physostigmine sulphate, while 0.5 milligram of prostigmine was equivalent to 1 milligram of physostigmine in 3 patients and apparently better in 1.

Prostigmine bromide tablets (15 mgm). *Man.* One tablet containing 15 milligrams of prostigmine bromide was administered by mouth in 16 experiments. During the experimental time (3 hours) the drug in 11 instances produced no decided action (Table II). On 5

occasions the action appeared about 2 hours after administration, as evidenced by an increase of total and propulsive motility with expulsion of material. These facts do not indicate that the drug is not effective by mouth because in all cases except one, the subjects reported the repeated evacuation of colon contents when they were at home. This action appeared during a period 5 to 8 hours after the tablet was given, and a decided increase in this effect followed ingestion of a meal.

Prostigmine methylsulphate (0.25 mgm) plus pituitrin (1.25 units). *Man.* In all of 16 experiments, the combination of 0.25 milligram of prostigmine methylsulphate and 1.25 units of pituitrin injected intramuscularly caused an increase in total and propulsive motility and resulted in the expulsion of colon material and flatus. The expulsion of material occurred within a few minutes and continued for several hours, the initial response being due to the pituitrin and the continued response to prostigmine. As in the experiments in which pituitrin was combined with physostigmine, it was difficult to be certain of synergistic action, since each drug is individ-

ually effective. However in all cases the action of prostigmine (0.25 mgm.) seemed to be more effective in expelling colon contents when combined with pituitrin than in those experiments in which it was injected alone. No side reactions or changes in blood pressure or heart rate were noted with this combination.

Ergotamine tartrate solution and tablets (Gynergen) Man. In 12 experiments ergotamine tartrate was injected in doses of 0.25 milligram, with no discernible effect on the colon. In 6 additional experiments 1 tablet of gynergen (1 mgm.) was given by mouth. Our motility records showed no deviation from normal expectancy, nor were latent actions on colon reported by patients. With these dosages no side reactions occurred.

In 14 experiments on the dog it was found that 0.35 milligram of ergotamine tartrate (0.0097 to 0.0184 mgm per kilogram) given intramuscularly caused an increase in both the propulsive and nonpropulsive motility. In 7 instances the increased motor activity culminated in defecation. However the human subjects varied from 63 to 86 kilograms therefore on the basis of body weight the dogs received 4 to 6 times as much ergotamine.

Ergotamine tartrate (0.25 mgm.) plus prostigmine methylsulphate (0.25 mgm.) Man. As indicated above ergotamine in 0.25 milligram doses injected intramuscularly had no action on the motility of the colon. However when this dosage of ergotamine was combined with 0.25 milligram prostigmine methylsulphate in all of 12 experiments a potentiation of the prostigmine action resulted. The motility initiated by this combination was even more propulsive than that resulting from 0.5 milligram prostigmine (1 c.c. of 1:2000 solution) when used alone. Motility appeared on an average much sooner (28 min.) and apparently had an increased capacity to move colon contents. The total quantity of motility initiated was about the same as that observed after prostigmine (0.5 mgm.), but the propulsive motility was somewhat increased (Table II). This propulsive motility was very powerful. On two occasions the most proximal balloon was tied into a simple knot even though the tube and balloon were reinforced by a flexible steel spring. Facilitation of the gastrocolic

reflex to a meal ingested several hours later was definite in all 4 subjects.

In 8 additional experiments, after a control period of 30 minutes, 1 tablet of ergotamine tartrate (1 mgm.) was given simultaneously with 1 tablet of prostigmine bromide (15 mgm.) In an average time of about 90 minutes the action of the prostigmine bromide became evident. Although the effect of the drugs together did not last longer than the prostigmine bromide alone, the response was more marked and was associated with repeated expulsion of fecal material and flatus.

Five of the experiments were conducted during the morning session and facilitation of the gastrocolic reflex to lunch was evident. An increased motility during the afternoon session was graphically recorded. Both the nonpropulsive and propulsive motilities were increased. The 3 remaining experiments of this series were conducted in the afternoon. The patients however reported facilitation of the gastrocolic reflex to their dinners 6 hours later as indicated by repeated evacuations of colon contents.

Simultaneous administration of prostigmine methylsulphate, pituitrin and ergotamine tartrate. Man. Table II presents the results of 12 experiments in which a combination of ergotamine tartrate (0.25 mgm.) prostigmine methylsulphate (0.25 mgm.) and pituitrin (125 units) was injected simultaneously. An increase in both total motility and propulsive motility resulted, the latter being very definitely increased and causing the expulsion of colon contents. The enhanced motility was evident within a few minutes, due to the pituitrin action and endured for several hours due to the marked synergistic action of the ergotamine and prostigmine. Only 12 experiments were conducted because of the potency of the mixture. On 3 occasions the proximal balloon was tied into a simple knot. This occurred immediately after very strong type II propulsive waves which caused expulsion of colon contents and sometimes the balloon and tube (Figure 2 C).

Most important is the fact that this strong action on the colon was not accompanied by side effects. The subjects felt well, with no significant changes in pulse rate or blood pressure.

EVALUATION

The importance of distinguishing between the two functional types of motility, propulsive and nonpropulsive, is confirmed by certain observations presented in this as well as in previous papers (1, 3, 4). For example, it has been shown that morphine sulphate (16 mgm) increases the total motility and tonus of the distal colon and the ileum of man (2). However, the increase in total motility is the result of an increase in motility of the non-propulsive type, the propulsive motility and discharge of colon contents is markedly decreased. In the present work if we had given attention only to the recording of total motility we should have concluded that pituitrin decreased or had little effect on the motility of the colon. The records of propulsive motility, however, showed that propulsive motility and discharge of contents from the colostomy were increased for a short period after injection of a small quantity of pituitrin. Physostigmine sulphate and prostigmine methylsulphate are examples of drugs which stimulate both functional types of motility. Thus we have examples of 3 types of drug action on the colon: *one exemplified by morphine in which the chief effect is an increase in nonpropulsive and a decrease in propulsive motility, a second exemplified by pituitrin in which the chief effect is an increase in propulsive motility with little or no increase in the nonpropulsive, and a third exemplified by prostigmine in which both types of motility are increased.*

The importance of using, at least in some experiments, a tandem balloon system in studying drug action on the colon is confirmed by observations made in this work. In a previous study it was observed that effective propulsive motility (the transportation of contents) is dependent upon the existence of co-ordination between adjacent segments. That is, if distal adjacent segments of the colon manifest high tonus, or types of motility not conducive to co-ordination of activity, the appearance of a propulsive wave in a proximal (oral) segment will not be propagated onto the adjacent distal segment to effect transportation of colon contents. In such instances, if the propulsive wave in the proximal segment is high grade and does not "pass

onto" the distal segment, the patient reports a "cramp-like sensation." This has been referred to as dyskinesia. In a number of instances dyskinesia was observed and a "cramp-like" sensation was reported after 1 milligram of physostigmine. No contents were passed from the colostomy. Contents were present in the colon, since later a wave of no greater amplitude than formerly would arise, be propagated to the distal segment and contents would be expelled. Any existing cramp-like sensation would then disappear.

Prostigmine methylsulphate and pituitrin in the doses used in our subjects, appeared to promote a co-ordinated type motility between segments, resulting in propulsion of contents. Propulsive waves were quite uniformly propagated and cramp-like sensations were not reported. It is entirely possible that in some subjects, depending upon the degree of dyskinesia existing between adjacent segments of the colon, the amount of gas present and the consistency of the colon contents, the same doses of the two drugs might cause cramp-like distress. It must be remembered here that our studies were made on presumably normal colons under uniform, controlled conditions.

The combination of *physostigmine sulphate with pituitrin* resulted in the addition of the effects of each. The rather prompt and transient action of pituitrin in the small dose used, was followed by the more delayed and prolonged action of physostigmine. The only evidence of synergistic action was observed in 1 patient who did not respond to 1 milligram of physostigmine alone, but did to the combination of pituitrin and physostigmine. The same was true of the *prostigmine methylsulphate with pituitrin* combination. This latter combination is to be preferred since doses of prostigmine (0.25 mgm) and pituitrin (1.25 units) which caused strong propulsive movements gave no side reactions as do similarly effective doses of physostigmine.

Ergotamine tartrate (0.25 mgm) alone had no significant effect on the motility of the colon of our subjects. When ergotamine tartrate was combined with prostigmine methylsulphate (0.25 mgm) the action of prostigmine was definitely augmented, i.e. 0.25 milligram of prostigmine was as effective as 0.5 milli-

gram given alone. Contents were still being discharged at the end of a 3 hour period of observation and the "gastrocolic" reflex was facilitated this indicates that the propulsive motility of the small intestine was also augmented. Ergotamine tartrate and prostigmine were combined on the presumption that the ergotamine would increase the excitability of the colonic musculature by direct action and hence augment the response to prostigmine. This explanation may be too simple, but is supported by the observation that ergotamine increases the sensitivity of the intestine to distention and the initiation of peristalsis (27). From the results on the normal colon, this combination we believe should be tried clinically in cases of postoperative distention.

The most effective combination, in regard to the duration of action appeared to be ergotamine tartrate (0.25 mgm.) prostigmine methylsulphate (0.25 mgm.) and pituitrin (1.25 units). It was effective and our subjects complained that, after receiving this combination material was intermittently discharged from the colostomy for 6 to 8 hours after injection. With the combination of the 3 drugs the most powerful propulsive contractions we have recorded (Fig. 3 C) occurred. As noted before, in 3 instances these contractions tied the most orally located balloon into a simple knot. No cramp-like distress or side reactions were reported to accompany the powerful propulsive motility initiated by this combination. We believe that this combination should also be studied in adynamic ileus and megacolon since the duration of action on the colon of 4 normal subjects extended over a period of 6 to 8 hours.

The concept of functional segmental motor activity of the colon. Our observations show that the colon is composed of functional segments which cannot be described on a structural basis. Anatomically the segments of the colon are usually referred to as the ascending, transverse, descending and sigmoid colon. On the basis of motor activity the colon is composed of small or large divisions depending on the type of motility which is being manifested at any particular time. When 3 centimeters (length) balloons in series are placed 7 centimeters apart, 2 adjacent segments may

manifest different types of motility. In this sense each segment represents a functional unit. When 2 adjacent segments manifest the same general type of motor activity so that a wave conducive to propelling material is propagated from one to the other then the 2 segments represent an integrated or co-ordinated functional unit. In a "mass peristalsis" as in defecation an entire anatomic division of the colon represents a functional unit, so that occasionally a "mass peristalsis" starting in the distal transverse colon may pass over a number of segments in sequence including the rectum.

We have no information regarding the presence or absence of motility in the segments of the colon between the balloons, except when a propagated wave passes from one balloon-containing segment to another. In mass, a single haustrum or a group of adjacent haustra may represent a functional motor unit, and the balloon may record the activity of the local group of haustra. Thus, a local type II contraction may represent propulsion from, or an attempt to propel material from, one haustrum to another. The type I contractions represent the nonpropulsive activity of the haustra exposed to the balloon. The change of a type I into a segmental type II wave which is not propagated to the adjacent balloon-containing segment would indicate that some stimulus has caused the local haustra to become co-ordinated so that local propagation of a wave for a short distance can and does occur. For a mass peristalsis the co-ordination must spread in sequence from one haustrum or group of haustra to another or the original stimulus must in some way exert a widespread integrating influence, probably sequential, on the more distal segments of the colon. The rise in tone or wave-like sustained contraction manifested in the type III activity must represent a simultaneous contraction of several haustra since it is difficult to visualize how the contraction of a single haustrum could produce the observed mechanogram.

This concept of the functional segmental motor activity of the colon serves as a basis for the explanation of the normal physiological activity of the colon and readily explains the findings or results of the so called unstable or

irritable colon, which represents a dyskinesia of the colon. This concept requires that, if a drug is to be effective in adynamic ileus, it must not only increase the tone of the musculature but must also act so as to facilitate the genesis and propagation of propulsive waves from one segment to another. A drug that would only increase tone and non-propulsive motility would lead only to a churning and local pooling of the contents giving a "sausage-string" effect. Considering the duration of action and the absence of side effects, prostigmine methylsulphate is the best single drug among those studied, for the genesis and propagation of propulsive waves from one segment to another. The other drugs as pituitrin and ergotamine tartrate may be used to supplement or potentiate prostigmine methylsulphate.

SUMMARY AND CONCLUSIONS

The functional motor activity of the canine and human colon can be best described as being propulsive or nonpropulsive in character. The relation between the types of contractions recorded by the balloon method and the functional result has been outlined.

The data obtained in 70 control studies on 4 human subjects with colostomy show that the propulsive motility in the distal colon constitutes on the average about 10 per cent of the total motility. This value is similar to that obtained in 4 dogs, the average being about 13 per cent. The effects of single drugs and their combinations were analyzed for the extent of change in the 2 types of functional activity. All solutions were given intramuscularly, the tablets were given by mouth.

1 Pituitrin in the relatively small dosage of 1 to 2 units caused an increase in the propulsive motility of the human distal colon but did not on the average increase the total motility above the control. In the dosage used its action usually did not last longer than 20 minutes. The action of pituitrin on the colon of the unanesthetized, trained dog with appendicostomy was opposite to that on the human colon. Doses of 1, 2, or 5 units invariably depressed motility and sometimes tonus. This depression, depending upon the dose, was manifest for from 30 minutes to

several hours, the distal colon being more affected than the proximal.

2 In doses of 1 milligram, physostigmine sulphate increased the total and propulsive motility of the canine and human colon. It was difficult to grade the dosage so as to avoid side reactions and yet stimulate adequately the propulsive motility of the colon.

3 The simultaneous injection of 1 to 2 units of pituitrin and 0.7 to 1.0 milligram of physostigmine sulphate resulted usually in a supplementary action on the human colon. In 3 subjects the pituitrin acted first, increasing propulsive motility and was followed by physostigmine action which increased both propulsive and nonpropulsive motilities. In one subject there was an apparent synergistic action because in 3 of 6 instances 1 milligram of physostigmine when injected alone elicited no definite colon response.

4 Prostigmine methylsulphate in doses of 0.25 milligram was approximately equal in its action to 0.5 milligram of physostigmine on the motility of the human and canine colon. The 0.25 milligram dose was not effective in all experiments. When the dosage was increased to 0.5 milligram effective propulsive motility resulted in all cases. The nonpropulsive motility was also increased. No side effects were noted with either of the above dosages in dog or man.

5 Prostigmine bromide tablets (15 mgm) given orally to the 4 human subjects resulted in an increase in total and propulsive motility, during the experimental time (150 min), on only 5 occasions. In 10 experiments increased expulsion of colon material occurred 5 to 8 hours after administration. In 1 instance there was no effect.

6 The simultaneous injection of prostigmine methylsulphate (0.25 mgm) and pituitrin (1.25 units) resulted in an increase of propulsive as well as nonpropulsive motility of the human colon. The pituitrin in this dosage initiated propulsive motility which lasted for about 20 minutes, then the prostigmine action appeared and usually endured for several hours. In 1 patient synergistic action apparently occurred since in all cases when the 2 drugs were injected simultaneously the response to prostigmine was definite, whereas

in those experiments in which 0.25 milligram of prostigmine methylsulphate alone was used the response was not definite.

7 Injection of ergotamine tartrate (0.25 mgm.) intramuscularly or 1 tablet (1 mgm.) by mouth had no discernible effect upon the colon of 4 human subjects with colostomy.

8 The simultaneous injection of ergotamine tartrate (0.25 mgm.) and prostigmine methylsulphate (0.25 mgm.) resulted in potentiation of the prostigmine. Both nonpropulsive and propulsive motilities were increased above that initiated with prostigmine (0.25 mgm.) alone.

9 Ergotamine tartrate in tablet form (1 mgm.) and prostigmine bromide in tablet form (15 mgm.) given simultaneously by mouth to the 4 human subjects resulted in the appearance of strong propulsive motility in from 1 hour to several hours after administration. The duration of action was not longer than that of 15 milligrams prostigmine bromide alone, but the greater efficiency in initiating propulsive motility which evacuated colon contents was evident.

10. The simultaneous intramuscular administration of ergotamine tartrate (0.25 mgm.) prostigmine methylsulphate (0.25 mgm.) and surgical pituitrin (1.25 units) resulted in the appearance of propulsive motility within a few minutes due to pituitrin action and the subsequent continuation of strong propulsive motility attributable to the potentiation of prostigmine by ergotamine.

11 Phystigmine sulphate, prostigmine methylsulphate and the combinations of prostigmine with ergotamine and pituitrin facilitated the gastrocolic reflex to a meal in gested several hours after administration of the drugs.

12 It is believed that a combination of ergotamine tartrate (0.25 mgm.) prostigmine methylsulphate (0.25 mgm.) and pituitrin (1.25 units) should prove to be more effective in the management of postoperative distention than any of the drugs used alone. On the basis of duration of action, the absence of side reactions with doses which are effective in producing strong propulsive motility

prostigmine is ranked as the best single drug yet investigated.

AMPUTATION OF THE LOWER EXTREMITIES IN OCCLUSIVE ARTERIAL DISEASES

A Ten Year Review

HARRY B MACEY, M D , and WILLIAM H BICKEL, M D , Rochester, Minnesota

THIS report is based on a study of those cases observed at the Mayo Clinic in 10 years, in which occlusive arterial disease of the lower extremities was treated by amputation. In order to make a comprehensive study we reviewed the records in groups of cases in which, respectively, the clinical diagnosis was thromboangitis obliterans, arteriosclerosis obliterans associated with diabetes, arteriosclerosis obliterans alone, and acute arterial occlusion. There were features common to all these groups, however, which should be considered (Table I).

The diagnosis of occlusive arterial disease of the lower extremities is based on the finding of diminished to absent pulsation in the femoral, popliteal, posterior tibial, and dorsalis pedis arteries. Confirmatory evidence, as would be expected, is noted more easily in the distal end of an extremity and may vary from lowered surface temperature of the part to ulcers, gangrene of the digits or frank gangrene of the foot in the more advanced cases. The most characteristic symptom is claudication, which is an aching or cramplike sensation occurring chiefly in the calf of the leg. Claudication is brought on by exercise and is relieved by rest. Other symptoms described by the patient may be coldness of the feet, a tingling sensation in the toes or changes in color such as pallor and rubor.

The diagnosis in advanced cases of occlusive arterial disease is not difficult. In early cases or in those of mild involvement, the arteries should be carefully examined as to quality of pulsation, and the skin should be observed for abnormal pallor when the affected extremity is elevated for a few minutes,

for slow return of color when the extremity is placed in dependent position after elevation, and for abnormal rubor when it has been in the dependent position for a few minutes. All these manifestations are pathognomonic of an occlusive process of the arteries.

In selecting the site for amputation, the surgeon should not be too strictly governed by standard levels, but should be guided by the blood supply as noted by means of exploratory incisions at the time of surgical intervention. Naturally, it is safer in any case of occlusive arterial disease to perform amputation above, or at the level of, the knee joint. However, in the case of a young person who has an arterial disease such as thromboangitis obliterans, an attempt to secure a satisfactory stump below the knee should be made when there is a reasonable chance to secure satisfactory healing. More will be said on this subject when thromboangitis obliterans is considered.

One type of amputation of lower extremities has been employed at the clinic fairly consistently throughout. In the thigh, a long anterior and a short posterior flap are used, with corresponding incisions throughout the muscles and fascia. The vessels are ligated doubly and the nerves are identified and injected. In some instances alcohol is used for injection, whereas in other instances 10 cubic centimeters of a 1 per cent solution of procaine hydrochloride is injected into the nerve both before and after it is severed. To our knowledge, neuromas have not formed in those cases in which procaine hydrochloride has been injected, but as to the question of the superior efficacy of either substance there is no definite proof.

In amputation below the knee a long posterior and a short anterior flap are used. The crest of the tibia is beveled and the fibula is

sectioned at a level 1 inch to 2 inches (2.5 to 5 cm.) higher than the tibial amputation. When amputation is made less than 5 inches (13 cm.) below the knee the prosthesis is worn with more comfort if the fibula is fixed to the tibia or if the remaining fibular fragment is excised. Drains are employed in those cases in which there is associated lymphangitis or spreading cellulitis. The wounds are closed snugly.

We noted that in all groups of occlusive arterial disease if there is present an open lesion with gangrenous tissue, one complication is potential that is, gas gangrene infection. Such a complication followed 4.1 per cent of the primary amputations which were performed (Table I). Among the 11 patients represented by these 11 amputations, there were 5 deaths, 3 of which occurred in the group of cases of arteriosclerosis obliterans without associated diabetes. Amputation in 2 of these 3 cases was carried out, respectively at the lower and at the middle third of the thigh and in the third case, below the knee. In 2 of the 3 cases death was attributed directly to gas gangrene infection. Death in the third case occurred as the result of pneumonia on the 18th day after operation, at which time the gas gangrene infection had been controlled however one must consider the infection as contributing to the death. Death in the 2 other of the 5 cases occurred in the diabetic group and was attributed directly to gas gangrene infection. One of these 2 patients had undergone am-

putation through the thigh and the other below the knee.

From the clinical observation of the formation of gas in the soft tissues and from the recovery of *Clostridium welchii* from culture in several cases of vascular disease in which gangrene and infection developed about the toes and feet, we believe that in every case in which an open lesion is associated with gas gangrene and infection postoperative gas gangrene infection is likely to occur. Prior to surgical operation, the patients appear to possess a defense mechanism against the local presence of the organism, as is evidenced by the absence of generalized symptoms of such a malignant infection. It is likely that the superficial position of the bacteria plays a rôle in their failure to produce general symptoms. In those cases in which virulent gas gangrene infection develops after surgical intervention, the symptoms of undue pain, elevated temperature and rise in pulse rate are manifest, usually within 24 to 36 hours, and inspection of the stump is warranted. A less virulent infection may develop several days after amputation. The organism may be introduced into the wound at the time of amputation or may be present in the lymphatic spaces before operation. Needless to say the stump, with its traumatized muscle and fascia and some inevitable postoperative bleeding, is a fertile field for the organism regardless of its point of entrance. With definite evidence of the presence of *Clostridium welchii* in the foot before surgical operation, one is inclined to believe, if postoperative infection develops, that the organism may have been in the tissue locally and that its action may have been hurried by the surgical procedure, which provided the anaerobic condition necessary for the bacterial growth. In our experience stumps have not been protected from gas gangrene infection by prophylactic polyvalent perfringens antitoxin.

THROMBOANGITIS OBLITERANS

Thromboangitis obliterans, more commonly referred to as Buerger's disease is a condition resulting from chronic inflammation of the blood vessels with formation of thrombus and a resultant decrease in arterial circulation to the affected part.

TABLE II—THROMBOANGITIS OBLITERANS—SITE OF PRIMARY AMPUTATION AND PRESENCE OR ABSENCE OF POSTOPERATIVE COMPLICATION

ON REUSE OF								
Complication	Patients or procedure	Site of primary amputation						Totals
		Below knee		Through thigh		Through knee (Gritti-Stokes)		
		Patients*	Primary amputations	Patients*	Primary amputations	Patients*	Primary amputations	
Present	Patients*	25		3		1		29
	Primary amputations		25		3		1	29
Absent	Patients*	33		26		1		60
	Primary amputations		38		29		1	68
Total		58	63	29	32	2	2	

*The number of patients represented in this table adds to 89. Actually there were only 83 patients. The discrepancy arose because 6 patients underwent primary amputation of one lower extremity without complication resulting but also underwent primary amputation of the other lower extremity with complication resulting. These 6 patients are counted both in the group in which complications were present and in that in which they were absent.

Thromboangitis obliterans affects, primarily, middle aged persons. It occurs chiefly among men, although it is not confined to males as has been previously thought. However, there were no women in the group of patients who, in the ten years from 1930 to 1939 inclusive, required amputation of one or both lower extremities for thromboangitis obliterans at the clinic. If either lower extremity must be removed for this disease, the patient should plan for a stay in the hospital of about 3 weeks. For our group of 60 patients whose recovery was uncomplicated (Table II) the average period of hospitalization, after the primary surgical intervention, was 21 days. Various methods of anesthesia may be used.

Little need be said, in addition to what is shown in Table II, concerning the site of primary amputation and the incidence of postoperative complications. The nature of the complications and the necessary secondary measures, however, have a bearing on the results and merit some remark.

Of the 25 primary amputations below the knee, which resulted in complications (Table II), 22 were followed by reamputation and 3 were not. Of the 22 reamputations, 7 were below the knee and 15 above. Following 2 of the 7 amputations and 3 of the 15 amputations just mentioned, gas gangrene infection occurred. In 1 of these 5 cases of gas gangrene, the blood stream became infected. Concerning the 25 amputations mentioned in the first

sentence of this paragraph it has been indicated that following 3 of them reamputation was unnecessary. Of these 3 amputations, subsequent to 2 of them, infection took place and subsequent to the third, a slowly healing ulcer developed.

Referring to Table II again. Of the 3 primary amputations through the thigh, which resulted in complications, 1 was followed by reamputation and 2 were not. Of the 2 instances just mentioned, the complication consisted in infection in one and a slowly healing ulcer in the other. The one amputation through the knee (Gritti-Stokes), which is found in the same category in Table II as the cases just considered, was followed by reamputation.

From what has just been said of reamputation, as well as from what is evident in Table II concerning the site of primary amputation, those who previously have been interested in the subject will deduce that in this group of middle aged men, more careful effort is made to amputate at the lowest level of circulatory adequacy than in any other group of patients. Although application of this principle results in a relatively high percentage of reamputations, there were no deaths in the group just reported, only one general complication occurred, and a serviceable stump below the knee was obtained in 76 per cent of the cases. We believe that this result justifies trial of primary amputation below the knee in a large percentage of those cases of thromboangitis

TABLE III.—ARTERIOSCLEROSIS OBLITERANS WITHOUT DIABETES—SITE OF PRIMARY AMPUTATION, PRESENCE OR ABSENCE OF POSTOPERATIVE COMPLICATIONS AND THE MORTALITY

Complications	Patients or procedures	Site of primary amputation					
		Below knee		Through thigh		Totals	Deaths
		Patients*	Primary amputations	Patients*	Primary amputations		
Present	Patients*	6		16		22	1
	Primary amputations				16	22	
Absent	Patients*	3		11		14	
	Primary amputations				11	14	
Totals		9	1	27	27	36	1

*The number of patients represented in this table adds to 34. Actually, there were only 30 patients. The discrepancy arose because 4 patients underwent primary amputation of one lower extremity without complication resulting but also underwent primary amputation of the other lower extremity with complications resulting. These patients are counted both in the group in which complications were present and in that in which they were absent.

obliterans in which amputation must be performed.

ARTERIOSCLEROSIS OBLITERANS WITHOUT DIABETES

In our series of surgical amputations for vascular deficiencies the cases in which diagnosis was made of arteriosclerosis obliterans without diabetes rivaled in number the cases of thromboangiitis obliterans. Clinically however these 2 conditions presented wide variance in statistical findings.

Seventy of the patients were males and 10, females. Because of the advanced age of these patients one would anticipate the presence of complicating conditions. Acceptable methods of anesthesia, therefore are fewer than the methods acceptable in cases of thromboangiitis obliterans. We favor spinal anesthesia in the presence of arteriosclerosis obliterans.

As is indicated in Table III of the 32 patients who experienced postoperative complications, 13 died. Of these 13 patients, 12 had been subjected to primary amputation through the thigh and of one the primary amputation was below the knee. The death of 3 of the 13 patients was attributed to bronchial pneumonia, of 2 to coronary disease with congestive heart failure of 2 others to cerebrovascular accidents, of 1 to uremia, of 1 to multiple emboli and of 3 to gas gangrene infection. These are in contradistinction to 5 cases of thromboangiitis obliterans in which gas gangrene infection occurred after surgical intervention, with no resultant deaths.

In the 9 remaining instances of the 22 in which postoperative complications occurred, the difficulty arose in healing of the stump. In 3 instances in which postoperative complications occurred and reamputation was not required, convalescence after primary amputation through the thigh was complicated by slow healing because of circulatory deficiency. Six patients, or approximately 8 per cent of the 80 patients in this group were subjected to reamputation before a satisfactory stump was obtained. It is interesting to note that 4 of the 6 reamputations were done on patients who had been subjected to primary amputation below the knee. The outstanding fact brought out in this series of 80 cases then is that, because of the 2 interdependent factors of advanced age and consequent complicating conditions 82 per cent of the primary amputations were through the thigh (Table III). Amputation below the knee should be reserved for the younger patients.

ARTERIOSCLEROSIS OBLITERANS WITH ASSOCIATED DIABETES

Arteriosclerosis obliterans with associated diabetes furnished the third largest number of cases in our series of amputations for occlusive arterial disease. In this group patients were in their late years of life. The proportion of men was not so marked as it was in the preceding groups of thromboangiitis obliterans and arteriosclerosis obliterans without diabetes. However, it again demonstrates among pa-

TABLE IV—ARTERIOSCLEROSIS OBLITERANS WITH ASSOCIATED DIABETES—SITE OF PRIMARY AMPUTATION AND PRESENCE OR ABSENCE OF POSTOPERATIVE COMPLICATION

Complication	Patients or procedures	Site of primary amputation					
		Below knee		Through thigh		Totals	Deaths*
		Patients*	Primary amputations	Patients*	Primary amputations		
Present	Patients*	9		9		18	7
	Primary amputations		9		9	18	
Absent	Patients*	10		35		45	0
	Primary amputations		10		38	48	
Totals		10	19	44	47		

*The number of patients represented in this table adds to 63. Actually there were only 61 patients. The discrepancy arose because 2 patients underwent primary amputation of one lower extremity without complication resulting but also underwent primary amputation of the other lower extremity with complication resulting. These 2 patients are counted both in the group in which complications were present and in that in which they were absent.

tients who are suffering with arterial disease, as 42 of the patients were men and 19 were women.

We favor employment of spinal anesthesia. The size of the dose should be governed by the general condition and size of the patient. It is better to err in the giving of an insufficient amount of anesthetic agent for completion of the operation and to rely on supplemental agents, such as pentothal sodium, than to give large doses of the spinal anesthetic substance.

As is indicated in Table IV, 72.7 per cent of the primary amputations were followed by an uncomplicated postoperative course. Of the 18 patients who experienced postoperative complications, 7 died. Five of these 7 patients had been subjected to primary amputation through the thigh and of 2 of the 7, the primary amputation was below the knee. The deaths of 2 of the 7 patients were attributed to bronchial pneumonia, of 2, to unknown cause, of 1, to renal failure, and of 2, to gas gangrene infection. Both of the patients who died from gas gangrene infection underwent previous amputation below the knee.

In the 11 remaining cases of the 18 in which postoperative complications occurred, the difficulty arose in healing of the stump. In 6 of the 11 cases, convalescence was complicated by slow healing as a result of inadequate circulation. The postoperative course of 3 patients was complicated by infection and sloughing. In the 2 remaining cases of the 11 the complications were inadequate circulation and gas gangrene infection, respectively, both

of these patients were subjected to primary amputation below the knee, and both were subjected to reamputation. Nine, or 47.4 per cent, of the 19 primary amputations below the knee were followed by complications.

The obvious fact brought out in our series of patients with arteriosclerosis obliterans is that the association of diabetes did not increase the mortality rate but that this was found to be less than the mortality rate in those cases of arteriosclerosis obliterans without associated diabetes. This fact may be attributed to the close co-operation of the internist and the surgeon, both in the preoperative preparation and the postoperative care of the diabetic patient. It is further shown that amputations below the knee should be reserved for the exceptional case in the younger patients.

ACUTE ARTERIAL OCCLUSION

The final group of cases, those of acute arterial occlusion, was the smallest group in the series. It is composed of 16 patients (10 males and 6 females) on whom 16 primary amputations were performed, 15 through the thigh and 1 a disarticulation at the hip. There was no case in which bilateral amputation was necessary. Although the patients in this group were young, with an average age of 52 years (Table V, A), they constituted the greatest operative risk and carried the highest mortality rate of any group studied. Ten of the patients presented clinical evidence of severe heart disease before operation, 3 of the 10 having rheumatic cardiac lesions. Among

Total	16	2	12.5	5

the 16 patients there were 4 deaths a mortality of 25 per cent for the group (Table V. B). One patient died of bronchial pneumonia on the 21st day after operation the second died on the 1st day after the surgical procedure and a third on the 2nd day both deaths resulting from cardiac complications. A fourth patient died of cerebral embolism on the 9th day after operation in this case the wound was healed and the patient had been dismissed she died at her home. Two of the deaths were of women and 2 of men. In 12 or 75 per cent of the cases the left lower extremity was involved.

In this group of 16 cases, the femoral artery was occluded in 5 the popliteal artery in 10 and the posterior tibial artery in 1 case. In only 2 of the cases was there any degree of circulatory involvement of the opposite extremity. In cases in which lesions were of the left side the popliteal artery was occluded in 9, the femoral artery in 2 and the posterior tibial artery in 1 case. Of these patients 6 were men and 6 were women. In cases in which lesions were of the right side the femoral artery was occluded in 3 and the popliteal artery in 1 case none of the patients were women and no deaths were reported. The average duration of occlusion before surgical intervention with the exception of 1 case

in which a gangrene infection was of 1 year's duration was found to be 12.6 days and the average period necessary for healing after amputation was 27.7 days. In 9, or 56 per cent of the cases, the postoperative course was uneventful and primary healing occurred. In 2 cases healing was delayed 38 and 32 days, respectively. In a third case reamputation was required but healing took place on the 13th day thereafter.

COMMENT AND SUMMARY

We believe that the discrepancy in the mortality rate among the many reports is caused by the difference in environmental factors and in facilities for treatment rather than by differences in surgical technique and the varying capacity of the surgeon. There should be the closest harmony between the internist and the surgeon for the utmost efficiency in handling cases of occlusive arterial disease. Occlusive arterial disease is a condition most frequently seen in men although it is not uncommon in women. The ratio found in the series we are presenting was approximately 6.5:1. However a more nearly equal ratio was seen in arteriosclerosis with diabetes and in acute arterial occlusion. Thromboangiitis obliterans rarely affects women.

If the individual with occlusive arterial disease is of a younger age group and more especially if he has thromboangiitis obliterans, one should seek the level of circulatory adequacy for amputation. For the more elderly patients, usually found in one of the arteriosclerotic groups, amputations below the knee should be discouraged.

A complication common to all groups of occlusive arterial disease is gas gangrene in section following amputation especially in cases in which amputations are done below the knee. As we said early in this paper the value of prophylactic polyvalent perfringens antitoxin is questionable. The value of therapeutic polyvalent perfringens antitoxin has been proved. Sulfonamide drugs in postoperative infections have been proved valuable adjuncts to the armamentarium of the surgeon. In cases of spreading cellulitis or associated lymphangitis in occlusive arterial disease one of the sulfonamide preparations may be ad-

vantageously placed in the wound at the time of amputation. In general, wounds should be closed snugly unless there is some definite indication for drainage at the time of the amputation.

Hasty amputation with only emergency preparation before operation is indicated only in cases of gangrene with spreading cellulitis, gas gangrene infection, or gangrene associated with diabetes in which the diabetes is uncontrollable.

Review of the cases of acute arterial occlusion suggests that this condition has a predi-

lection for the left side and in all the cases of our series, amputation below the knee was precluded. In our opinion, acute arterial occlusion is not an emergency condition requiring immediate amputation, in the majority of cases the surgeon may safely wait for establishment of collateral circulation and a line of demarcation. Further, in acute arterial occlusion, one may anticipate a high mortality rate. This is explained by the fact that the condition which necessitates amputation is, as a rule, a complication of some underlying severe systemic pathological change.

EXTERNAL BILIARY FISTULAS

A Study of 23 Cases

N. FREDERICK HICKEN, M.D., LESLIE B. WHITE, M.D., and Q. B. CORAY, M.D.
Salt Lake City, Utah

PERSISTENT external fistulas occasionally follow surgical attacks on the extrahepatic biliary system. These tantalizing complications annoy the patients and harass the surgeons for both realize that the primary operations have failed to remove the obstructive lesions which were interfering with the free flow of bile and associated secretions into the duodenum. Corrective therapy requires the removal of the obstructions or the formation of new biliary channels.

This study is based on an analysis of 23 cases of postoperative biliary fistulas which have followed routine operations for gall stones. Etiologically they may be divided into three groups: those due to incomplete removal of the primary obstructions, those caused by surgical accidents, and those in which the external sinuses were planned for decompressive purposes only.

Incomplete primary operations accounted for 88 per cent of the persisting fistulas. This means that the provocative obstructions were not removed either because the operators did not recognize them or were incapable of performing the necessary corrective procedures. Ninety-five per cent of the initial explorations were for gall stones but in 20 instances these elusive calculi were incompletely removed. In 12 cases, 60 per cent, stones were left in the common bile duct; in 6 instances, 26 per cent, they were not removed from the gall bladder; in 1 patient multiple stones were left in the cystic duct, and in another they were overlooked in both the gall bladder and cystic duct. In every instance the operative notes stated that all stones had been removed and it was not until the draining sinuses refused to heal that true appraisals were made.

It was interesting to note that 57 per cent of the external fistulas followed cholecystotomies while only 43 per cent occurred after cholecystectomies. The higher incidence occurring with simple drainage of the gall bladder can be explained by the fact that the majority of the primary operations were performed in small rural hospitals or in charity institutions where the younger men were acquiring experience. It may be argued that the group submitting to cholecystostomy were too ill to undergo a more formidable operation but such was not the case. Studies of their hospital records reveal that all these cases were scheduled for cholecystectomies, but conditions were encountered which compelled the "occasional operator" to employ simple drainage. Ballfour and Ross estimate that 90 per cent of their 166 cases having biliary fistulas resulted from a failure to remove the gall bladder at the initial operation. They affirm that in performing a cholecystectomy the cystic and common bile ducts must be exposed thus minimizing the possibility of overlooking a migratory stone. No one who can not recognize and cope with choledochal lesions should attempt to operate for gall stones.

Surgical accidents such as, ligation, severance and crushing of the common bile duct account for a small percentage of these fistulas. On 2 occasions the choledochus was accidentally clamped while the surgeon was attempting to control annoying hemorrhages. Inexperience, inadequate exposure and speedy haphazard work propagate such errors.

Therapeutic external fistulas may be deliberately formed so as to decompress an obstructed biliary tree. For example a cholelithiasis may be so intense or the patient's condition so precarious that palliative drainage is imperative. Remedial operations are not employed until definite improvement has been made.

From the Surgical and Roentgenological Services of the Dr. George Memorial Lister Day Sanitarium Hospital.

Short-circuiting procedures, such as cholecystoenterostomies, choledochenterostomies, and hepaticoenterostomies are preferred to external drainage but unfortunately they cannot always be employed. In one instance we encountered such a generalized fibrosis of the choledochus and common hepatic duct that the formation of an external fistula afforded the only surcease from the intractable pruritis.

PREVENTION

An appreciation that 95 per cent of these external sinuses occur as unexpected complications following operations for gall stones emphasizes the importance of prevention. The observance of certain accepted surgical principles will greatly minimize the incidence of these tantalizing errors.

A The importance of an accurate clinical diagnosis cannot be overestimated. It is not sufficient to know that the patient has gall stones but one should determine whether there may be a complicating cholangitis, acute cholecystitis, cholemia, or hepatic insufficiency. To be unexpectedly confronted by these serious complications may necessitate a simple cholecystostomy without being able to determine the functional status of the bile ducts. In 5 such instances the failure to recognize the presence of acute cholecystitis before operation necessitated conservative operations with the result that choledochal stones were not discovered and chronic fistulas resulted.

B Adequate preoperative preparation and proper timing of all surgical interventions are absolutely essential in preventing such complications. The improperly prepared jaundiced patient is no candidate for exploration of the bile ducts. Likewise, the failure to provide ample time for acute infections to subside may necessitate palliative measures. For example, an acute cholecystitis usually responds to conservative therapy and extensive remedial operations can be safely employed during the quiescent phase which would be forbidden during the height of the inflammatory reaction. It is here that experience and judgment pay the highest returns.

C It is obligatory that the functional status of the bile duct should be accurately determined before any type of extirpative

Fig 1 The gall bladder, cystic duct, choledochus and duodenum were all visualized by the introduction of 55 cubic centimeters of diodrast, 70 per cent, into the external sinus. Note the gall stones partially occluding the orifice of the cystic duct, thus interfering with the emptying of the gall bladder and accounting for the biliary fistula.

surgery is undertaken. It has been our practice to explore the common bile duct if it contains stones, if it is dilated or indurated, if there has been an antecedent jaundice, if there is an inflammatory pancreatitis, and if unable to find other causes for the bilogenic dysfunctions.

While these indications for choledochotomy are definite, unfortunately the recognition of their presence is a matter of individual interpretation. What is thought to be normal by one surgeon may be considered pathological by another. It is the border line case which gives us the most concern and provides the most fertile field for errors. Visual inspection and palpatory examinations often fail to detect the incomplete choledochal obstructions. Errors of omission can be entirely prevented by the employing of cholangiographic studies during the operation (5). If the bile ducts appear patent and the contrast fluid flows unhampered into the duodenum no further exploration is warranted. If, however, obstructive lesions are visualized, the proper remedial procedure can be employed. The diagnostic cholangiograms are accurate and give the surgeon a sense of security.

EXTERNAL BILIARY FISTULAE

A Study of 23 Cases

N. FREDERICK HICKEN, M.D., LESLIE B. WHITE, M.D., and Q. B. CORAY, M.D.
Salt Lake City, Utah

PERSISTENT external fistulas occasionally follow surgical attacks on the extrahepatic biliary system. These tantalizing complications annoy the patients and harass the surgeons for both realize that the primary operations have failed to remove the obstructive lesions which were interfering with the free flow of bile and associated secretions into the duodenum. Errors of omission can be entirely prevented by the employing of cholangiographic studies during the operation (5). If the bile ducts appear patent and the contrast fluid flows unhampered into the duodenum no further exploration is warranted. If, however, obstructive lesions are visualized, the proper remedial procedure can be employed. The diagnostic cholangiograms are accurate and give the surgeon a sense of security.

Fig. 1. a, Postoperative cholangiogram reveals dilated biliary tree with complete obstruction of the ampulla of Vater for the contrast media does not pass into the duodenum. b, Same 8 weeks later. The external decompression has permitted the pancreatitis to subside partially for the duodenal flow around the stone and escapes into the duodenum. Note the thread like pattern of the ampulla of Vater which is indicative of pancreatitis. This patient was not jaundiced after operation and the stone healed spontaneously in spite of the choledochal stone.

D. External fistulas can be prevented if the postoperative studies detect provocative obstructions, thereby permitting immediate corrective therapy. Every patient submitting to a cholecystostomy or a choledochotomy should have a complete cholangiographic study before the drainage tubes are withdrawn (6). When the ducts appear patulous the drains can be removed with impunity. Should pathological obstructions be present they can be diagnosed by the recognition of their identifying characteristics. For example gall stones cast incriminating "negative shadows" while blood clots and inspissated plugs of mucus produce pleomorphic filling defects which float around within the ducts (Fig. 1). Pancreatitis exerts a concentric compression of the ampulla of Vater so that when the contrast fluid passes through the narrowed ductal lumen it forms a distinctive thread-like pattern (Fig. 2). Carcinoma of the pancreas produces a slow but progressive obstruction of

the ampulla of Vater resulting in a tremendous dilatation of all other segments of the biliary tract. Biliary dyssynergia is characterized by a temporary but complete obstruction of the terminal choledochus which spontaneously disappears as the spastic contractions of the sphincter of Oddi subside.

When the postoperative cholangiograms demonstrate a choledochal stone attempts should be made to dislodge it by means of the biliary flush. Best and Hicken (2) have succeeded in washing residual calculi from the ducts into the intestinal tract, thereby obviating a second exploration. They suggest that the sphincter of Oddi be completely relaxed by the administration of nitroglycerine and atropine sulfate before the drainage tube and choledochus is lavaged with warm olive oil. By these ductal irrigations they "flushed" stones from the common bile duct into the duodenum and recovered them in the feces (3). Butsch, McGowan, and Walters follow

Fig 3 This fistula closed 1 week after removal of the T tube in spite of choledochal stones. It is apparent that the calculi are not completely obstructing the duct. The rapidity with which the fistula healed, the absence of jaundice, and quick recovery of the patient gave no clinical signs of the overlooked stones, this emphasizes the value of cholangiograms.

Fig 4 A woman, 76 years old, suffered from a perforation of an acute gangrenous gall bladder. A cholecystostomy with extraction of 2 large gall stones was performed. Deferred cholangiograms revealed an incarcerated ampullar stone which was overlooked at the primary operation. The resulting fistula healed spontaneously within 8 weeks in spite of the choledochal stone.

ing the suggestion of Pribram, dissolved the migratory stones by the intraductal instillations of ether. While both of these methods should be utilized before subsequent operations are resorted to, unfortunately they seldom accomplish the desired objectives. We have, however, been able to dissolve plugs of mucus and blood clots by irrigating the common bile duct with a solution of the essence of caroid.

If conservative procedures fail to remove the offending obstruction, operative intervention should be employed as soon as the patient's condition permits. It is unwise to wait for a permanent sinus to form, for fear that an ensuing cholangitis, hepatitis, cholemia, or hepatic insufficiency might complicate the problem.

CLINICAL FEATURES

It has been our experience that when the cholangiograms revealed the ducts to be patulous that all external drainage subsided within 3 days after the drainage tubes were with-

Fig 5 Postoperative cholangiograms visualize choledochal stones that had been overlooked at the time of the primary operation. The patient was not jaundiced, the external sinus drained for 10 weeks, then it closed spontaneously in spite of the fact that ampullar stones were present.

Fig. 2. a, Postoperative cholangiogram reveals dilated biliary tree with complete obstruction of the ampulla of Vater for the contrast media does not pass into the duodenum. b, Some 8 weeks later the external decompression has permitted the pancreatitis to subside partially for the diodrast flow around the stone and escapes into the duodenum. Note the thread-like pattern of the ampulla of Vater which is indicative of pancreatitis. This patient was not jejunized after operation, and the stone healed spontaneously in spite of the choledochal stone.

D External fistulas can be prevented if the postoperative studies detect provocative obstructions, thereby permitting immediate corrective therapy. Every patient submitting to a cholecystostomy or a choledochotomy should have a complete cholangiographic study before the drainage tubes are withdrawn (6). When the ducts appear patulous the drains can be removed with impunity. Should pathological obstructions be present they can be diagnosed by the recognition of their identifying characteristics. For example, gall stones cast incriminating negative shadows while blood clots and inspissated plugs of mucus produce pleomorphic filling defects which float around within the ducts (Fig. 1). Pancreatitis exerts a concentric compression of the ampulla of Vater so that when the contrast fluid passes through the narrowed ductal lumen it forms a distinctive thread like pattern (Fig. 2). Carcinoma of the pancreas produces a slow but progressive obstruction of

the ampulla of Vater resulting in a tremendous dilatation of all other segments of the biliary tract. Biliary dyskinesia is characterized by a temporary but complete obstruction of the terminal choledochus which spontaneously disappears as the spastic contractions of the sphincter of Oddi subside.

When the postoperative cholangiograms demonstrate a choledochal stone attempts should be made to dislodge it by means of the biliary flush. Best and Hicken (2) have succeeded in washing residual calculi from the ducts into the intestinal tract thereby obviating a second exploration. They suggest that the sphincter of Oddi be completely relaxed by the administration of nitroglycerine and atropine sulfate before the drainage tube and choledochus is lavaged with warm olive oil. By these ductal irrigations they "flushed 1 stones from the common bile duct into the duodenum and recovered them in the feces" (3). Butsch, McGowan and Walters follow

saline, it may become clogged. Likewise, if the secretions are mucoid or hemorrhagic they tend to obstruct the tube and inhibit free drainage. This can be prevented by filling the T tube with a solution of the essence of caroid which liquefies the clots and dissolves the mucus. As soon as bile is detected in the stools, the drainage tube can be clamped so as to force this essential secretion into the duodenum. If the flow of bile is sluggish the administration of dehydrocholic acid acts as a cholagogue thus producing an effective physiological biliary flush. Should there be a spastic contraction of the sphincter of Oddi, this may be supplemented by the use of nitroglycerine and atropine sulfate.

How long shall the common bile duct be drained? Cholangiography affords the only accurate answer to this question. When the cholangiograms demonstrate the bile ducts to be patent then the drainage tubes can be safely removed. Should there be a residual pancreatitis or cholangitis, the external drainage must be continued until these inflammatory reactions have subsided (Fig 7).

RESULTS

Twenty-three patients with external biliary fistulas underwent 28 separate operations with a mortality rate of 26 per cent. It was interesting to note that in 16 private cases there was but 1 death, 6 per cent. This does not mean that the charity patient does not receive the same conscientious treatment as the private client but rather that the former neglect to seek early therapy because of economic embarrassment.

An analysis of the causes of death emphasizes the dangers of late complications. One patient, having had a fistula for 11½ years and persisting jaundice for 6 months, died because of hepatic shock incidental to an extensive cirrhosis. Carcinoma of the liver proved fatal to 1 woman who had suffered

with a draining sinus for 36 months. Post-operative hemorrhage accounted for 1 death but this was before vitamin K therapy was fully understood. Pylephlebitis, biliary peritonitis, hepatic, subhepatic, and subphrenic abscesses likewise exacted their toll. It is evident that the majority of these complications could have been prevented by timely surgery.

SUMMARY

- 1 Twenty-three cases of persistent external biliary fistulas are presented with particular reference to etiology, prevention, diagnosis, and treatment.
- 2 Ninety-five per cent of these fistulas occurred as complications following cholecystostomy and cholecystectomy.
- 3 The failure to remove all the gall stones at the primary operation accounted for 88 per cent of the fistulas.
- 4 The indications for and the technique of preoperative, operative, and postoperative cholangiography are presented.
- 5 The diagnostic and therapeutic value of cholangiograms is emphasized by case presentations.
- 6 The surgical and postoperative management of the various types of biliary fistulas is given.

TESTICULAR BIOPSY FURTHER STUDIES IN MALE INFERTILITY

CHARLES W. CHARNY, M.D. and DAVID R. MFRANZE, M.A., M.D.
Philadelphia, Pennsylvania

In 1940 one (2) of us reported studies on testicular biopsy and its application in the diagnosis of male infertility. This procedure consists of the removal of a minute piece of tissue from the periphery of the testis through a small incision in the scrotum. It is a simple innocuous procedure and may be performed in the office under local anesthesia. In our experience there have been no undesirable after-effects, every patient resuming his usual activity the next day.

While the performance of biopsy was at first limited to instances of azoospermia, it soon occurred to us that this procedure could be utilized in patients with any type of spermatozoan deficiency whether it be morphological or numerical. The more biopsies performed the better we appreciated the superiority of this method over any other procedures. The two older methods available today are aspiration of the testis and the manifold biological studies of the ejaculate. Testicular aspiration even when spermatozoa are obtained gives merely quantitative data and is valuable only in the differential diagnosis between obstructive and nonobstructive azoospermia. In the study of the ejaculate the finding of a large percentage of abnormally formed spermatozoa points only to faulty spermatogenesis. Both these older methods, however fail to give information regarding the nature of the intrinsic lesion in the seminiferous tubules. The insight into actual pathogenesis, as revealed by testicular biopsy, is in our opinion, the *sine qua non* in a thorough study of male infertility.

The present series of testicular biopsies, performed as part of the study on males with reduced fertility numbers 95. This series comprises a variety of pathological types including instances of both testicular under

development resulting from a congenital endocrine imbalance and testicular degeneration of a normally developed testis brought about by inflammation toxic processes, or post pubertal endocrine disturbances. An analysis of the findings indicates that these two lesions can be differentiated by the data obtained through testicular biopsy and that this differentiation as will be shown is of utmost importance in determining the prognosis and type of treatment. Lest the objection be raised that the tissue obtained through biopsy may not necessarily be representative of the entire gland it should be pointed out that large sections of normal testis obtained at autopsy done immediately after death show a general uniformity of the seminiferous tubules (Fig. 1) and also that sections of biopsies from different portions of the same testis obtained at intervals of 6 weeks show similar pathological processes throughout.

THE NORMAL SEMINIFEROUS TUBULE

A cross section of a testis shows two distinctly different types of tissue the seminiferous tubules, in which spermatogenesis takes place and the interstitial tissue which contains the cells of Leydig. In the seminiferous tubules the successive phases of spermatogenesis are arranged according to a definite sequence. The youngest and least developed cells are situated on the basement membrane of the tubule, the *membrana propria*, while the mature forms are more centrally located. Accordingly the spermatogonia, the cells in which spermatogenesis begins, and the next generation, the primary spermatocytes, remain in their early growth phases adjacent to the basement membrane. Advancing toward the center the primary and secondary spermatocytes are seen undergoing division and further development. The next layer of cells is composed of groups of sperma-

From the departments of Urologic Surgery and the Laboratories of the Mount Sinai Hospital, Philadelphia.

Fig 1 Typical portion of testis, removed at autopsy immediately after death, illustrating uniformity of tubules ($\times 60$) (Formalin fixed)

Fig 2 Normal seminiferous tubules Note presence and regular arrangement of various generations of spermatogenic cells Membrana propria of normal thickness ($\times 150$)

tids Finally and innermost, one sees groups of immature spermatozoa (Fig 2)

In addition to these spermatogenic elements, the seminiferous tubule shows another type of cell, the so called cells of Sertoli. These are slender, columnar elements standing upright on the basement membrane and spaced at fairly regular intervals. They are presumably supporting elements, though some consider them capable of developing, under certain conditions, into true spermatogenic cells.

The wall of the seminiferous tubules, the membrana propria, consists of thin collagenous fibers and a delicate elastic network, and varies in thickness from 3 to 6 microns. The interstitial tissue—the tissue between the tubules—consists of thin collagenous fibers, blood and lymph vessels, nerves, and several varieties of cells—fibroblasts, resting wandering cells, mast cells, embryonic perivascular cells, and the interstitial cells of Leydig which are believed to elaborate the internal secretion of the testis.

Occasionally one notes seminiferous tubules showing degenerating spermatogenic cells involving all generations, particularly spermatocytes and spermatids. Such degenerating cells lose their connection with the rest of the epithelium, are cast off into the lumen, and disintegrate into granular and fatty debris. Tubules exhibiting such degenerative changes,

if not excessive, need not be considered pathological, especially if they are surrounded by tubules with normal spermatogenesis in full progress.

THE PATHOLOGICAL SEMINIFEROUS TUBULE

Careful study of the 95 testicular biopsies herein reported revealed that the pathological changes, although varying considerably in degree, could be separated into two distinct types (1) intratubular—those in which the degenerative or developmental lesion is confined solely to the seminiferous tubules, and (2) peritubular—those in which peritubular fibrosis, either inflammatory or replacement, is seen in addition to the intratubular lesion.

Of the 95 biopsies 16 showed normal spermatogenesis. Of the 79 remaining, 51, or 65 per cent, showed moderate to marked peritubular fibrosis, while only 28, or 35 per cent, showed a normal amount of peritubular connective tissue despite definite damage to the tubular epithelium.

Type I Intratubular lesions The pathological changes confined to the tubules have been found to vary in severity from simple desquamation of the innermost layer of cells, the spermatids, to more severe degenerative changes in which both the spermatocytes and spermatogonia are involved or, finally, to a stage in which the tubule consists of merely a single layer of undifferentiated cells appar-

Fig. 3. Case . . . Section of testis, before treatment, showing mostly chorionization and incomplete epithelial differentiation. Only the large tubule appears capable of producing spermatozoa. No peritubular fibrosis ($\times 90$).

Fig. 4. Case . . . Section from surgically corrected cryptorchid testis showing trophic tubules lined by single layer of undifferentiated cells. \ peritubular fibrosis ($\times 90$).

entirely incapable of growth and division. In the milder cases, the younger cell forms are not affected and differentiation into spermatids continues. Under such circumstances, further cell growth is interrupted and a testicular biopsy reveals an increase in the number of spermatids. In the more severe forms degeneration is more prominent a great deal of debris often being seen in the lumen, and the tubule is lined with only one or two layers of cells.

Whatever the etiological factors may be the intratubular degenerative process may be halted at any point and, since the basal layer of cells, the spermatogonia, has not been affected regeneration may take place under suitable circumstances. Thus if the disturbing factor be a pituitary deficiency restoration to normal could be effected by the administration of a pituitary gonadotropic substance.

The 4 cases cited are selected from a group of 28 showing intratubular damage only. Of these 28 improvement in the semen picture or biopsy or both followed the administration of equine gonadotropin in 11 instances. These 11 cases, we believe are patients with mild insufficiency of pituitary gonadotropin. The 7 remaining cases probably represent either testicular lesions of nonendocrine etiology or are instances of endocrine deficiency so advanced that regeneration following treatment

with the gonadotropins at present available has not occurred.

CASE 1. Mild degree of tubular damage without fibrosis. G. C. aged 29 years, had moderate amount of girdle obesity. Basal metabolic rate was -8 . Semen examination revealed a total count of 9,000,000 spermatozoa, of which 38 per cent were morphologically normal. Following the administration of an equine gonadotropin the total sperm count as raised to 80,000,000 with only 20 per cent abnormal forms and with corresponding improvement in the histological picture (Fig. 5).

CASE 2. Severe tubular damage without fibrosis. F. L. aged 28 years. This was an instance of under development in a man with cryptorchidism which had been surgically corrected at the age of 25 years. The testes measured 3.5 by 2.0 centimeters in size. Semen examination showed azoospermia. There was no response to the administration of equine gonadotropin (Fig. 4).

CASE 3. Acute tubular degeneration without fibrosis. F. S., aged 5 years, had been given 3 milligrams of tibestrol daily for a total of 450 milligrams in order to suppress his hypersexuality which had caused him repeated incarcerations for criminal rape. His testes were reduced to two-thirds of their original size and his libido was so suppressed that a semen specimen could not be obtained. It is important to note that during this period of testicular degeneration, he had no symptoms referable to the testes (Fig. 5). Ten months following the cessation of therapy, second biopsy showed no pronounced evidence of regeneration. Libido had returned to normal (Fig. 6).

Other instances of advanced tubular degeneration, being reported greater detail by Dr. C. W. Drury.

Fig 5 Case 3 Section from stilbestrol induced degeneration. Tubules are lined by only one or two layers of healthy cells and display central necrosis. Note interstitial edema and absence of peritubular fibrosis ($\times 150$)

Fig 6 Case 3 Section from same patient as in Figure 5, 2 months after cessation of stilbestrol, showing restoration. Regenerative process proceeding, but not yet complete. Note focal fibrosis ($\times 150$)

CASE 4 Tubular underdevelopment and degeneration without fibrosis. S. G., aged 29 years, displayed many of the stigmas of hypogonadism. He shaved his beard once a week. He had trochanteric obesity, with a prominence of the breasts and abdominal fat. The penis was small, the testes measured 2.5 by 1.5 centimeters. Semen examination revealed azoospermia (Fig 7). He received intramuscular injections consisting of 40 milligrams of testosterone propionate and 120 international units of equine gonadotropin weekly for a period of 4 months. Re-examination revealed no change in size of testes, an increase in size of penis, with normal

libido and potentia. There was no improvement in the semen (Fig 8).

Type II Peritubular fibrosis The presence of peritubular fibrosis is indicative of either the end stage of an inflammatory process or of a severe degenerative process which has produced, in addition to epithelial damage, an infolding and thickening of the membrana propria, a shrinkage of the tubules, and subsequently replacement fibrosis. Such peri-

Fig 7 Case 4 Section from patient with hypogonadism. Marked underdevelopment. Note small size of tubules. No peritubular fibrosis ($\times 150$)

(This tissue was fixed with formalin.) All other tissue, except that used in Figure 5, were fixed with a modified (B. McClung) Bouin's solution

Fig 8 Case 4 Section from testis of hypogonad after treatment with testosterone propionate. No increase in size of tubules or in the number of epithelial layers. Note appearance of necrosis and its similarity to stilbestrol induced necrosis of Figure 5 ($\times 150$)

Fig. 9. Case 5. Section from testis showing degeneration following upon an inflammatory process. Note small degenerated tubules, thickening of membrana propria, and peritubular fibrous tissue. ($\times 50$)

tubular fibrosis must not be confused with the apparent increase in the number of interstitial cells of Leydig—a phenomenon caused by a relative reduction in the size of the tubules. The importance of this peritubular fibrosis is that it signifies an accompanying involvement of the membrana propria adjacent to the mother cells, the spermatogonia, and implies previous injury to them. The degree of peritubular fibrosis varies from a simple thickening of the membrana propria to instances in which the fibrous ring is as thick as the tubule itself. In the most advanced cases, fibrosis is represented by actual scarring with complete obliteration of the tubules.

It is of the utmost importance to note that not one of the patients with peritubular fibrosis, even of the mildest degree, responded to the administration of equine gonadotropin. The 2 cases cited are selected from a group of 51 showing tubular damage associated with varying degrees of peritubular fibrosis.

CASE 5. Mild tubular damage associated with generalized peritubular fibrosis. D. L. aged 3 years, showed no evidence of endocrine disturbance. H. g. no history of pain or swelling of the testes which were normal to palpation. Total sperm count was 6,000,000 with 4 per cent abnormal forms. In addition to the microscopic picture there was also gross evidence of previous inflammation of the testes. At biopsy the focal layers of the scrotum, particularly the parietal layer of the tunica vaginalis testis, were thickened, and there was an excess of

hydrocele fluid present. The administration of equine gonadotropin failed to produce any change in the semen picture (Fig. 9).

CASE 6. Severe tubular damage accompanied by generalized peritubular fibrosis and partial obliteration. A. L. aged 3 years, exhibited marked familial, evenly distributed obesity. H. g. no history of testicular disease. Basal metabolic rate was -4 . Roentgenogram of sella turcica normal. The right testis as normal, the left definitely reduced in size. During the performance of testicular biopsy gross evidence of previous inflammation was apparent. On the left side the two layers of the tunica vaginalis testis were adherent. Semen examination revealed total of 9,000,000 spermatozoa, 15 per cent abnormal forms, which undoubtedly originated in the right testis. Treatment with equine gonadotropin failed to produce any change in the semen (Fig. 1).

CORRELATION OF TESTICULAR BIOPSY AND SEMEN STUDY

The correlation of the semen findings and the histological pattern of the biopsy was as follows:

Of 76 patients with oligozoospermia, the biopsy and semen specimen examinations agreed in 66 or 87 per cent. of the 19 patients with azoospermia, the biopsy and semen specimen examinations agreed in 13 or 68 per cent. In the group with oligozoospermia the discrepancy in 13 per cent of the cases does not represent a percentage of error in the interpretation of the biopsy or semen findings. These cases, we believe are instances of oligozoospermia with normal spermatogenesis in whom the lesion is confined to the ejaculatory ducts and is obstructive in nature. They are always associated with prostatic and seminal vesicular infection. The semen is reduced in volume, contains a large number of pus cells, and the spermatozoa display relatively normal morphology. In the group with azoospermia the disagreement in 32 per cent is, of course, confined to those cases in which spermatogenesis is normal and in which the obstructive lesion in most cases, is more apparent. Of the 6 cases, 4 had bilateral obstruction of the epididymis and 2 had complete obstruction of the ejaculatory ducts with aspermia.

EVALUATION

When this study was begun it was hoped that a careful analysis of the testicular biopsy

sies would lead to a correlation between histological findings and specific etiological factors. It soon became apparent, however, that the pathological changes observed in the biopsies had no specific relation to the causative agent. It was found, moreover, that the presence or absence of peritubular fibrosis was a most valuable differentiating finding. Thus, no fibrosis was found in any of the clinical entities associated with underdevelopment of the testes, such as in the pituitary-gonadal deficiencies, in primary hypogonadism, and in cryptorchidism. Such testes uniformly showed tubules smaller in size than normal and lined by incompletely developed or undifferentiated epithelial elements. On the other hand, the acquired degenerative lesions, such as those due to toxins, inflammations or postpubertal endocrine disturbances, almost invariably showed some degree of peritubular fibrosis. The only exceptions apparently occurred in the mild cases of tubular degeneration, and in the very acute instances which did not, therefore, represent end stages. An example of the latter is the injury produced by stilbestrol (Case 3). Such cases are especially interesting in that they illustrate clearly the regenerative potentialities of the testes, when the toxic agent is removed or a stimulating remedy is introduced. The authors believe that if the stilbestrol had been administered over a sufficiently long period of time, tubular damage would have become so extensive that shrinkage would have occurred, generalized replacement fibrosis would have set in and regeneration would have been much less in evidence. As a matter of fact some parts of the section showed areas of focal fibrosis.

The evidences of tubular degeneration induced by the administration of both stilbestrol and testosterone propionate in our cases are fairly conclusive. It is clinical confirmation of the findings of several investigators who demonstrated tubular degeneration following the administration of a variety of androgens in the experimental animal. It is especially significant that in our case the testosterone propionate produced degeneration of the seminiferous tubules in a hypogonad, one in whom male sex hormone therapy is indicated according to our present concepts.

Fig 10. Case 6. Section from left testis showing destruction of tubules with replacement fibrosis ($\times 150$).

One point that deserves re-emphasis is that the pathological process in any testis is fairly uniform throughout and that a small specimen removed at biopsy is almost invariably representative of the entire testis. It is not uncommon, however, to find different degrees of involvement in the two testes even though the etiological agent is identical in each case. An example of this is the patient in Case 6, in whom the left testis was almost completely fibrosed, as demonstrated by biopsy, while the right one was severely and irreparably damaged by fibrosis of similar etiology but was still sufficiently spared to produce the spermatozoa found in the semen. It is interesting to note, however, that this patient's semen contained 58 per cent abnormally shaped spermatozoa.

It has not been sufficiently stressed that the majority of males with reduced fertility who are almost routinely treated with some type of endocrine product, do not show any clinical evidence of endocrine disturbance. Nor do these patients show any evidences of endocrinopathy when studied by the available laboratory procedures, such as basal metabolic rate, roentgenogram of the sella turcica, and urinary and blood levels of androgens and gonadotropins. There is, moreover, no logical justification for concluding that these patients have an isolated endocrine dysfunction of the seminiferous tubules. The observations in the present series of 95 testicular biopsies lend

additional support to the contention that the great majority of these testicular lesions are degenerative and are for the most part, due to local or distant inflammatory or toxic processes. Since no endocrine imbalance exists, such seminiferous tubules cannot be expected to respond to endocrine therapy.

It is not possible at the present time to determine the specific etiology of the lesions in the seminiferous tubules. Since most of the inflammatory and degenerative changes occur insidiously, the characteristic signs and symptoms of inflammation are lacking and the patient usually gives no history of such a complication (see Case 3). It may be pointed out moreover that these nonendocrine degenerative changes have been recognized before in autopsy material and have been reported upon by a considerable number of investigators. Berbench and Jaffe report degenerative lesions involving the seminiferous tubules in a large percentage of men who contracted a great variety of acute infections. Oberdorfer reports degeneration of seminiferous tubules in every German soldier dying of influenza in 1918 whom he examined at autopsy. He stresses an important concept with which we are in complete agreement, namely that almost all inflammatory lesions involving the seminiferous tubules begin in the epithelial structure of the tubules and that the peritubular fibrosis, though prominent is always secondary and indicates epithelial damage as well. A large variety of diseases may produce hematogenous lesions. Some of these provocative ailments are typhoid, paratyphoid mumps, diphtheria, scarlet fever, variola, influenza, typhus fever, tonsillitis, glanders, pneumonia, malaria, gout, rheumatic fever, furunculosis, osteomyelitis, cholecystitis, appendicitis, and localized focal infections with pyrogenic organisms.

SUMMARY AND CONCLUSIONS

1. Testicular biopsy is an innocuous procedure no more disabling than a Rubin test in the female, and should be established as a routine procedure in the study of male infertility.

2. The failure of tubular development is indicated histologically by the presence of small tubules which are filled with undifferentiated cell forms. Peritubular fibrosis is not present.

3. Degenerative lesions, if acute are recognized in testicular biopsies by the presence of necrosis and desquamation of the tubular epithelium. If the lesions are of long standing peritubular fibrosis is a distinct feature and signifies either the end stage of an inflammatory process or the replacement fibrosis which results as a consequence of shrinkage of the tubules.

4. The presence of peritubular fibrosis suggests severe damage to the youngest epithelial cells of the tubules probably affecting their regenerative potentialities.

5. The administration of sex hormones, either stilbestrol or testosterone propionate, induces tubular degeneration both in the hypersexual male and in the hypogonad.

6. The majority of male patients with relative infertility have no endocrine disturbances. Their semen deficiencies are the result of degenerative lesions of the seminiferous tubules caused by either regional or constitutional inflammatory or toxic processes. Endocrine therapy is not indicated in such instances.

SOME MODIFICATIONS ON THE ASEPTIC DOUBLE VALVED TUBOGASTROSTOMY

JACOB A GLASSMAN, M D , M S , Chicago, Illinois

SINCE the publication of a former paper entitled "A New Aseptic Double-Valved Tubogastrostomy" I have had many opportunities to observe and to study the technique employed by various surgeons who have been kind enough to try this method. Often it was noted that, when placing the pursestring suture around the base of the diverticulum which was formed by traction on the anterior wall of the stomach, the operator attempted to make a perfect circle. In other instances the surgeon needlessly ligated gastric vessels and cut into the gastrocolic ligament to mobilize part of the greater curvature and even the posterior wall of the stomach so as to achieve such a circular pursestring suture in the seromuscular layer. Indeed, the diagrammatic sketch in my earlier paper did illustrate a circular stitch, but I have since learned by further experience that an irregular circular or even an oval shaped pursestring suture, when tensed finally to the proper degree of constriction, forms a diverticulum which is entirely satisfactory. This modification of my method, made possible because of the elasticity of the stomach wall, eliminates the necessity of infringing upon the gastric vessels at the greater and lesser curvatures. Before the second pursestring suture is applied in the creation of this diverticulum, the Babcock forceps is released and reapplied to the point selected as the final apex.

It is obvious that when the operator tenses the pursestring suture the stomach wall nearest to the sliding knot suffers the greatest amount of tension and constriction. This is avoided by introducing a pursestring suture which is "back stitched" after every fourth stitch is tensed until the base of the diverticulum is completely encircled. This precaution imparts relatively equal tension and constriction to all points and prevents undue crushing at any one point.

Numerous requests have been received by me to explain why I chose to include 2 valves in the tubogastrostomy. During the development of the technique it was found that food settling along the greater curvature and exerting a downward pull rendered the first valve slightly incompetent.

Therefore, a second valve was introduced, distal to the first, and was found to be unaffected by the weight of the feeding. However, in those instances in which there is not enough stomach wall to make a diverticulum that would permit the formation of 2 valves, a method which includes but one valve has been developed and tried by me and it has proved competent in preventing leakage of the gastric content, both in animal experiments and on human subjects. The technique of producing an aseptic tubogastrostomy with such a single valve is as follows:

- 1 With a Babcock forceps, traction is applied upward until the stomach wall is converted into a cone shaped diverticulum.

- 2 A pursestring suture—of braided silk, or No. 2 chromic catgut—is carried through the seromuscular layer at the base of the diverticulum in the manner indicated in Figure 1, A.

- 3 The Babcock forceps is released and reapplied to a final apical point on the diverticulum, and a second re-enforcing pursestring suture is inserted about 4 millimeters above the first (Fig. 1, B). (In a personal communication, L. Aries suggested placing the second pursestring suture midway between the first and third.)

- 4 Then a third pursestring suture is inserted about 1 centimeter above or peripheral to the second.

- 5 Lembert stitches are now placed in the seromuscular layer at right angles to all pursestring sutures (Fig. 1, C) in sufficient numbers to encircle adequately the base of the partially constricted diverticulum. The Lembert stitch employed here is somewhat modified, that is, the suture is inserted about 8 millimeters below the first pursestring and carried to a point about 1.5 centimeters beyond the second.

- 6 Interrupted seromuscular sutures are inserted in the anterior wall of the stomach at points superior, inferior, and lateral to the base of the tubal projection in order to fix the stomach wall to the peritoneum and posterior rectus sheath (Figs. 2 D and F). In a similar manner the tube itself is attached to the anterior rectus sheath.

- 7 An opening into the apex of the tube by means of cautery may be made any time from the

additional support to the contention that the great majority of these testicular lesions are degenerative and are for the most part due to local or distant inflammatory or toxic processes. Since no endocrine imbalance exists such seminiferous tubules cannot be expected to respond to endocrine therapy.

It is not possible at the present time to determine the specific etiology of the lesions in the seminiferous tubules. Since most of the inflammatory and degenerative changes occur insidiously, the characteristic signs and symptoms of inflammation are lacking and the patient usually gives no history of such a complication (see Case 3). It may be pointed out moreover that these nonendocrine degenerative changes have been recognized before in autopsy material and have been reported upon by a considerable number of investigators. Berberich and Jaffe report degenerative lesions involving the seminiferous tubules in a large percentage of men who contracted a great variety of acute infections. Oberdorfer reports degeneration of seminiferous tubules in every German soldier dying of influenza in 1918 whom he examined at autopsy. He stresses an important concept with which we are in complete agreement, namely, that almost all inflammatory lesions involving the seminiferous tubules begin in the epithelial structure of the tubules and that the peritubular fibrosis, though prominent, is always secondary and indicates epithelial damage as well. A large variety of diseases may produce hematogenous lesions. Some of these probative ailments are typhoid paratyphoid, vaccinia, diphtheria, scarlet fever, variola, influenza, typhus fever, tonsillitis, glanders, pneumonia, malaria, gout, rheumatic fever, furunculosis, osteomyelitis, cholecystitis, appendicitis, and localized focal infections with pyogenic organisms.

SUMMARY AND CONCLUSIONS

1. Testicular biopsy is an innocuous procedure no more disabling than a Rubin test in the female and should be established as a routine procedure in the study of male infertility.

2. The failure of tubular development is indicated histologically by the presence of small tubules which are filled with undifferentiated cell forms. Peritubular fibrosis is not present.

3. Degenerative lesions, if acute, are recognized in testicular biopsies by the presence of necrosis and desquamation of the tubular epithelium. If the lesions are of long standing, peritubular fibrosis is a distinct feature and signifies either the end stage of an inflammatory process or the replacement fibrosis which results as a consequence of shrinkage of the tubules.

4. The presence of peritubular fibrosis suggests severe damage to the youngest epithelial cells of the tubules, probably affecting their regenerative potentialities.

5. The administration of sex hormones, either stilbestrol or testosterone propionate, induces tubular degeneration both in the hypersexual male and in the hypogonadal.

6. The majority of male patients with relative infertility have no endocrine disturbance. Their semen deficiencies are the result of degenerative lesions of the seminiferous tubules caused by either regional or constitutional inflammatory or toxic processes. Endocrine therapy is not indicated in such instances.

farthest from the site of lesion, that is, as far from the cardia as possible without encroaching upon the pylorus. The rationale guiding here is based on the assumption that the farther removed the gastrostomy site is from the malignancy, the longer it will take for the cancer cells to spread via a contiguous route to the tubogastric mouth and involve its lumen. In those few instances of carcinoma involving the lower third of the esophagus as well as the cardia and fundus of the stomach, the procedure of choice is jejunostomy.

NINE YEARS' CLINICAL EXPERIENCE WITH STEEL WIRE AS A SUTURE MATERIAL

GERALD H. PRATT, M.D., F.A.C.S., New York, New York

OPERATIVE success depends upon mechanical technique, asepsis, and wound healing and despite the advances in laboratory and clinical research, little progress has been made in understanding or improving this latter fundamental operative requisite. While the necessity for anatomical reapposition and a minimum of trauma has been stressed, these requirements in many instances are imperfectly practiced. In the utilization of sutures and ligatures, the advance has been particularly slow. Such important matters as the selection of sutures have been left to the hospital purchaser, and the note on the operation sheet "routine abdominal closure" is an admission of content to follow out-dated and traumatizing methods of ligation and wound suturing. The publication of 126 articles on sutures and ligatures in the last 3 years is a more encouraging indication of the awakening to the responsibility for this important portion of the operation.

Ligating and suturing necessarily are as old as surgery. Not only were nonabsorbable sutures used, but catgut was described by the Arabian Rhazes, who wrote in 900 A.D. of the stitching of wounds with strips of sheep in-

testines. We know that Galen used catgut in addition to other sutures, but it was 1816 before Physick demonstrated the absorbability of this material. With Lister's discovery of the way to sterilize catgut, in 1869, this suturing material became the popular one. The strands were heavy and the needles traumatic, and even such a technician as Kocher reported an infection incidence of 70 to 80 per cent with this suture material. These infections led to his adoption of the silk suture which Halsted popularized after observation of Kocher's experience with the silk suture technique. This silk suture school has persisted in many places to this time. With the advent of the so called modern surgery, where stress was placed upon speed, catgut had a rebirth, and it has remained the most widely used suture material to this day.

At the Babcock Clinic in Philadelphia, dissatisfaction with the serum collections in clean wounds so often manifested after closure with catgut, stimulated an effort to find a more satisfactory suture material. From 1931 to 1935, such materials as cotton, linen, silk, Japanese and American fishline, silver and copper wires were utilized with varying success. Silk in the clean cases, in which the necessary finer instruments and technique were employed, was

liquid food, since a greater time is allotted for adhesions to form and for edema to disappear. This step culminates an operative procedure that requires a minimum of time and trauma and that is aseptic throughout.

In Figure 3 H a diagrammatic cross section illustrates the arrangement of the various layers of the stomach wall after the invagination resulting from the three pursestrings has been completed. It will be noted that while the modified Lembert suture invaginates the three pursestring sutures, it also produces a more abundant overlapping of mucosal folds within the tubal structure which are more than adequate in maintaining competent closure. Although the gastrotomy possessing only one valve has proved competent and is preferred by O'Donoghue, Aries, and others, I still favor my original double valued tubogastrostomy whenever an adequate amount of stomach wall is present.

At this point I would like to add a few remarks regarding the selection of the ideal site of the gastrotomy. In cases of carcinoma of the upper or the middle third of the esophagus, the operator may proceed to perform gastrotomy in any suitable portion of the anterior wall of the stomach. But in cases in which the malignancy involves the lower third of the esophagus or the cardiac portion of the stomach, the operator prefers to utilize that portion of the anterior stomach wall

stances similar to those in which the sutures are to be used. Preparations and solutions or suspensions of the suture material have the disadvantage of presenting the material to the host in an unnatural fashion. Sutures, them-

selves, inserted in the human exactly as they will be presented in the wound closures, is the ideal way to test for the body's response to these foreign materials.

The author, under Dr Babcock's directions, implanted some 750 sutures of different materials in surgically prepared areas in 125 patients to learn the reaction of the patients to these materials. Sutures of plain No 1 catgut, chromic No 1 catgut, silkworm gut, alloy steel wire, silver wire dermal, and various types of fishline were inserted through the skin in different areas of the surgically prepared field and gross, bacteriological, and at times pathological observations were made, at 5 day, 7 day, 10 day, and 14 day intervals. The report of this work has been published previously (Babcock, 1935) but in every in-

satisfactory. In other instances, in which sepsis was present, the resulting sinuses made it most undesirable. The fishline, like catgut and some cotton, would absorb fluid, lengthen and swell with inevitable tensile weakening. Silver wire so admirably employed by Sims in his closures of vesicovaginal fistulas, had the disadvantage of breaking on the knot and its oxidation subcutaneously left a discoloration.

In 1933 the first alloy steel wire was employed at the Babcock Clinic and a thorough

investigation and clinical study were made. In reviewing the work on suture experiments one is confronted with the conflicting reports based on results of nearly identical investigations. These studies were based on animal work. Although animal experimentations are necessary the results are frequently fallacious, and pro and con interpretations may be made at times from the same results. It is our contention that experiments to demonstrate sensitization and allergic manifestations to sutures should be conducted under circum-

response but at the end of 10 days in over 50 per cent there was some necrosis surrounding the suture. Wire gave the least reaction and the steel without the skin discoloration due to the oxidation of the silver wire, was quite imperceptible in 95 per cent of the cases. In the last year a second series of experiments on patients have been performed. Four suture materials, chronic catgut, silkworm gut, silk, and steel wire have been placed near clean surgical wounds. Each strand has been passed

Fig. 9. High amputation for obliterative vascular disease. Closure with steel wire. Primary cure.

through the deep fascia, and the sutures have been subjected to a regulated strain at various intervals after operation. Results so similar to the experiments previously reported have been obtained that the previous work is collaborated.

The allergic factor in catgut has been subject to more study. The work of Kraissl, Kisten, and Cimotte was confirmation of the factor of allergy to catgut in wound healing. They reported disruption in 35.7 per cent of the abdominal wounds in guinea pigs previously immunized with catgut and a sensitivity reaction to catgut in 332 humans. Hinton's findings that 9 of 112 patients who had had a previous operation were sensitive to fresh sheep gut (0.8 per cent solution) is further confirmation of the part reaction may play in the various stages of dehiscence. Taylor's report that catgut is a culture medium has been confirmed many times, and Whipple was able to reduce his incidence of wound infections from 7.55 to 2.04 per cent by changing from catgut to silk.

It is obvious that the ideal suture material is one in which there is a minimum of trauma necessary to insert it, a tensile strength sufficient to assure its maintenance and the least possible tissue response to it. In our experience steel wire fulfills these requirements more satisfactorily than any other suture at present available.

For the last 8 years, steel wire has been employed to exclusion by the author as retention and skin sutures with success in all abdominal as well as other wounds. It has been buried in the closure of fascia in inguinal and all ventral or incisional hernias. It has been particularly successful in the presence of sepsis and its efficiency has permitted primary closures in appendicitis with peritonitis, in colostomies after 1st stage Mikulicz operation and in fistulas. It has replaced all other sutures in plastic operations (Figs 1 and 2).

As in the use of silk, the technique must be varied. Small bites of tissue should be taken (as shown by Preston's experiments) and smaller needles and finer instruments with less trauma are utilized. Tissues must be merely approximated, without pulling the knot tightly, as the steel wire will not give

with tissue swelling. A square knot should be tied and the ends cut on the knot (see Fig 3). The surgical nurse must prevent kinking of the wire during its preparation and the first assistant can save valuable time by following the suture through to prevent a wire snarl. The wire should be of such size as to have only sufficient strength for the purpose for which it is being used. A No 36 or No 37 on the Sharpe and Smith gage is effective in the skin, while a No 33 or No 34 makes an ideal buried fascia suture. For heavy bone approximation a No 30 gauge is sufficient (see Figs 4 and 5). For the bowel, fine No 36 interrupted steel wire suture is well tolerated and especially effective on the serosal surfaces, will cause so little reaction that the tendency to adhesions and obstruction is minimized. Jones and his co-workers have confirmed the incidence of lowered infection by the use of wire in bowel work. His report of a reduction of infection in abdominal wounds after 116 cases of resection of the colon from 27.5 per cent in those in which catgut was used to 0.85 per cent in those cases in which alloy steel sutures were employed, is so significant that further comment on this work is unnecessary.

In this last year, during an operation for carcinoma of the cecum, an opportunity was presented to study steel wire buried in a ventral hernia closure 4 years previously. The fascial section and wire were excised, and not only were the sutures bright and shining, but the surrounding tissue showed neither gross nor microscopic evidence of tissue or foreign body response (Fig 6, $\times 45$).

In the 9 years that this suture material has been used, we have never seen tissue reaction to it. In a few instances in which overenthusiastic residents have squeezed the wound edges by ligating the sutures too tightly, a local necrosis has developed, due to constricting avascularity. In an analysis of the last 145 appendix operations in which 75 were of the acute, gangrenous type, all closed with the steel wire, there has been wound edge infection in only one. Figure 7 shows the abdominal wound 7 days after removal of a ruptured gangrenous appendix. While there has been drainage, it has been between the

sutures which are still *in situ* and no reaction has occurred around them, nor has there been wound breakdown.

In 85 inguinal hernioplasties, steel wire has been used to close the layers from the peritoneum, while in all recurrent inguinal and ventral hernias the wire has been buried in the fascia. Experience with wire as the only suture in hernias has led to its adoption for even suturing the base of the sac and transplanting the base under the rectus muscle. An x-ray film shows buried steel wire in the fascia of a large ventral hernia 4 years after operation. Sutures were of No. 34 alloy steel wire, and the wound healed primarily (Fig 8). There has been but one recurrence and this was in a ventral hernioplasty in an elderly individual with bronchiectasis who had had 2 recurrences before and who coughed his hernia out in the first 48 hours. In these hernias we believe that wire plays a most important part and in our hands is much more satisfactory than such foreign materials as silk, kangaroo tendon, or the routine fascial transplants. The fascial sutures require such traumatic needles and large openings that it is surprising not to observe some with recurrence due to needle apertures alone.

In major amputations for vascular disease when only steel wire has been used in closure, we have had 92.3 per cent primary unions in the last 3 years, 26 cases. Figure 9 demonstrates how primary healing is obtained even in high amputations with the steel wire. The stump is in an easily contaminated area, but healed satisfactorily. Previous experience with other suture materials was not satisfactory.

The wound after ligation of the saphenous vein at the fossa ovale has been approximated with the wire and the infections so prevalent in this area when we used silk have been reduced to 8 in the last 150 patients.

With many others we have felt that wound disruption or avulsion is most often due to inadequate postoperative support, rather than the type of operation, a predilection or autonomous suture destruction. At one time we saw three avulsions on a surgical service in a

month following the routine adoption of Montgomery strings instead of adhesive strap support. The incidence of diathesis is greatest at the time of retention suture removal. Prior to burying the wire fascia sutures it had been our practice to retain the retention sutures *in situ* for a long time and even to permit patients to leave the hospital with the sutures in place. This was easily handled as one felt safe in doing this with the steel wire as no suture abscesses will be formed. In more than 500 major abdominal operations there has not been a wound disruption. In one instance in which a double barrelled colostomy after a 3 stage Mikulicz operation for carcinoma of the hepatic flexure was closed primarily with the steel wire only the patient returned 2 years later complaining that she felt a wire suture. Examination showed one of the wires had become unknotted and its tip was presenting at the skin edge. Its removal was simple and this patient has had no other complaints in 5 years of observation.

SUMMARY

Nine years clinical observation has confirmed experimental work showing less tissue reaction to steel wire sutures. It is effective in abdominal closures in which it may be used as a buried suture and, in infected or contaminated areas, it is particularly indicated. A finer technique and approximation without strangulation is necessary in its use. It has been adopted to exclusion in all hernias and markedly reduced the morbidity and the disability time. Patients so sutured may be returned to industrial work in 4 weeks rather than the routine 8.

Its wide use in intestinal anastomoses, as the serosal sutures and in the plastic surgery field is stressed.

A STUDY OF THE EFFECT OF MORPHINE, ATROPINE, AND SCOPOLAMINE ON THE BRONCHI

OTTO V HIBMA, Jr, M D, and ANTHONY R CURRERI, M D, F A C S, Madison, Wisconsin

THIS study is concerned with the effect upon the tracheobronchial tree of the commonly prescribed drugs or combination of drugs, for premedication to anesthesia, and with morphine, the drug most commonly used for postoperative relief of pain. The drugs studied were morphine sulfate, $\frac{1}{4}$ grain, atropine sulfate, $\frac{1}{50}$ grain, scopolamine hydrobromide, $\frac{1}{100}$ grain, morphine sulfate, $\frac{1}{4}$ grain, and atropine sulfate, $\frac{1}{50}$ grain, morphine sulfate, $\frac{1}{4}$ grain and scopolamine hydrobromide, $\frac{1}{100}$ grain.

There has been considerable speculation and controversy over the mode of action of these drugs on the bronchi and in what manner they affect the bronchial secretions which are brought to the oropharynx. Certainly, opinions on the subject vary among clinicians. This difference of opinion may be due to the fact that conclusions are drawn from infrequent clinical observations rather than laboratory or clinical experiments.

Waters and others, in studying these drugs demonstrated that in so far as their effect upon respiration, circulation, blood pressure, tidal exchange, minute volume exchange, and nausea and vomiting was concerned, the combination of morphine and scopolamine was the most satisfactory. They also showed that the most marked depression in respiration and circulation occurred $1\frac{1}{2}$ to 2 hours after administration of these drugs.

On the basis of our studies and clinical observations both the surgical and anesthesia departments of the Wisconsin General Hospital have concluded that the combination of morphine and scopolamine in individualized doses in the ratio of 25:1 has the least depressant effect upon the raising of bronchial secretions and the suppression of cough reflex.

In order to obtain some definite data on this subject a clinical experiment was carried out on a young white female who presented a bronchopleurocutaneous fistula. Her case history follows.

White female aged 18 years was admitted to the Wisconsin General Hospital on May 20, 1940, with the chief complaint of a lung abscess. Following a fourth opera-

tion in 1938 for intestinal obstruction, she developed a left lower lobe lung abscess. She was treated in two other clinics before her admission. The treatment had been conservative, consisting of inadequate postural drainage, bronchoscopic aspirations, bed rest, diet, and "tonics." Her progress was unsatisfactory, and she was referred to this hospital. Her complaints on admission were as before, namely, intermittent fever, cough with the raising of sputum, hemoptysis, weakness, and weight loss.

On admission her temperature was 101.8 degrees, and the patient appeared toxic, undernourished, and chronically ill. Physical findings were consistent with a left lower lobe lung abscess. X ray studies revealed bronchiectasis, atelectasis, and encapsulated fluid in the left lower lobe. X ray also revealed a chronic pansinusitis.

In view of the inadequate conservative treatment previously, the patient was again given a trial on postural drainage, which resulted in no improvement. Therefore, on June 27, 1940 cauterization of the lung abscess was instituted. Multiple small abscess cavities were encountered and aspirated, and a pack was inserted. On the seventh postoperative day the pack was removed, and a large abscess cavity with many bronchopleurocutaneous fistulas was noted. Following this her condition improved rapidly. She gained 50 pounds in weight in 6 months. No cough, sputum, fever, or abnormal blood counts persisted at the time of discharge. A large bronchopleurocutaneous fistula was still present.

METHOD

The experimentation was not begun until the patient's sputum and cough were gone and she was gaining weight. After the experiment was completed, lipiodol was instilled, both through the fistula used for the experiment and from above through the trachea, and the diagnosis of bronchiectasis of the left lower lobe was confirmed. The lipiodol which was instilled through the bronchopleurocutaneous fistula was seen to enter a relatively large bronchus in the left lower lobe.

All of the data for this experiment were obtained by the same operator so that the technique followed was uniform. An easily accessible, fairly large bronchial opening (a bronchopleurocutaneous fistula) was selected and used throughout.

Powdered carmine dye was deposited by means of a small eye curette into this same bronchial opening. Carmine dye was used because of its insolubility and lack of absorption in body secretion and because it is nonirritating. Its bright color made it easily detectable in small amounts. The dye was deposited just within the bronchial opening during ordinary inspiration with the patient

TABLE I.—EFFECT OF DRUGS ON APPEARANCE TIME OF CARMINE DYE

Drugs and dosages	Number of trials	Average time interval between giving of drug and dye—hours	Average appearance time—minutes	Percentage change from control of 8.66 minutes*
Morphine gr. $\frac{1}{4}$				
Morphine gr. $\frac{1}{8}$			3.6	+79.1
Morphine gr. $\frac{1}{16}$				+79.1
Atropine gr. $\frac{1}{100}$				+3.6
Atropine gr. $\frac{1}{200}$		14	8	+3.1
Scopolamine gr. $\frac{1}{100}$		14		+8.6
Scopolamine gr. $\frac{1}{200}$		14	8	
Morphine gr. $\frac{1}{4}$ Scopolamine gr. $\frac{1}{200}$	6	14		+4.2
Morphine gr. $\frac{1}{8}$ Atropine gr. $\frac{1}{200}$		5	17.8	+109

*The positive percentage indicates the increased time; like negative percentage indicates decreased appearance time.

on her right side. It was deposited during inspiration because the expiratory blow from the bronchial opening was sufficient to blow the fine powder from the cigarette, thus making it impossible to get any of the dye into the bronchus. It was appreciated that the height to which the dye was inspired was variable but it was sufficiently uniform so that the ranges of the control "appearance times" were uniform.

The dye was deposited $\frac{1}{4}$ to 2 hours after the hypodermic injection of the drug being studied. The reason for the selection of this time interval is that Waters and others have shown that the maximum effect of these drugs is secured between

$\frac{1}{4}$ to 2 hours after their administration hypodermically.

The patient remained on her right side after the dye had been deposited. The time of deposition was noted and recorded. A third person sat at the bedside and recorded the first appearance of the dye in the sputum. The patient was intelligent and co-operative throughout the period of the experimentation. She did not cough until she got the stimulus to cough, i. e. until the cough reflex was stimulated by the foreign particles. The dye almost invariably appeared with the first cough. After two to three consecutive coughs the stimulus was gone. No more dye appeared even though she coughed later in the day. The time between the deposition of the dye and its first appearance in the sputum will henceforth be called the appearance time.

Only one trial was performed a day in order to avoid cumulative effect of the drug, and often one

day or more was allowed between trials to avoid addiction to the morphine. The patient did not know what the medication was nor what its effect should be.

Before the controls to this experiment were performed, many daily carmine dye instillations with out medication were done until it was determined that the results were uniform. At this point it was decided that the effects of the acute infection and of the surgery upon the bronchial tree were past and that the results were due to normal action of the bronchi themselves. A subsequent left lobectomy and pathological study showed bronchi with normal cilia. During the course of experimentation the sputum was at a minimum and there was no drainage from the bronchial opening.

RESULTS

It was found that the position assumed by the patient made no difference in the appearance time of the carmine dye. Trials with the patient on her right side, on her left side on her back, and in the sitting position gave comparable results. Because of the ease with which this experimentation could be done with the patient on her right side this position was chosen as the one of choice for the trials.

Fifteen control instillations, without medication, were performed. The average appearance time (that is the time elapsing between the instillations of the carmine dye and the dye appearing in the sputum) was 8.66 minutes. Controls were performed also during and after the trials with medication, and it was found that the control times remained uniform.

The drugs were then tested in the dosages as given, and the percentage change from the control time of 8.66 minutes was calculated, as shown in Table I.

The question, of course, then arose as to how long these drugs exerted their effect. Attempts at repeated dye injections were then tried. It was found that the experiment could satisfactorily be carried out for only a period of 3 hours. The results of these trials appear in Table II.

EVALUATION

The function of raising secretions or small foreign particles from the bronchi probably depends locally on three separate actions, namely: (1) the character of the bronchial secretions, (2) the action of the bronchial cilia, and (3) the cough reflex. Any variation from normal in any one of the actions may cause a deviation from normal in the appearance time.

It was realized at the outset that an experiment of this sort has many sources of error. These were minimized and eliminated wherever possible. We are not, therefore, interested in the actual appearance times, but rather in the "trend of change" as indicated by the percentage change over the normal control times, and the comparative amount of change caused by one type of medication as compared to the other. We feel sure that these results do indicate the trend of change and the comparative amount of change caused by these drugs on bronchial action.

Atropine and scopolamine themselves have little, if any, depressive action, but they do change, both objectively and subjectively, the character and amount of the secretions from the mucous glands. Whether they have any depressive or stimulating action on the cilia of the bronchi is not known. We do know that morphine causes a generalized depression of cellular metabolism and irritability. That it has a depressive action on certain respiratory functions has already been indicated (1, 2). It causes depression in the cough reflex. If morphine affects these ciliated cells as it affects most other cells of the body, we can rightly surmise that the ciliary action is also depressed.

With morphine alone the appearance time was increased 11.6 per cent over that of the control. The effect here was probably due to the generalized depressive effect, especially of the cough reflex and of ciliary action.

With atropine alone the appearance time was greatly increased, 36 per cent over the control, more so even than with the morphine alone. The cause of this perhaps lies mainly in the change in the amount and character of the bronchial secretions.

Scopolamine alone apparently had little effect. We know however that scopolamine does at least change the amount and character of the secretions, but in this experiment the change apparently was not sufficient to alter the appearance time noticeably.

When the combination of morphine and atropine was used, the change was more marked than with either drug alone, 107 per cent as compared with 11.6 per cent and 36 per cent. The appearance time was greatly prolonged. The drugs apparently here have a synergistic action, with all three of the factors, namely, bronchial cilia, cough reflex, and bronchial secretions, being altered to cause this increase in appearance time.

When morphine and scopolamine were given together, the appearance time was again greatly increased although the change was not as marked

TABLE II —EFFECTS OF DRUGS ON APPEARANCE TIMES AFTER 3 HOURS

Drug and dosages	Number of trials	Average time interval between giving of drug and of dye—hours	Average appearance time—minutes	Percentage of change from control time of 8.66 minutes
Morphine gr $\frac{3}{4}$ Atropine gr $\frac{1}{50}$	5	3	14.5	+91.8
Morphine gr $\frac{3}{4}$ Scopolamine gr $\frac{1}{100}$	4	3	11.0	+27.8

as appeared with the morphine and atropine together, 62.7 per cent as compared with 107 per cent. It was prolonged greatly as compared with either drug alone, 62.7 per cent as compared to 11.6 per cent and -2.3 per cent, and apparently their actions were again synergistic.

The results of the repeated dye injections show that the effects of the drugs are prolonged, in this case well over 3 hours from the time of giving the drugs—morphine-atropine combination 91.8 per cent over the control, and morphine-scopolamine combination 27.8 per cent over the control.

When comparing the relative effects of the morphine and atropine, and morphine and scopolamine, they bear out what we have always felt clinically at this hospital, but have never shown experimentally before, namely, that the morphine and scopolamine given in individualized doses (ratio here is 25 to 1) is a better preanesthetic combination than the former. The percentage change of morphine and atropine here over the control was almost twice that of the morphine and scopolamine.

SUMMARY

1 Morphine sulfate, atropine sulfate, and scopolamine hydrobromide were studied both alone and in combination, to determine their effect upon the bronchial tree, in a patient with a bronchopleurocutaneous fistula. The "appearance time" of the carmine dye was used as the method of testing the effect of drug action.

2 In 15 control experiments, the average appearance time of the dye was 8.66 minutes. The control time was checked during the course of the experiment and was found to be uniform.

3 Morphine sulfate caused an increase in the appearance time of 10 minutes, or a percentage change of 11.6 per cent over the control.

4 Atropine sulfate, $\frac{1}{100}$ grain, caused an increase in the appearance time of 3.1 minutes, or 36 per cent over the control. Atropine sulfate, $\frac{1}{50}$ grain, caused an increase in the appearance

time of 3.3 minutes, or 37.2 per cent change over the control.

5. Scopolamine hydrobromide caused a decrease in the appearance time of 0.3 minutes, or a 2.3 per cent change over the control.

6. Morphine-atropine combination increased the appearance time 9.3 minutes, or a .07 per cent change over the control.

7. Morphine-scopolamine combination increased the appearance time 5.4 minutes, or a 62.7 per cent change over the control.

8. Three hours after the morphine-atropine had been given the appearance time was increased 5.9 minutes, or a 91.8 per cent change over the control.

9. Three hours after the morphine-scopolamine had been given the appearance time was increased 3.4 minutes, or a 27.8 per cent change over the control.

10. The sources of error in this type of experiment were appreciated. As a result the trend of change and the comparative amount of change of one medication as compared to another are the findings of importance in this study rather than the actual appearance times.

A SIMPLE OPERATION FOR STABILIZATION OF THE KNEE JOINT

HARRY C BLAIR, M D , Portland, Oregon

AN operation for stabilization of loose knee joints following injury to the crucial ligaments is described herein. The operation is simple to perform, it does not necessitate opening of the knee joint, it eliminates the need of long postoperative immobilization, and it makes possible, and desirable, early walking with the aid of a knee cage.

Looseness of the knee joint as a result of injury to the crucial ligaments is a serious disability. Milch pointed out that injury to the crucial ligaments usually involves other supporting structures of the knee, particularly the internal lateral ligament when the anterior crucial has been traumatized. He believed that primary surgical treatment should be directed toward the repair of the internal lateral ligament rather than the cruciate. Bennett stated that a knee may be fairly stable in spite of severance of the anterior crucial ligament, provided that the internal lateral ligament is normal. According to Cubbins and his associates, early operation following complete dislocation of the knee is not indicated. They advised immobilization of the knee for 120 days, arguing that some knees so treated will recover.

The operation which Hey Groves (5, 6) described for the repair of torn crucial ligaments with fascia lata established the principles upon which most of the subsequent repairs have been based. A modification of the Hey Groves operation to include strengthening of the internal lateral ligament was later reported by Alwyn Smith. Fascial transplants, however, do not restore a knee to normal function after long continued disability due to injury of the collateral ligaments of the knee even though stabilization may be effective (9).

Less difficult procedures than those advocated by Hey Groves and Alwyn Smith have since been devised and have given satisfactory results. Bennett plicates the capsule and uses two parallel strips of fascia for further reinforcement (Fig 2, A). Cotton and Morrison draw a strip of fascia through holes drilled in the tibia and femur, crisscrossing the strip as it is pulled through the hole (Fig 2, B). Ryerson, has modified this procedure somewhat, he drills the holes in the tibia about $\frac{7}{8}$ inch apart, making the anterior

hole at a lower level, and ties a square knot in the fascial strip near the femur before he draws its long end through the tibia (Fig 2, C). D. M. and B. M. Bosworth implant a fascial strip in a tunnel in the posterior part of the tibia, draw it through another tunnel in the femoral epicondyle, then pass it through a tunnel in the anterior part of the tibia, and finally suture the fascial strip at the femoral epicondyle (Figs 2, D and 2, E). The Bosworths stated that when the external collateral ligament is repaired, the attachment may be made to the tibia and the head of the fibula.

The operation now reported is based on Testut's observation that movement of the knee joint is centered in the posterior portion of the femoral condyles. By superimposing roentgenograms

Fig 1 Schematic drawing of roentgenograms taken with the knee in complete extension and 90 degrees' flexion. A indicates nearly fixed point.

Fig. 2. Stabilization operations previously described in which the reinforcement is placed on the medial or lateral side of the knee.

taken with the knee in extension and at different angles of flexion, a nearly stationary point is localized in the center of the ring formed by the extension of the arc made by the posterior and inferior portions of the femoral condyles (Fig. 1). Theoretically, this point does not change its distance from any fixed point in the tibia during flexion and extension of the knee joint. A strip of fascia applied so that it crosses the fixed point, as is done in the present operation, will therefore remain at the same degree of tension with the knee in extension and in any degree of flexion. Practically, this arrangement of fascial strips has been successful since it has given good functional results under adverse conditions.

It has now been almost 10 years since I performed the first stabilization operation by the method now described. Up to the present time I have performed this operation on 10 patients.

These drawings are reproduced by permission of the various authors and the publishers of the periodicals in which they originally appeared: Bennett, *Arch. Surg.*; Brown and Morrison, *New England J. Med.*; Ryerson, *Gen. Clin. H. America* (Part II); D. Bosworth Company; and Bosworth, *J. Bone Joint Surg.*

Two patients who were re-examined in 1930, 8 years after the operation, reported that they had had no disability during this period. One was then employed as a truck driver although the industrial accident commission had paid him 60 per cent lost function of a leg 6 months after the operation. The other patient was working as a hook tender in a logging camp, and had been employed continuously at this arduous work since approximately a year following his operation. This patient had been awarded 45 per cent lost function of a leg 3 months following the operation.

OPERATIVE TECHNIQUE

A strip of fascia, approximately 12 inches long and 1 inch wide, is removed from the fascia lata of the contralateral extremity. A stripper is not used because it is difficult to obtain fascia of the proper width and length by this means. The fascia is cut into four strips, each of which measures approximately $\frac{3}{8}$ inch in width and 6 inches in length. The strips are tied into Gallie needles, and placed in a piece of gauze soaked in saline.

After the fascia has been prepared, an incision 6 inches long is made in the midline on the lateral side of the affected knee. A similar incision is also made on the medial side of the same knee. The skin and the superficial fascia are then dissected free from the deep fascia for a distance of 2 inches on either side of both incisions.

Lateral side (Fig. 3) The first fascial strip is placed in the insertion of the biceps muscle at the head of the fibula, and its lower end is secured in place by suturing it through itself. It is then carried obliquely forward to a position near the superior pole of the patella. Here the free end is passed deep into the tendinous expansion of the suprapatellar tendon, turned back on itself held tightly in place, and secured with a number of interrupted catgut sutures. The fascial strip does not penetrate the knee joint.

The second fascial strip is attached to the deep fascia on the anterolateral surface of the tibia. This strip is carried obliquely backward, crossing the first, and its free end is fastened securely to the fascia and some of the fibers of the biceps muscle. The two strips should cross on a level with the fixed point in the femoral condyle.

Medial side (Fig. 4) The third fascial strip is started as far back as the posteromedial border of the tibia, at about the same relative level as the head of the fibula and is buried deep in the fascia which in this region covers the tendons of the internal hamstring muscles. Some of the fibers of these tendons may be included in the suture. The fascial strip is then brought obliquely forward and

Fig. 3 Lateral view of the knee showing the order of placing the fascial strips, the method of their fixation, and the tension of the tissues after the fixation is completed

Fig. 4 Medial view of the knee showing the method of the placing of the 3rd and 4th crossed fascial strips in this region

upward, and its free end is inserted just medial to the superior pole of the patella

The fourth fascial strip is started at the same level, on the anteromedial border of the tibia. It is carried obliquely backward and upward, crossing the third strip, and is sutured to the fascia overlying the internal hamstrings. The suture may include some of the fibers of these muscles. These two fascial strips, like the first two, should cross on a level with the fixed point in the femoral condyle. When all the strips have been sutured into place, the first runs parallel to the third, and the second to the fourth.

No sutures are used except those of interrupted catgut which secure the fascial strips as described. The skin of each incision is usually closed with silk, and a compression dressing of sterilized cecil cotton¹ is applied.

When the skin stitches are removed, a non-padded walking cast, extending from the groin to,

and including, the toes of the affected extremity, is applied for 2 weeks (the postoperative care of the first 2 patients did not include the nonpadded cast). During the 2 weeks' period the patient is urged to bear some weight. At the end of this time, a long knee cage with 12 inch leather thigh and leg cuffs is supplied. The cage allows 10 degrees' flexion at the start. Flexion thereafter is gradually increased over a 2 or 3 months' period of time.

Abnormal mobility is present in the knee for some time after the operation. And often the hypermobility increases during the 4 to 5 weeks' period immediately following the operation. After this, however, the knee will begin to tighten. The patient is permitted to walk as he sees fit, and no limit is placed on his activities so long as he wears the brace with which he is supplied. Some of the patients have returned to work before this support was removed. The brace should be worn until the quadriceps muscles have developed and the hypermobility of the knee joint has decreased. Sometimes it is necessary to wear the knee cage for 5 or 6 months, or even longer.

¹Cecil cotton is a nonabsorbent bleached batting which comes in 8 ounce weight containing 50 per cent staple cotton and 50 per cent cotton linters, and in 16 ounce weight containing 75 per cent staple cotton and 25 per cent mill run linters. A good grade of nonabsorbent bleached cotton batting would be just as satisfactory.

CASE REPORTS

CASE 1. D. male aged 37 years, as admitted to St. Vincent's hospital on December 6, 1931 because of a knee joint pop in and out during flexion, and that the knee dislocated back and laterally. This knee had been injured on February 6, 1931 and in 3 1/2 years of that year the internal semilunar cartilage had been removed.

On examination the patient as found to have torn posterior cruciate ligament. The knee joint as extremely lax.

The stabilization operation now reported as performed on December 8, 1931. Three weeks later the patient as discharged from the hospital. At that time he as fitted with long knee cage which allowed approximately 15 degrees flexion of the knee. Six months after his discharge his claim with the industrial accident commission as closed with permanent partial disability and of 60 per cent.

This man as re-examined in 1932, approximately 8 years after his operation. He as then employed as a truck driver. He had, however, not returned to his former work in the woods and had been able to continue it. During his work in the woods he had noticed that when he jumped from one log to another he usually slighted on the extremity which had not been operated upon. Nevertheless, few years later he had been able to take part in log rolling contest.

CASE 2. L. G., male aged 30 years, was admitted to St. Vincent's hospital on February 2, 1932 complaining of weakness and abnormal motion of the right knee. He had sustained fracture of the right tibia in 1917 and the knee joint on January 23, 1932.

On examination it as found that the right leg could easily be moved on the thigh both anteriorly and posteriorly. There as also some increase of mobility medially and laterally.

The stabilization operation as carried out on February 12, 1932 and on March 1, 1932, the patient left the hospital. The cast which had been placed on the extremity at the time of the operation was removed before the patient as discharged. After his discharge he as on no support. On June 9, 1932 his claim with the industrial accident commission as closed with permanent partial disability and equal to 45 per cent loss of function of leg.

This man as also re-examined approximately 8 years after his operation. At that time he stated that he had not been disabled by the knee, and that he never thinks about it any more. He had returned to his job as a book tender in logging camp about a year after the operation, and had been employed continuously since then. His work as arduous and dangerous, and necessitated jumping and moving about quickly on uneven ground.

CASE 3. J. H. male aged 45 years, had been injured on August 5, 1937 when a large log rolled against the outer side of his lower right leg. A smaller log had struck the thigh on the inner side causing dislocation of the right knee. The dislocation had been reduced immediately and cast had been applied. Following this the patient had continued to be on support until November 5, 1937.

Examination on January 3, 1938, revealed instability of the right knee, some genu recurvatum, and weakness of the external lateral ligament. It as possible to displace the knee anteriorly and posteriorly. The peroneal nerve as paralyzed.

On April 1, 1938, the stabilization operation as performed. At the same time the peroneal nerve as exposed at the point where it crosses the fibula, and considerable scar tissue as removed from this region. After the stitches as removed nonpadded cast as applied. Three weeks later the patient was supplied with brace.

I August, 1940, the patient returned to St. Vincent's hospital for examination on September 1, 1940. At that time his knee as completely stable, and the function of the peroneal nerve had returned. The patient said that he had been working in logging camp.

CASE 4. J. C. V. male, aged 36 years, had twisted his right knee on August 3, 1937 when he had fallen between two logs. He had been able to continue his work by not allowing his knee to extend completely. On March 4, 1938, the internal semilunar cartilage had been removed.

Examination of the right knee on August 5, 1938, revealed that the anterior cruciate ligament as torn and that the external lateral ligament was also injured. In addition, there as some stretching of the posterior cruciate ligament. The knee could not be displaced backward to any great extent, yet the patient had genu recurvatum.

On September 20, 1938, the operation for stabilization as performed. The nonpadded cast as applied after the stitches as removed and brace as supplied weeks later.

When this man as examined again on May 1, 1940, it as observed that the knee as stable as far as form and back and displacement are concerned, but that there as still some back knee. This caused slight disability.

I now believe that after operation on patients who present back knee, the knee should be placed in about 5 degrees of flexion for at least 6 weeks before movement is begun.

CASE 5. C. K. male aged 40 years, as examined on August 1, 1930. It as found that the right leg could be displaced forward on the femur when the knee was in slight flexion. A diagnosis of torn anterior cruciate ligament as made. This man stated that he had dislocated his knee on March 5, 1931 when he had jumped off board.

On August 28, 1930, the stabilization operation as performed. The nonpadded cast as applied after the stitches had been removed, and three weeks later brace as supplied. A little over a year following the operation the patient returned to his work selling timber. I letter cited on June 1, 1941 he stated that the operation as certainly a wonderful success.

CASE 6. F. K. male, aged 24 years, seen on October 2, 1938, because of an injury to his left knee which he had sustained while playing football. A diagnosis of torn external semilunar cartilage and injury to the cruciate ligament of the left knee as made.

On May 1, 1939, the left external semilunar cartilage as removed. And on October 1, 1939, the stabilization operation as performed. Following this procedure the extremity as placed in nonpadded cast. Later the patient was given long knee cane.

This young man as re-examined on November 7, 1940. At the time anterior displacement of the tibia on the femur as still present.

The displacement I believe, as probably due to relaxation of one of the fascial strips which occurred shortly after the operation. I have not been able to obtain permission to operate on this boy again. Meanwhile, however, reopened the incision on the medial side of the knee of one of his patients because of the same complication. One of the fascial bands, he found, had failed to hold and had to be reset in its position. The other was in place and had greatly hypertrophied.

Sufficient time has not yet elapsed to determine the outcome of the first 3 operations. One patient could not be traced.

SUMMARY AND CONCLUSIONS

The operation which has been described herein was first attempted because the patient had refused to have his knee opened, yet, because of the severity of his condition, required some stabilization procedure. From a cursory examination of the present technique, it would seem that fascial strips which are not drawn through bone cannot stabilize the knee joint. Practical application of this procedure over a long period of time has, nevertheless, except for 1 instance, been successful. This, it would seem, proves that it is not absolutely necessary to anchor fascial strips in bone in order to secure satisfactory stabilization. Moreover, Meekison, who had occasion to reopen the knee of one of his patients, observed that the fascial strip which had remained in place had greatly hypertrophied. This would indicate that fascial transplants applied in the manner just described have a normal physiological action.

While this stabilization operation has already been successfully carried out following severe in-

juries to the crucial and collateral ligaments, it is particularly applicable following minor injuries to these ligaments, that is, injuries which make wide exposure of the knee joint inexpedient.

Finally, as has already been stated, the stabilization operation now described is simple to perform. Prolonged hospitalization is unnecessary, and the patient within a relatively short time is able to resume his former activities.

bruising injury which could lead to interarticular changes and ultimate future disability. Further, the patella has a cosmetic value which must not be overlooked. Its removal obliterates the normal contour of the knee and creates an asymmetry between the injured and uninjured leg. There is generally, also, fear or apprehension expressed by the patient with respect to possible impairment of stability when removal is suggested. This is particularly true on the part of those engaged in occupations which require them to assume kneeling positions frequently, such as housewives, mechanics, plumbers, the clergy, and so forth. From the standpoint of a compensation or insurance case the removal of a whole bone, sesamoid or long bone, and the resultant defect, constitutes in itself substantial damage and potential disability.

3 *Plastic tendon repair and removal of loose fragments.* The limitations and disadvantages of the two preceding methods of dealing with the problem of fractures of the patella, from a physiological, anatomical and economic standpoint, have led to the growing popularity of a third school of thought which advocates the removal of all but a single attached fragment. This fragment may form either the distal or the proximal pole of the patella and the opposing patellar tendon is sutured to and through this remaining fragment.

To evaluate the appropriateness of this principle which I recommended years ago, many of the leading fracture surgeons were canvassed by questionnaire, with the result that 113 surgeons responded as having used this method on from 1 to 39 cases. A total of 554 cases have been studied. Of this number 479 have been analyzed with respect to age, sex, type of fracture, number of days between operation and beginning of weight-bearing, period of limited function, length of time between operation and return to work, and resulting ultimate partial permanent disability. There were 75 cases with incomplete statistical data but sufficient information was available from the many comments to prove valuable in making deductions. The 479 cases were divided into two groups. The first 424 cases comprised fractures operated upon within 2 weeks after injury. The second group, consisting of 55 cases, included those operated upon after the 2 week period.

In this series of cases the average age was 40 years. When one considers the ages by decades it is quite evident that this fracture seldom occurs in the very young and very old, and is distinctly a fracture of middle life. Males outnumbered females almost two to one.

Simple comminuted fractures were by far the commoner type in which this procedure was used, although it was used in a large group of simple fractures that were not comminuted. It is interesting to note that this method proved quite adaptable in 56 compound fractures.

Three hundred and fifty-five fractures were operated upon within 2 weeks. In 69 additional cases the exact day was not designated, but other circumstances reported seemed to indicate that they were operated upon early, so therefore they are considered in this group. The average number of days between accident and operation in this group was 3.6 days. However, there were 104, or 29 per cent, operated upon within the first 24 hours and 198, or 55 per cent, within 3 days, while 287, or 80 per cent, were operated upon within the first week and only 68, or 20 per cent, during the second week. Many of the fractures operated upon within a few hours were compound injuries in which débridement and clean up offered a chance of primary closure and healing. It was interesting to note that the more experience a surgeon had had with this technique the earlier he operated.

Of the 55 patients operated upon more than 2 weeks after injury, in 21 repair was done within 2 and 4 weeks, and 16 more were operated upon within 3 months. In this group are the fractures that were referred late to the surgeon, conservative treatment having failed to bring or hold the fragments together. There were 15 compound fractures which, due to tissue injury, infection, and other complicating circumstances, were unsuitable for early closure. Also there were 15 cases of nonunion or separation of fragments, following previous operations to approximate the fragments with wire and other suture material around and through the fragments. The necessity of a secondary operation probably contributed to a portion of the ultimate disability in 8 of these cases, 2, 5 per cent, 2, 10 per cent, 1, 15 per cent, 2, 20 per cent, 1, 30 per cent. Several of the patients in this group had complications of such importance that repair of the patella and tendon was necessarily delayed.

Not all of the reports gave the period of immobilization, but of the 316 cases in which this question was answered the average period was 4.17 weeks. Among these 16 had only a compression bandage after operation, and 67 had 2 weeks or less immobilization. The period of immobilization varied with the seriousness of the injury and complications. Some surgeons, using stainless steel wire and other nonabsorbent, or slowly absorbent, suture material, believed that immo-

Fig 4. Lower patellar tendon drawn snugly against patellar fragment and kangaroo suture tied securely. Capsule and tendon structure closed.

Fig 4

bilitation was not of major importance and that the suture and compression bandage were sufficient.

Severe complications and long bed confinement in 79 cases and conservative surgical judgment which kept patients off their feet in perhaps an equal number more raised the average time before walking was allowed to 5 weeks. Contrast this to the 75 who were allowed to walk within 2 weeks and the 76 within 3 weeks, and it will appear reasonable that without complications to interfere restricted flexion with early weight bearing prevents atrophy and gives confidence both of which are essential to a good result.

The average loss of time from work was 9.9 weeks for the 268 cases reported upon. Of this total number there were 189 fractures of the patella having no complications that had an average of 8.3 weeks loss of time. There were 79 cases with complications whose average loss of time from work was 4 weeks. There were students, clerks, teachers, and many others who were away from work only a short time. On the

other hand, those engaged in more active occupations had a longer period of disability. Liability and compensation insurance as well as various types of psychosocial, often entered into this picture. Further, one must remember that 78 of these patients were between 50 and 60 years of age and

63 others were over 60 years of age. These fractures, when the patient is past middle age, require maximum healing and rehabilitation time.

In the consideration of the subject of disability of any impaired part of the body there is such a tremendous personal equation that must be taken into account, in connection with every opinion, that one must be guarded in the estimation of percentages. There may be a slight quadriceps weakness which in one individual is no more disabling while for another it would constitute considerable disability. Likewise, one might have extensive loss of normal flexion and have relatively little disability for almost any type of labor.

Four hundred and thirty three reported disability aspect; disability 350 were reported with disability leaving 83 cases with partial disabilities. Of these 83 cases 73 had disabilities under 5 per cent which left only 10 cases with disabilities above 5 per cent. Among the 10 cases with disabilities there were 61 who had no complicating injuries, disease, or infection that contributed to the estimation of their partial permanent disability. Of a total series of 433 cases this included 1 patient with fractures of the patella without complications who had disabilities of 10 per cent up to 5 per cent in seven cases, the results were spoken of as excellent.

Fig. 4

Fig. 5

Figs. 4 and 5. The patella by carrying the quadriceps tendon γ from the femoral condyles lessens the leverage action of that muscle and lessens the effort required for extension. The removal of the patella decreases this leverage action—by an angle of 24 to 30 degrees—and greater effort is required to extend the leg. The principle of the patella action is similar to the levered effort exerted when a bucket of water is drawn up over a pulley rather than when it is dragged over the edges of the well.

Fig. 6

Fig. 7

Fig. 8

Figs. 6, 7 and 8. Types of fracture of the patella in which removal of all but one fragment and plastic repair of the tendon is particularly indicated.

Fig. 8. The lower fragment of transverse fracture should be removed.

desired, and satisfactory. From a compensation standpoint most fractures of the patella, after arthrotomy, leave a disability that must be considered in making a settlement, while a year after the impairment of function will be negligible. It is interesting to note that in this series there were 56 compound fractures of the patella and out of these (26) had disabilities. Of the cases 10 had complicating injuries, which left uncomplicated compound fractures of the patella with disability. Fifteen of the 26 patients had a disability between 5 and 15 per cent and

8 had more than 15 per cent disability. In addition to these there were 3 compound fractures with admitted disability in which percentage was unestimated. This left 30 compound fractures of the patella with no disability.

Among the conditions incident to this operation that contributed to disabilities were several to which I wish to direct some attention.

First, post-operative infections. There were 4 of these and no explanation or reason was given for them. Three were serious and long disabling with 50, 50 and 15 per cent disabilities. The

have been several valuable suggestions and modifications for this procedure. All of them aim toward accomplishing and restoring better and more secure apposition of the opposing tendon-bone ends. Hoyt and O'Donoghue suggested wire as a suture through, or around, the bone fragment and the opposing tendon. We have preferred a braided wire to a single wire. Carter not yet tried stainless steel wire, but the many interesting and satisfactory results from its use would lead me to feel that there was considerable virtue in its security. As yet in none of these cases, in many of which patients were operated upon over 2 years ago, has it been necessary to remove the wire. Therefore, the wire apparently did not cause irritation with functional activity. Contraction of the quadriceps has led occasionally to difficulty in reapposition of the fragment and tendon. The low tourniquet often contributes to this. We have found that a traction suture through the patella helped in bringing the tissues together. However, Stern states that inadequate relaxation is accomplished by the use of either a spinal anesthesia or an extensive infiltration with one-half of one per cent novocain directly into the bellies of the quadriceps muscles, which makes it much easier to oppose the fragment and the tendon.

Prince, in his April, 1940, letter to the Orthopedic Correspondence Club, modified the technique not only by suture of the tendon to the fragment, but also by embedding the upper end of the tendon under the periosteum of the upper portion of the fragment. Stern has modified this still further. He also bores holes from above obliquely downward in the fractured surface just in front of the articulating portion. The suture material is introduced into the patellar tendon about an inch below the upper end, and then the tendon is brought into contact with the fractured base and up over the top of the patella. Here, after the method of Prince, the upper end of the tendon is embedded under the periosteum of the patellar fragment.

These modifications may add to the better union and healing of the repaired patellar tendon and have the virtue of bringing the remaining patellar substance down farther on the condyles which is so essential to the strength of the quadriceps action. A factor of technique which we believe of extreme importance to the restoration of good function is the plastic repair of the capsule and ligamentous substance which is usually torn on either side of the patella.

Among those who submitted cases were 11 surgeons who reported 10 to 39 cases, inclusive, and 24 surgeons who reported 5 to 10 cases inclusive, or a total of 35 surgeons with considerable experience with this procedure. The largest groups reported were Boyd, 39 cases, Hoyt, 24 cases, and Dillehunt et al., 19 cases, each with generally rather gratifying results.

CONCLUSIONS

Bear in mind that this is not a comparative evaluation of the various approaches to the treatment of fractures of the patella, but rather a study of a large group of cases in which a single operative principle has been applied. The conclusions are not my own but are the expression of the averages, clinical data, and opinions of those who furnished the cases. However, they verify convictions held ever since I recommended this procedure.

- 1 Fracture of the patella is common in middle life and seldom occurs among the young and aged.
- 2 It occurs in males more than twice as often as in females.
- 3 Communited fractures are twice as frequent as any other.
- 4 Compound fractures deserve the same consideration here as such fractures elsewhere.
- 5 The more familiar the operator becomes with this technique the earlier the fracture comes to surgical repair.
- 6 If there is extensive damage to integument and underlying tissues many prefer to delay operation (average 3.5 days) and allow a "tissue comeback."
- 7 This fracture is often associated with other complicating injuries that influence the ultimate outcome.
- 8 Early weight-bearing with restricted flexion should be encouraged ($1\frac{1}{2}$ to 3 weeks), provided complications do not interfere.
- 9 Loss of time away from work is directly proportionate to the severity of the injury and complications, 8 weeks for uncomplicated fractures and 14 weeks for complicated fractures.
- 10 There were but 22 fractures that were not complicated by other injuries that had disability. This number is only 5 per cent of the total cases completely studied. In none of these was the disability over 15 per cent. The average was 7.5 per cent while those with complications had an average of about 16.5 per cent of function.
- 11 This large sesamoid has an important functional value to the knee joint particularly when fully flexed (Figs 4 and 5), in that it checks the

indicates with fine precision that the normal tissues are unable to tolerate the intensity of the radiation that is being administered. Appearance of this sign is an indication for immediate reduction of the intensity of treatment or of the size of the field.

Injury to Blood. The intracavitary application of radium is not complicated by any noteworthy injury to the blood elements and with rare exceptions the same holds true for external radiation. Lavedan and others have proved that treatment with the most intense methods of external radiation with radium as well as x-rays results only in a slight and temporary leucopenia followed by restoration to normal within a short period after the completion of treatment.

In the writer's experience the white blood cells of a small proportion of patients have a special sensitivity to radiation. I estimate the incidence as less than 5 per cent. In these cases the first few exposures result in an unusual diminution of the leucocytes, sometimes necessitating an interruption of treatment. With these rare exceptions, no serious or permanent damage to the blood-forming organs is encountered following the fractional method of radiation.

Wintz admits that under certain conditions with the massive dose treatment severe blood changes finally leading to death cannot be totally avoided, but he believes that this risk must be taken in dealing with a lethal disease. In view of the favorable results of the fractional method of treatment, this risk does not seem justified.

The general apprehension regarding the dangers of injury to the blood-forming organs accompanying massive radiation for cancer of the cervix is not supported by the most authentic evidence. All difficulties can be eliminated by a roiding the single massive radiation and by identifying the occasional patient with hypersensitivity of the white blood cells.

Injury to Bladder. Injury to the bladder as a result of radiation in cervical cancer is uncommon if the treatment is given with reasonable precision. Serious damage to the bladder can occur only as a result of faulty radiation. A mild irritation of the bladder mucosa may become evident during treatment; the symptoms, however, generally disappear within a short period. Small superficial erosions of the bladder in case are sometimes observed on cystoscopic examination soon after intracavitary radiation. These lesions are said to be more common than has been generally supposed. They apparently heal within a short time and probably result in no serious permanent damage. On the whole bladder in-

jury does not constitute a serious problem in the radiotherapy of cervical cancer.

Injury to Rectum. The rectal mucous membrane is certainly one of the most, if not the most, sensitive tissues in the body to radiation. This fact, combined with the proximity of the rectum to the radium foci placed against the cervical lesion exposes the rectum to possible radiation injuries. Before the dangers associated with the uses of radium were adequately recognized, serious rectal damage often resulting in rectovaginal fistula was not uncommon. Today this complication is extremely rare. It must be noted that advanced stages of the disease untreated result in rectovaginal fistula in a small but definite proportion of cases, so that the presence of this condition does not necessarily indicate an incorrect radiation.

Radiation effects upon the rectal mucous membrane result in definite clinical signs which vary in degree in proportion to the intensity of the radiation. The first and mildest reaction consists of a watery diarrhea without abdominal pain, with two to four liquid stools daily. These signs develop frequently during the beginning of the third week of external radiation when a little less than half of the treatment has been completed (4000 r units or 50,000 mg hrs.). This reaction naturally develops somewhat earlier in some patients. It constitutes a highly important clinical sign in that it indicates that the level of tolerance has been reached. A reaction of this degree does not require any changes in the radiation with the exception of reducing the size of the skin portal. The importance of making this one change can hardly be overemphasized.

If the rectal reaction becomes more severe, resulting in six to eight stools daily accompanied by colic-like pain, the indication is that the radiation is too intense. Under these circumstances either the daily dose must be reduced or the size of the field diminished or the treatment must be discontinued for several days or longer.

A profuse, severe diarrhea accompanied by colic-like pain is due to overdosage and should be a coded. Healy has directed attention to severe intestinal reactions occurring toward the end of the radiation and stimulating the clinical picture of acute appendicitis.

Late postirradiation sclerosis of pelvic tissues. Late sclerosis of the pelvic tissues may occur years after intensive radiation for cancer of the cervix. This state may be accompanied by occlusion of the vagina and cervix followed by pro-metria, vaginal sclerosis, rectal obstruction, and occlusion of the ureters followed by pyelonephro-

sis or pyelonephritis. Regaud and Hermet have made a study of this late complication. They have described them as tumor formations usually located in one side of the pelvis and frequently involving the rectum, uterus, and bladder. In the beginning they are comparatively soft and lack the induration of a true recurrence. The contour is diffuse and the mass is painful to the touch. In one group of cases a closed pyometra with periuterine edema and diffuse parametrial inflammation simulates a local recurrence.

The diagnosis of these lesions may be exceedingly difficult. Such lesions may persist for many years before they disappear. A pyometra can be excluded by careful exploration of the cervical canal. In the other forms a differential diagnosis between postradiation sclerosis and recurrence is finally established only by the course of the disease.

I have encountered several cases in which mild palliative radiation was given for suspected late parametrial recurrences. The patients were discharged with an apparently hopeless prognosis. Several years later information has reached me that these patients are alive and well. There can be little doubt that these are examples of pelvic sclerosis and not recurrent carcinoma. The importance of recognizing this possibility is obvious and one should avoid giving a hopeless prognosis in the face of this possibility.

Postradiation intestinal obstruction resulting from benign stricture of intestine. This complication, although rare, is of the greatest importance. The writer has encountered two examples. Jones of Cleveland has reported 7 cases. Unless this possibility is considered, a diagnosis of recurrence is usually made. The clinical picture is classically that of intestinal obstruction. Jones has made the following observations:

"In 520 patients having cervical carcinoma who received radiation therapy there have been seven known cases of benign stricture of the intestine caused by obstruction which might easily have been construed as, or confused with, metastatic deposits. In five the obstruction was in a movable segment of the sigmoid and in two in the small intestine. Since similar methods of therapy are in general use, it seems probable that the incidence of the lesion is greater than is surmised, and if similar cases have been attributed to metastasis in the past, the mortality statistics relating to metastasis from cervical carcinoma are open to question. The intestinal obstruction developed in the seven patients from eight months to eight years after radiation therapy for cervical carcinoma. If the condition actually is a benign stricture caused by irradiation, it is obvious that additional roentgen treatment would only aggravate the condition and hasten the end. Therefore, a patient in whom unusual abdominal symptoms are present, particularly if they simulate intestinal obstruction, may have a stricture of the intestine and may be restored to normal health by resection of the colon."

"Before attributing this disability to metastasis, thorough re-examination by sigmoidoscopic and roentgenographic studies should be made to eliminate the possibility of this curable complication. Strictures in the small intestine are difficult to visualize unless the obstruction is practically complete. Barium in large amounts is inadvisable, and therefore, exploratory operation is warranted, especially in patients in whom there is no evidence of recurring carcinoma in the pelvis."

Localized infection. Before the more serious and sometimes fatal generalized infections are discussed, brief reference will be made to the less serious infections which remain localized and from which the patient generally recovers. These may be divided into three groups:

1. *Early pyometra* due to occlusion of the cervical canal and appearing toward the end or within several weeks after radiation. This complication should always be considered and recognized as early as possible. Dilatation of the cervical canal and drainage frequently terminates this complication.

2. *Late pyometra* occurs from one to several years after treatment. The condition has to be differentiated from recurrence. The treatment is the same as for early pyometra. Occurring long after treatment, the diagnosis is more likely to be missed.

3. *Late infectious parametritis.* This complication arises usually one to three years after radiation treatment. It may be due to a reactivation of an old latent infection or to a new infection which becomes localized in tissues of a lowered resistance. This inflammatory complication must be differentiated from recurrent cancerous disease.

Localized and generalized infection during irradiation of cervical cancer. Infection during the process of irradiation is by far the most important complication associated with the radiotherapy of cancer of the cervix, the 2 per cent mortality charged against this procedure being due almost exclusively to the activation of hemolytic streptococci by the radiation. What are the circumstances under which this serious event occurs and how can it be avoided?

The incidence of hemolytic streptococci in cervical cancer is variously reported by different authors. Dehler reports that most cancers of the cervix contain streptococci and that over two-thirds of these are hemolytic. Claiberg, however, found nonhemolytic streptococci in 97 of 122 cases of streptococcal infection in cervical cancer. Philipp considers that hemolytic streptococci are the most commonly encountered organisms as well as the most virulent, although not all hemolytic streptococci are virulent.

In an effort to determine the virulence of the microorganisms, Ruge devised a clinical test which has been amplified by Philipp. The Ruge-Philipp test determines the ability of the patient's microorganisms to grow in a medium containing the patient's own blood. If the bac-

teria grow and multiply they are considered virulent. If they fail to grow or if they diminish in number they are considered of uncertain virulence. With this classification it was found that radiation treatment in the presence of a virulent streptococci resulted in 1 death (2 per cent). One patient developed severe complications and 48 had a smooth convalescence. Of 22 carriers of virulent streptococci 5 or 19 per cent died. 8 showed severe complications and 13 showed a smooth convalescence.

Many procedures have been advocated to combat this complication. Antiseptic douches, hypertonic salt solutions, copper salts, vaccines, autovaccination, and antistreptococcus serum have been recommended. A chemical known as rubral has been tried in the Curie Institute. None of these procedures have succeeded in effectively eliminating this complication.

Backe reports that among 44 cases of advanced carcinoma of the cervix treated intensively between 192 and 1927 by external radiation 7 or 16 per cent died during treatment of infectious complications whereas between the years 1928 and 1930 only 2 of 19 patients died of infection, 5 per cent. This author is probably correct in attributing the difference to an improvement in the technique and distribution of the radiation. It would seem from this evidence and other data that cautious, well distributed radiation diminishes the danger of infectious complications.

Since the introduction of sulphanilamide and its derivatives, several reports have appeared in the literature indicating their value in the treatment of these infections. In 1938 Goff reported a striking result in a pelvic cellulitis complicating radium treatment of a carcinoma of the cervix. He used sulphanilamide. In 1939 Bowring and Fricke reported the cases of 3 patients treated by sulphanilamide with excellent result.

SUMMARY

Most of the complications associated with the radiation treatment of cervical cancer are due to a faulty technique and are avoidable.

Edema of the skin and irritation of the rectal mucosa are two important signs indicating that the limits of tolerance have been reached. These signs, particularly the latter should be

carefully looked for and used as guides in the intensity of treatment. Careful attention to these signs at once obviates most of the avoidable complications.

3. Postirradiation pyometra and sclerosis of the pelvic tissues occurring one to several years after treatment may simulate recurrent cancer so closely that a differential diagnosis is impossible. This source of error should be considered in rendering a prognosis and planning treatment in this group of cases.

4. Signs of intestinal obstruction appearing months or years after irradiation of cervical cancer should raise the suspicion of benign stricture of the intestine.

5. Infection constitutes a notable exception. This complication is largely unavoidable. The activation of latent hemolytic streptococci is a real danger and is associated with 1 to 2 per cent mortality. Virulent hemolytic streptococci are probably less frequent in early lesions.

6. A bacteriological examination should be made in every case before treatment as the infected cases require special attention.

7. An effort should be made to combat the infection by the best methods of anti-streptococcal therapy. Sulphanilamide has been used with considerable success.

THE SIGNIFICANCE OF THE VENOUS CIRCULATION ABOUT THE ELBOW IN THE PATHOMECHANICS OF VOLKMANN'S CONTRACTURE

THOMAS HORWITZ, M D, Philadelphia, Pennsylvania

THE concept that venous obstruction plays an important rôle in the mechanogenesis of Volkmann's contracture of the upper extremity has been premised, in great part, on the belief that the venous communication between the deep and superficial venous systems in the elbow region is a single venous channel and is susceptible to compression, as by a subfascial hematoma, within the confines of the antecubital compartment. The anatomical facts to be related in this investigation indicate that the venous communications between the deep and superficial networks are numerous and that the collateral system is widespread and well protected. This adds further evidence that the concept of venous obstruction as an important factor in the causation of Volkmann's deformity is untenable.

ANATOMICAL CONSIDERATIONS

The venous patterns about the elbow region, in the lower arm and in the upper forearm, were recorded by the writer from a study of 67 upper extremities—34 left and 33 right—in 34 human male cadavers, of which 19 were colored and 15 were white, and with ages varying from 22 to 85 years with an average age of 57 years. Anatomical dissections of the venous network in the upper extremities of 10 additional adult human male cadavers were made by the writer, following roentgenographic studies of the venous circulation with a radiopaque medium—30 per cent aqueous solution of sodium iodide.

The patterns of the superficial veins of the upper extremity have been investigated extensively and reported by Berry and Newton, Okamoto, and Charles. The observations in the present study were confined to the deep venous systems and their communications. In the hand and forearm the fetal type persists throughout life and the superficial veins are dominant, in the arm and axilla the deep veins are most important. With

rare exceptions the deep arm and forearm veins, the ulnar and radial arteries, and each artery is accompanied by a vein.

Brachial veins. The brachial veins are commonly two in number, the ulnar being larger than the radial. They join to form the axillary vein, which then joins the venous system of the neck. The origin from the radial and ulnar arteries of the elbow, the venous network is a complex venous network that is not connected to the brachial artery. The brachial artery has several collateral branches from the brachial artery, the anticus muscles, the veinous network, the brachial artery, the internal and external lateral veins, and, occasionally, the ulnar veins, and they joined, separately or together, to form the axillary vein. At the level of the lower border of the subscapularis muscles. In one specimen the axillary vein appeared to be a single vein, the brachial veins, usually, in others, it appeared to be a single vein, the basilic vein. Asymmetry in the arrangement of these veins of the same cadaver was eight times noted. The symmetry of their arrangement means, the brachial veins are a few single vein. Occasionally, when well developed, the basilic vein receives the venous return of the arm. It is frequently the medial or ulnar vein (accompanying the inferior ulnar artery) was very well developed and accompanied the brachial artery to terminate instead of one of the brachial veins, does. In one specimen both brachial veins were tied into the deep brachial vein, terminated in a large medial collateral vein. The more common arrangement is illustrated in Figures 2 to 8.

Radial and ulnar veins. The radial and ulnar veins, the ulnar being usually the larger, joined within the antecubital fossa to form the brachial veins. The ulnar veins receive the anterior and posterior interosseous veins deep to the pronator

Fig. 1. Diagrammatic representations of variations in the formation of the communicating vein of the elbow in 67 upper extremities of 34 human cadavers. The incidence is as follows: type 1a occurred in 16 cadavers bilaterally and in 28 cadavers unilaterally; types b, c, d and 2, each in 1 cadaver or unilaterally; type 3a, in 3 cadavers unilaterally; type 3b, in 1 cadaver unilaterally; type 4a, in 1 cadaver unilaterally and in 20 cadavers bilaterally; and type 4b,

in 1 cadaver bilaterally. b, brachial vein; r, radial vein; ulnar vein; int, interosseous vein (anterior and posterior); c, communicating vein of elbow; cephalic vein = c, median cubital vein = l, lateral condylar branches, m, medial condylar branches, m, medial collateral vein. The obliquely parallel lines represent the relative position and course of the fibers of the lacertus fibrosus.

teres and flexor digitorum sublimis muscles and medial to the bicipital tendon. The venous patterns at this juncture varied considerably (Figs. 1 to 8).

High formation of the radial and ulnar arteries from the brachial artery in the upper or middle thirds of the arm was present bilaterally in 3 and unilaterally in 5 cadavers, while in one specimen the radial and ulnar arteries arose directly by division of the axillary artery. In these instances the radial and ulnar veins ascended in the arm and either terminated separately in the basilic vein or joined just prior to doing so (Fig. 3). In one specimen in which there was a high division of the brachial artery the radial veins terminated in the cephalic vein, while the ulnar veins ascended in the arm to end in the basilic vein (Fig. 1, Type 3b).

COLLATERAL VEIN SYSTEMS ABOUT THE ELBOW REGION

1. *Communicating vein of the elbow* (Figs. 1 to 8). The communicating vein of the elbow was always anastomotic but the valves of the deep and superficial veins were so placed as to require the blood to flow from the depth to the surface. It terminated in the cephalic vein, above or below the origin of the median cubital vein, or in the median cubital vein, close to the origin of the latter from the cephalic vein, or occasionally, into both veins. In Figure 1 the formation of the communicating vein has been grouped broadly into four types. In the first type, the most frequent, this vein received branches from the radial and ulnar veins. In the second type the communicating vein arose from the venous plexus formed by the juncture of the radial and ulnar

veins, in the third type this vein received a communication only from the radial veins, and in the fourth type it was formed by branches from the anterior interosseous and radial veins. In all types the communicating vein received additional branches from the veins draining the lateral condylar muscles. Symmetry of the venous pattern in this region on both sides of the same cadaver was slightly more frequent than asymmetry.

In this investigation there were observed 3 distinct avascular collateral veins or venous networks in the elbow region, in addition to the so called communicating vein (Figs 2 to 8). That there are in addition to these 4 communications, other collateral systems present about the elbow region, which are too delicate to delineate from gross dissections, is evidenced by the complex networks visualized by means of a radiopaque medium (Figs 7a and 8a).

2 A large communication was almost invariably present between the ulnar veins and one of the brachial veins or the basilic vein, by way of the medial collateral vein that lay ventral to the trochlea and brachialis anticus muscle and deep to the flexor group of muscles arising from the medial humeral condyle (Figs 2, 3, 4, 6, 7, and 8).

3 A less constant communication arose from one of the lateral condylar veins, which pierced the triceps muscle substance and coursed posteriorly along with the radial nerve in the radial sulcus, joining the deep brachial veins (Figs 2, 3, 5, 7, and 8).

4 A communication, the least frequent of all, arose from the ulnar or medial collateral veins, passed behind the internal condyle of the humerus in relation with the ulnar nerve, meeting the veins which accompanied the superior ulnar collateral artery, and terminating in the basilic vein (Figs 7 and 8).

ROENTGENOGRAPHIC STUDIES WITH RADIOPAQUE MEDIUM

How effectual these collateral systems may be in transferring blood from below to above the elbow region was illustrated by roentgenography following the injection of a radiopaque solution (30 per cent sodium iodide) into the upper extremities of 10 cadavers.

In some of the specimens the brachial veins alone were ligated just above the elbow region. The solution of sodium iodide was injected into one of the radial or ulnar veins, and it appeared immediately in the arm above the site of ligation (Fig 2). In these instances all of the communicating systems about the elbow region were intact.

Fig 2

Fig 3

Fig 2 Scheme of (a) the superficial and (b) the deep veins and communicating systems 1, 2, and 3 (see text) of the elbow region. In this specimen the brachial veins were ligated above the elbow region but this did not interrupt the proximal flow of a radiopaque medium in the arm. *b v*, brachial veins, *r v*, radial veins, *u v*, ulnar veins, *int v*, interosseous veins (anterior and posterior), *b*, basilic vein, *c*, cephalic vein, *m c*, median cubital vein, *c v*, communicating vein of the elbow (*r*). The interrupted horizontal line represents the level of the elbow joint.

Fig 3 Scheme of (a) the superficial and (b) the deep veins and communicating systems of the elbow region in a specimen with high division of the brachial artery in the upper third of the arm. Ligatures about the radial veins (which lay superficial to the ulnar veins) and the communicating vein of the elbow failed to interrupt the proximal flow of a radiopaque medium in the arm. *b v*, brachial veins, *r v*, radial veins, *u v*, ulnar veins, *int v*, interosseous veins (anterior and posterior), *b*, basilic vein, *c*, cephalic vein, *m c*, median cubital vein, *c v*, communicating vein of the elbow (*r*). The interrupted horizontal line represents the level of the elbow joint.

In 10 specimens the communicating vein of the elbow was ligated just distal to its termination in the cephalic or median cubital veins, and the brachial veins were ligated just above the site of their formation, through very small incisions. The contrast medium was injected via one of the ulnar or radial veins, which was ligated just distal to the cannula, and the specimen was roentgenographed during the injection. The solution, despite these ligations, immediately entered and coursed up the arm in every instance, as noted in the roentgenograms (Figs 4a, 5a, 6a, 7a and 8a), and by the immediate escape of the fluid (colored for purposes of recognition) from the cut surface of the proximal end of the specimen.

EVALUATION

It is generally accepted that external constriction is not essential for the development of Volk-

Fig. 4. This figure (as Figures 5, 6, 7 and 8) is a diagrammatic representation of (a) the superficial veins and (b) the deep veins and communicating systems of the elbow region of cadaver specimen. The brachial veins are ligated above the elbow joint and the communicating vein of the elbow is ligated just prior to its entrance into the superficial system at point A. The failure of these ligations to interfere with the proximal

flow of radiopaque fluid in the arm is illustrated in the corresponding Figure 4a. (Figures 5a, 6a, 7a and 8a correspond to Figures 5, 6, 7 and 8) a brachial vein, radial vein, ulnar vein, and interosseous vein (anterior and posterior), basilic vein, cephalic vein, median cubital vein, communicating vein of the elbow (A). The interrupted horizontal line represents the level of the elbow joint.

mann's contracture and that a fracture need not be present (Hill and Brooks). Although peripheral nerve lesions may complicate the clinical picture they are not constant and are not as a rule anatomically defined.

The protagonists of the concept of venous obstruction as an important factor in the etiology of Volkmann's contracture, emphasize the experimental evidence of Brooks (2), Middleton (3), and Wertheimer, Dechaine and Fried, who produced a condition resembling ischemic contracture

of muscle by sudden venous occlusion. They suggest that the fundamental pathomechanics of this condition are abnormal pressure conditions—by a subcutaneous hematoma—in a limited space—the antecubital compartment—containing muscles and surrounded by resistant fascia and bone and drawn by pressure of anatomical arrangement that factors obstructs. Middleton (3, 4) has discussed this anatomical arrangement in the elbow region he suggests that a venous plexus with a diameter of about 2 centimeters drains the deep

structures of the entire forearm. This concept is supported by descriptions of the venous network of the elbow region in most anatomical textbooks and has been accepted as factual by many writers on the subject of Volkmann's contracture (Jones and Lovett, 14, Meehan, Garber)

There is increasing evidence, however, that arterial obstruction rather than venous obstruction plays a significant rôle in the etiology of this deformity.

1 Contractures of limbs in experimental animals were observed to occur following the production of arterial obstructive lesions, by Von Nario, Brooks, Johnson and Kirtley, 3, Wilson, and Griffiths, 10. It was noted by Jepson, and by Burman and Sutro that venous stasis alone was insufficient to produce permanent contractures of the limbs, and that, in addition, proximal constriction of the soft tissues was necessary.

2 Exploration in cases involving the upper extremity in the acute or threatening stage failed to reveal evidence of subfascial hematoma in the antecubital fossa. The muscle bellies were found to be engorged and discolored, but this was more common in the brachialis anticus muscle than in the forearm flexor muscles. There were subcutaneous extravasations and small hematoma-formation about the fracture site but no occlusion of the main veins could be demonstrated. In almost all of the arms explored, there were lesions affecting the brachial artery—vasospasm, incarceration between bony fragments, angulation, laceration or tear. In some arms in which the injured portion of the brachial artery was resected, there was evidence of injury to the adventitia or media or to both of these layers of the resected arterial segment (Griffiths, 10, Jones, 13, Plewes).

3 Volkmann's contracture has followed proved instances of arterial occlusion. Griffiths (9, 10) noted that in 3 cases in a series of 20, patients operated upon for arterial embolism, developed typical Volkmann's contracture—one of the forearm and hand, and two of the calf and foot—despite successful restoration of the arterial circulation. Similar contractures following arterial obstruction in the lower extremity have been reported by Grieg and by Dieulafoy.

4 The evidence derived from the anatomical material in this investigation, that a sufficient

collateral venous circulation exists normally in the elbow region, well protected between muscle planes and external to the confines of the antecubital fossa, indicates that the theory of Middleton, on which the protagonists of the concept of venous obstruction have relied to a considerable extent, is untenable.

CONCLUSIONS

The belief that arterial obstruction plays a more significant rôle than venous obstruction in the pathogenesis of Volkmann's contracture is receiving increasing clinical and experimental support. To this is added evidence that the theory of Middleton, on which the protagonists of the concept of venous obstruction have relied, is untenable. The anatomical studies in this investigation indicate that a widespread venous anastomosis exists normally in the elbow region, well protected between muscle planes and external to the confines of the antecubital space.

REINFORCEMENT OF THE DELTOID LIGAMENT FOR PRONATED FLAT FOOT

Inversion Fasciodesis of Os Calcis

HENRY MILCH M.D. F.A.C.S. New York, New York

SOLUTION of the problem of flat foot has been sought by many in both surgical and nonsurgical procedures. The latter based mainly on the belief that acquired flat foot is a consequence of muscle inadequacy have led to the elaboration of a system of therapy which depends on foot braces, shoe modifications and a ritual of muscle exercises. In our experience even when religiously prosecuted, these have proved futile in the cure of the truly pronated flat foot. In the main, the failures have been attributed to lack of co-operation, but the fact that pronation may occur even in the presence of a well developed musculature seems to have been overlooked. Despite this, and possibly in deference to the natural reluctance of parents to submit their children to surgery for relief of what appears, at outset, to be a relatively innocuous affliction, the conservative treatment has been maintained and by some extolled.

That the affliction is not so innocuous, nor the conservative treatment so effectual is indicated by the variety of surgical procedures which have been devised from time to time. Moreover the very multiplicity of the suggestions is, in itself proof that no single method of surgery has thus far adequately solved the problem. Practically almost every important bone, muscle, ligament, and joint of the tarsus has been surgically attacked. Generally speaking the procedures employed fall into two categories—the anterior operations directed toward correction of the depressed longitudinal arch and the posterior directed toward inversion of the pronated heel.

That one or another of the anterior group of operations may successfully correct a true planus need not be denied. But whether the correction of the anterior deformity can effect a correction of the posterior deformity by pressure from below may be seriously doubted. It is, in fact to the failure of such efforts that various procedures intended to supplant or invert the everted hind foot owe their origin. On the whole the anterior group of operations has proved to be more successful in restoring the longitudinal arch than the posterior

group has been in overcoming the pronation of the heel. In retrospect, it appears that these results might have been expected because of the failure to correct the pronation deformity at the apex of its angle of deviation—the subtalar joint. The realization of the importance of the proper handling of this joint above that of any of the other tarsal joints in the treatment of pronated feet seems to be the very basis of the good results obtained by Clark and later by Zadek.

In part, some of the difficulty which has been encountered is due to the fact that two anatomically different situations have been grouped together as a single clinical entity. Anatomically the foot is a unit composed of a number of separate segments. Physiologically the foot consists of two separate organs, the hind foot and the fore foot. *Pes planus* describes a flattening of the longitudinal arch, that is, a change in anatomical relationship between fore foot and hind foot, and *pes valgus* a rotation of the hind foot in relation to the longitudinal axis of the superimposed leg. *Pes plano-valgus* describes the combined form.

Obviously the cure of *pes planus* must be by surgical means which act across the mediotalar joints to stabilize the fore foot in relation to the hind foot while the cure of *pes valgus* must be effected across the subtalar joint so as to stabilize the hind foot in relation to the leg. In the absence of a stabilized hind foot, it is useless to discuss the problem of the longitudinal arch.

By comparison with the lower or anthropoid forms, in which the arch is depressed and the os calcis everted, the human hind foot is supinated. Naturally the development of the longitudinal arch has been associated with this inversion of the heel, and *arch supination* has been considered the mechanism of its accomplishment.

Largely under the influence of Keith, who expressed the opinion that "with the maintenance of the normal arch, ligaments are not directly concerned" but that "the longitudinal arch of the foot is dependent on properly and automatically balanced muscles in leg and foot," the belief has been propagated that the cause of flat foot is a muscle weakness. Even Morton, who stated

categorically that "the term 'balance' as applied to foot structure does not refer to muscle activity but to the arrangement of the bones and ligaments which furnish a stable base upon which body weight can be supported with the least demand for muscular exertion and propelled evenly balanced upon the lever axis," admitted the importance of the flexors of the foot in elevation of the arch and in rotation of the os calcis. Though he denied the significance of the supinating mechanism, Morton concluded that the longitudinal arch appeared in consequence of the leverage action in a foot in which the body weight had shifted from the outer toward the inner side of the foot. As a consequence of such teaching, the nonsurgical treatment has been designed to increase the power of existing invertors, while the surgical treatment has been devised to supplement their action either by fusion or by actual muscle transplantation.

More recent observations upon the embryology of the human foot cast interesting light upon the etiology of flat foot. Boehm showed that at about the end of the third intrauterine month, the foot is held in a position of marked supination, adduction, and internal rotation, i.e., in the position of extreme equino cavo-varus. Thereafter the supination tends to recede and though still present at birth, the appearance of the adult foot is acquired slowly and as a result of *pronation*. This general impression was confirmed by Boeker in his study of the prints of infantile feet. At birth, the foot is held in supination and the sole of the foot, as well as the big toe, preserves many of the characteristics of the prehensile foot. When the infant begins to walk, but little weight is carried by the big toe which is still prehensile and is not used for progression. The thrust is balanced on the outer side and the fore foot acts as the steadying force while the heel is raised from the ground. At the age of 2½ years, most of the weight is still over outer side of foot and the longitudinal arch appears flat. By the age of 10 the body weight has moved toward the inner side, the big toe gives evidence of greater weight bearing, and the longitudinal arch is fairly well formed. By 14 years, with increasing weight and medial shift of the thrust, the big toe transmits a larger proportion of the body weight and a still higher adult type of arch is present.

In fact, it appears that active pronation is the fundamental process and that the development of the longitudinal arch is the result of the conversion of the fully supinated foot into one characterized by relative pronation of the fore foot. In any flexible foot it can readily be demonstrated that with the heel fixed, relative pronation of the fore foot invariably results in an increase in the

Fig 1. Average sequence and duration of weight bearing on heel, midfoot, and forefoot as related to sequence and duration of contraction of the posterior tibial and peroneal muscles (From Schwartz, loc cit)

height of the longitudinal arch. Indeed, it was in the hope of accomplishing exactly this effect that the "skew" elevation of inner border of heel and outer border of the sole of the shoe was devised.

It is in the realization of the importance of the fore foot pronating mechanism that the studies by Schwartz acquire added biological significance.

"The heel receives and supports body weight for 0.436 seconds. The posterior tibial muscle contracts simultaneously with placement of the heel on the floor, but its duration of contraction is only 36.1 per cent of the total stance phase of the step, 0.694 seconds, 57.5 per cent of the total time the heel is on the floor. Therefore it is evident that this short period of reflex function of the tibialis posticus does not prevent the foot from pronating while walking.

"This too early discontinuance of a positive force that could prevent pronation is accompanied by peroneal contraction which further provokes the characteristics of pronation in each step. The peronei begin to contract 0.166 seconds after the heel contacts the floor and continue to contract for 79.8 per cent of the stance phase of the step, as against 36.1 per cent previously stated for the posterior tibial" (Fig 1).

Here again the relative importance of the pronating mechanism of the fore foot as contrasted with the supinating mechanism of the hind foot is demonstrated. Contrary to the general belief, it is the absence of active fore foot pronation rather than of active hind foot supination that leads to pes planus. Without a powerful pronat-

REINFORCEMENT OF THE DELTOID LIGAMENT FOR PRONATED FLAT FOOT

Inversion Fasciotomy of Os Calcis

HENRY MILCH M.D. F.A.C.S. New York, New York

SOLUTION of the problem of flat foot has been sought by many in both surgical and nonsurgical procedures. The latter based mainly on the belief that acquired flat foot is a consequence of muscle inadequacy have led to the elaboration of a system of therapy which depends on foot braces, shoe modifications, and a ritual of muscle exercises. In our experience, even when religiously prosecuted, these have proved futile in the cure of the truly pronated flat foot. In the main, the failures have been attributed to lack of co-operation but the fact that pronation may occur even in the presence of a well developed musculature seems to have been overlooked. Despite this, and possibly in deference to the natural reluctance of parents to submit their children to surgery for relief of what appears at outset to be a relatively innocuous affliction, the conservative treatment has been maintained and by some extolled.

That the affliction is not so innocuous, nor the conservative treatment so effectual is indicated by the variety of surgical procedures which have been devised from time to time. Moreover the very multiplicity of the suggestions is in itself proof that no single method of surgery has thus far adequately solved the problem. Practically almost every important bone muscle ligament, and joint of the tarsus has been surgically attacked. Generally speaking, the procedures employed fall into two categories—the anterior operations directed toward correction of the depressed longitudinal arch and the posterior directed toward inversion of the pronated heel.

That one or another of the anterior group of operations may successfully correct a true *planus* need not be denied. But whether the correction of the anterior deformity can effect a correction of the posterior deformity by pressure from below may be seriously doubted. It is, in fact, the failure of such efforts that anxious procedures intended to supinate or invert the everted hind foot owe their origin. On the whole, the anterior group of operations has proved to be more successful in restoring the longitudinal arch than the posterior

group has been in overcoming the pronation of the heel. In retrospect, it appears that these results might have been expected because of the failure to correct the pronation deformity at the apex of its angle of deviation, the subastragalar joint. The realization of the importance of the proper handling of this joint above that of any of the other tarsal joints in the treatment of pronated feet seems to be the very basis of the good results obtained by Clark and later by Zadel.

In part, some of the difficulty which has been encountered is due to the fact that two anatomically different situations have been grouped together as a single clinical entity. Anatomically the foot is a unit composed of a number of separate segments. Physiologically, the foot consists of two separate organs, the hind foot and the fore foot. *Pes planus* so describes a flattening of the longitudinal arch, that is, a change in anatomical relationship between fore foot and hind foot, and *pes valgus* a rotation of the hind foot in relation to the longitudinal axis of the superimposed leg. *Pes plano valgus* describes the combined form.

Obviously the cure of *pes planus* must be by surgical means which act across the mediotalar joints to stabilize the fore foot in relation to the hind foot while the cure of *pes valgus* must be effected across the subastragalar joint so as to stabilize the hind foot in relation to the leg. If the absence of a stabilized hind foot, it is useless to discuss the problem of the longitudinal arch.

By comparison with the lower or a thoroped forms, in which the arch is depressed and the os calcis everted, the human hind foot is supinated. Naturally the development of the longitudinal arch has been associated with this inversion of the heel, and *active supination* has been considered the mechanism of its accomplishment.

Largely under the influence of Keith who expressed the opinion that "with the maintenance of the normal arch, ligaments are not directly concerned" but that "the longitudinal arch of the foot is dependent on properly and automatically balanced muscles in leg and foot," the belief has been propagated that the cause of flat foot is a muscle weakness. E. C. Morton, who stated

is to prevent exactly that malposition which is characteristic of the pronated hind foot.

To simulate this action of the deltoid ligament, to elevate and invert the os calcis, the following operative procedure has been devised. Under a tourniquet placed around the calf, a curved incision is made, extending from the scaphoid tubercle backward around the tip of the internal malleolus and then upward to a point about 3 inches above the malleolar tip. At a point sufficiently above the epiphyseal line, to prevent injury to the growing zone, the medial surface of the tibia is subperiosteally exposed. A tunnel, running anteroposteriorly, is made, beginning on the medial surface of the tibia, above the epiphyseal line. Through this, a guide suture is passed. The incision is opened so as to expose the abductor hallucis below and the tendon of the tibialis posticus in front. The sustentaculum tali is visualized between the tendons of the tibialis posticus and the flexor longus digitorum muscles. With a broad, blunt, periosteal elevator, all the tissues lying below the sustentaculum and pos-

terior to the calcaneocuboid articulation are elevated, and a transverse calcaneal tunnel is drilled, so as to emerge on the lateral surface of the os calcis, in the region of the trochlear process. The guide suture previously passed through the tibia is now passed down along the inner aspect of the ankle, beneath the tendon of the tibialis posticus muscle, and around inferior surface of os calcis. A small external counter incision is made, and from without inward the graft is passed back through tunnel made in the calcaneus (Figs 2, 3).

A small incision is now made over the fascia lata, at the lower portion of the thigh. With the fascial stripper, a long strip of fascia is removed subcutaneously and is passed through the drill holes, exactly along the course of the guide sutures. The heel is strongly supinated and the strands of the fascial graft are sutured to the bone and are then united to each other, if possible. The wound is closed in layers and a plaster-of-Paris boot is applied, with the foot in the maximum of inversion. Immobilization is maintained for a period of 6 weeks. Upon removal of the

Fig. Sagittal section. The heel by shaded line indicates the fascial graft.

ing force the supinating counteraction of the ground against body weight leads to dorsal extension and supination of the first metatarsal with flattening of the arch and loss of the inner support of the foot tripod. (This is not uncommonly seen following peroneal transplantation in muscle balancing operations.)

But while the action of the peroneal muscles and the gravitational effect of body weight tend to pronate the foot as a whole, pronation of the fore foot alone can be accomplished only if some mechanism is provided by which the hind foot can be prevented from pronating. That the tibialis posterior plays a part in supinating the hind foot cannot be denied, but the relatively short period of its action indicates that the ultimate defense against pronation of the heel must be sought in the ligamentous structures whose anatomical function normally is the limitation of excessive motion. That this is the case is shown by the marked valgus which characterizes the stance in patients suffering from hypotonia. It is further substantiated by the high arch and supinated heel of the club foot as contrasted with low arch and pronated heel of patient with an union fracture of tip of tibial malleolus.

These facts were clearly suggested by the elder Whitman in his discussion of weak feet. At first glance it may seem that the depression of the arch is the most noticeable peculiarity in a characteristic case of flat foot and that the popular name is, therefore, an appropriate one. On closer examination, however it will appear that

the foot is not flat because its "keystone" has sunk, but that the lowered arch is caused by lateral displacement (abduction). It has been stated that under normal conditions, in the act of passive weight bearing, the astragalus rotates downward and inward upon the os calcis, depressing its anterior and internal border until the movement is checked by the strong ligaments.

Clearly the therapeutic indication is the restoration of the ligamentous support along the inner aspect of the ankle to check excessive pronation of the heel. As early as December 1936 this was attempted by transplantation of the tibial insertion of the deltoid ligament. Though the procedure was successful in maintaining the varus of the heel, some limitation of ankle joint motion resulted, and this, combined with fear of injuring the epiphyseal cartilage in growing children led to a search for another means of effecting a ligamentous check on excessive pronation of the heel. The key to the problem was suggested by a study of the normal deltoid ligament.

The deltoid ligament is strong, flat, triangular band attached above to the apex and anterior and posterior borders of the medial malleolus. It consists of two sets of fibers, superficial and deep. Of the superficial fibers, the most anterior (tibioscapular) pass forward, to be inserted into the inferiority of the navicular bone and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament, the middle (calcaneotibial) descends almost perpendicularly to be inserted into the whole length of the sustentaculum tali of the calcaneus the posterior fibers (posterior tibiofibular) pass backward and laterally, to be attached to the lower end of the talus and the prominent tubercle on its posterior surface, medial to the groove for the tendon of the flexor hallucis longus. The deep fibers (anterior tibiofibular) are attached above to the tip of the malleolus and below to the medial surface of the talus. (Gray).

This ligament, by far stronger than the lateral ankle joint ligament is obviously directed toward the prevention of external rotation of the hind foot. In this, it is supported by the powerful interosseous talocalcaneal ligament, whose fibers are so directed as to counteract any tendency toward eversion of the os calcis.

But the whole function of these ligaments is not only to act as a check to external rotation of the os calcis. If it were so, biomechanical stresses would have led to the development of the deltoid ligament in the plane of the internal malleolus. This is not the case. By far the larger part of the ligament fans out to be inserted much anterior to this plane. This makes it evident that this portion of the ligament develops in response to stresses which tend to roll the os calcis inward and forward. In other words, it appears that the upward and forward direction of the ligament

Fig 6 Case 2 Lateral view before operation

Fig 7 Case 2 Lateral view after operation

quently admitted to the hospital and on August 20, 1940, the right foot was operated upon, on September 3, 1940, the left foot was operated upon. The deltoid reconstruction operation described was performed on both sides, the heels being pulled into marked varus by means of fascial graft, and being maintained in this position by means of plaster of Paris boots for a period of 6 weeks. At the end of September, the plaster boots were removed and it was noted that the wounds had completely healed, but on the right side there was definite limitation of motion and evidence of a local inflammation. X-ray examination disclosed that this was due to some osteolytic lesion in internal malleolus.

This was, at first, thought to be due to pressure of the fascial graft against the underlying internal malleolus. However, the contour of the defect did not seem to be consistent with this interpretation, and re-examination of the preoperative x-ray films revealed some lesion which had been overlooked. Wet dressings were applied to the right leg, and in time the swelling subsided and a fair range of motion returned. On October 30, weight bearing was permitted, and shortly thereafter the patient was discharged from the hospital, walking in shoes with a wedging in the inner borders of the heels. On January 21, 1941, it was noted that both heels were in the neutral position. The longitudinal arches were well preserved and the prominence noted over the scaphoids had disappeared. The patient walked quite well, but on the right side some perimalleolar inflammation still persisted. On the left side, the range of motion at the ankle was excellent; on the right side, a slight residual limitation of motion persisted (Fig 5). Under physical therapy, this swelling gradually diminished and the range of motion in the right ankle increased. In June, 1941, it was observed that well formed arches were present on both sides. The feet were quite flexible, gait was normal, and the patient made no complaints. The arch supports were discontinued and patient permitted stock shoes with only small wedge along inner border of the heels. Up to present correction has been retained.

The second case proved of special interest because of the association of accessory scaphoids and markedly pronated heels. The accessory scaphoids caused no pressure symptoms and were neglected in the surgical procedure. The result obtained tended to confirm the opinion that the ligamentous repair was the essential element in the correction of the flat foot condition.

CASE 2 Mary R. aged 13 years, was brought to the hospital in the early part of September, 1940 because of flat feet and a painful prominence over the inner aspect of both feet which had been present for a period of about 2 years. Examination disclosed marked pronation of both heels, dropping of the longitudinal arches, and prominences over the scaphoids. The roentgenogram was reported as showing bilateral accessory scaphoids (Fig 6).

However, it was noted that when the heels were held in the varus position, the arches could be promptly restored. Because of this and despite the presence of the accessory scaphoids, it was felt that the pronation of the heels represented the primary deformity, and the operation here described was performed bilaterally. The postoperative convalescence was uneventful, and in the latter part of October, 1940, the plaster was removed. The wounds were found to be completely healed. The patient was fitted with Whitman plates and was then permitted to walk in wedged shoes. She was seen in December, 1940, at which time photographs (Fig 7) were taken. The patient noted complete absence of symptoms and restoration of well formed longitudinal arches. Foot plates were discontinued, and up to the present the arches have remained elevated. The accessory scaphoids are still present but do not appear to cause the patient any discomfort.

The procedure here outlined would seem to have its special application in adolescent patients between the ages of 8 and 14 or 15 years, in whom excessive pronation of the heel persisted. In younger children, the operation would probably present greater difficulties and might be unnecessary. In older patients, the definitive establishment of the tarsal joints would probably vitiate the result. In the proper age group, the procedure has the merit of being completely extra-articular and of avoiding the danger of injury to the epiphyseal growth zone. Thus far, the feet operated upon have remained flexible, painless, and with well formed arches.

Fig. 4. Case 1, before operation. Note the medial concavity of the arches. On the lateral view the prominent scaphoid tuberosity is clearly visible.

plaster a well molded foot plate is prepared and patient is allowed to bear weight in well fitted shoes.

Since the operation is intended solely for those cases in which excessive pronation has resulted from a loss of the restraining action of the deltoid ligament, it is clear that it should not be employed when the pronation is caused by bony deformity. Obviously a valgus due to a malunited fracture

of the lower end of the tibia is not amenable to correction by this procedure. It is essential therefore to determine by roentgenograms of the ankle joint that (1) the plane of the articular surface of the tibia is perpendicular to long axis of the bone, (2) the astragalus is held in its normal position by a well developed ankle mortise and (3) there is no abnormality in the os calcis. If these facts can be established, the pronation may be attributed to a loss of deltoid ligament support.

Theoretically the operation is applicable to all such cases regardless of age. However it would appear to be undesirable to attempt drilling of the os calcis before sufficient bone had been laid down to minimize the danger of interference with normal growth. Similarly it would appear unwise to defer operation beyond the time when a physiological readjustment of the tarsal articu-

tions might be reasonably expected. Quite arbitrarily therefore it is suggested that the optimum period for operative intervention is between the ages of 7 or 8 and 14 or 15 years.

The first of the cases treated by this method was operated upon in 1937. Usually a well formed arch in a thoroughly flexible foot has resulted. In general, the greater the supination of the hind foot, the higher has been the longitudinal arch. But even when the arch has not been completely restored the elimination of pronation of the hind foot has been accompanied by a marked relief of symptoms. There is usually complete relief of pain and the sense of fatigue present before operation.

The following case reports present special points of interest.

CASE. RAMOS B. aged 9 years, was admitted to the hospital in August, 1940. At the age of 2, the child had been seen and treated at the hospital for bow legs. He was brought to the hospital at the present time by his parents. He noted "prominent bones on the inner aspect of both feet." On examination it was noted that there was marked valgus of both heels, especially the left, with pronation of both feet and flattening of the longitudinal arches (Fig. 4). At first it was thought the patient was suffering from accessory scaphoids or enlarged scaphoid tubercles but x-ray examination showed no evidence of any abnormality in the scaphoid region. The patient was con-

Fig. 5. Case 1, after operation. On right, the supination of the heel is greater than on the left. On lateral view the arch on the right side is better than on left. The prominence of the scaphoid tuberosity has disappeared.

question appeared only with the publications by von Zoegemann-Manteuffel (1898). Since his time a literature has accumulated that is not only large but increasing, due at least in part to recent accessions in the medical periodicals of North America and Central Europe. No effort has been made here to assemble a complete tally of all the cases published, and bibliographic efforts have been confined principally to the years since 1913. Faltin in 1902 found 79 reported cases, Ekehorn, in 1904, 92, Bunsdshuh, in 1913, 110, Kunz in 1928, 155, Podlaha, in 1929, 168. Taking Bunsdshuh's (1913) review as a basis, a cursory search of the readily available sources has yielded 194 cases (including the current one) since the date of his report. The total of 304 recorded cases is without doubt incomplete. The geographical distribution of the 194 cases collected is of more than mere statistical interest, in view of the geographical aspects of the etiology of the disease, which will be discussed later. It also shows that the incidence in North America is relatively greater than is generally assumed (Table I).

ANATOMICAL FACTORS IN ETIOLOGY

It has been accepted from the beginning that torsion of the right colon depends on an abnormal degree of mobility of cecum and ascending colon, this would make cecal volvulus basically a congenital disease, Lynch (1933) listing it as the most important of the abnormalities of the colon which require surgery. The anomalous freedom of the right colon¹ has been almost universally conceded to be an embryological accident, failure of obliteration of the fetal right mesocolon with the consequent persistence of an adult mesentery, though von Thun (1913) has suggested that general enfeeblement of the abdominal organs and acquired enteroptosis might also play a part.²

The sequence of events in the fetal abdominal cavity by which the colon gains its adult position and attachments is too well known to require detailed repetition here. It may be said, in brief, that the cecum gains its mature locus through the operation of three processes: rotation, which carries the originally left sided ascending colon across the abdomen, descent, by which the cecum sinks from a subhepatic situation into the right iliac fossa, fixation, whereby the right mesocolon is lost and the right colon made adherent to the posterior abdominal wall. Mobility of the cecum depends largely on the degree to which this last process extends. If fixation is incomplete, the cecocolon enjoys a greater or lesser amount of freedom of movement, it may retain its own proper mesentery, or, if the terminal ileum is loose, a common ileoceccocolic mesentery may result. Descent is substantially complete by the eighth month of fetal life (Hertwig, 1902; Keith, 1910), the cecum has then attained its adult position. Fixation proceeds thereafter, but the final peritoneal relationships are not fully established until about 4 months after birth (Harvey, 1918). The possibility of hypofixation is balanced by that of hyperfixation, in which the process goes to excess, yielding an entirely retroperitoneal cecum, and spreading at times to involve the normally mobile terminal ileum. General hyperfixation, of course, precludes any possibility of cecal volvulus. However, hyperfixation is often local (Carslaw, 1928), the principal sites being the beginning of the transverse colon (by the duodenorenal ligament) and the hepatic flexure (by the right renocolic ligament), though it can occur anywhere on the ascending colon. Such a point of local hyperfixation, combined with looseness of the proximal large bowel, provides an anatomical situation obviously favorable for a cecal volvulus—there being a mobile segment and a fixed spot to act as a hub.

A right colon which has failed to gain normal stability by fusion of its mesocolon with the posterior parietes is, nonetheless, often protected by the formation of secondary supportive attachments. Such structures as Jackson's membrane, Lane's band, and various pericolic membranes are to be explained on such a congenital basis (Connell, 1913; Gray and Anderson, 1913; Munroe, 1926). Flint (1921) has often seen a band anchoring the otherwise free cecum laterally,

quired not congenital. This is volvulus of the cecum alone about the long axis of the bowel. It can occur only in a cecum which has become secondarily pouched and distended. Pouching must be taken as an acquired cecal characteristic for the fetal cecum is a tapering one which merges imperceptibly into the base of the appendix.

¹It must be noted that the normally fixed cecum is usually free enough to be lifted out of the wound in the process of performing an appendectomy. Flint (1921) believes that study of cadavers is misleading on this point. This normal mobility is clearly evidenced by the x ray findings of Moody (1929). Engel (1857) ascertained that 70 per cent of ceca can be raised readily. Dreyer (1911) gives a figure of 67 per cent. The whole colon is much more mobile than many suppose. Barclay (1932) in fact would have it shifting about the abdomen under certain circumstances, in an acrobatic manner. Carson (1926) is of the opinion that real fixation of the cecum is entirely abnormal. The mobility with which we are here concerned—that which allows of cecal volvulus—is of quite a different order than the normal freedom.

²There is one form of volvulus usually considered rare, though Corner and Sargent (1905) think it may be common which is regarded as ac-

VOI VULUS OF THE CECUM

Anatomical Factors in Its Etiology Report of a Case

JOHN A. WOLFER, M.D. F.A.C.S. LINDSAY E. BEATON, M.D. and
BARRY J. ANSON, Ph.D. (Med.Sc.) Chicago, Illinois

VOLVULUS of the cecum, usually in volving to some extent the proximal colon and terminal ileum is generally regarded as one of the rare causes of intestinal obstruction. Yet, on the basis of incidence alone cecal torsion deserves more than passing notice. Lenormant (1929) found that 3.4 per cent of his 38 cases of intestinal obstruction were due to a twist of the right colon. Jacobsen (1941) analyzing 53 cases, obtained a figure of 11.6 per cent. Pratt and Falls (1927) state that 5 to 6 per cent of instances of ileus in the United States is caused by cecal torsion; this percentage—which to the present authors, seems amazingly high—is challenged by Sweet (1935) who found only 1 per cent of 520 cases determined by this condition. Estimations of the proportion of cecal volvulus, as compared with volvulus of other locations, vary widely. Jacobsen (1941) states that 31.6 per cent of all cases of volvulus are of the right colon. Gushé (cited by Sauré and Lejeune, 1934) 7 per cent. Sweet (1935) 11.3 per cent.

There are three reasons for accordng this disorder serious consideration. Homans (1921) has noted that while it is less common than sigmoid volvulus, it is surgically more important than the latter. Moreover the mortality is high, exceeding 50 per cent. The need for early diagnosis and immediate surgical intervention in the usual acute case is emphasized by Chailant's (1931) figures: of 96 patients operated upon, 59 per cent died; of 23 not operated upon all died. The significance of cecal volvulus is further heightened by the possibility that, in addition to the acute cases ordinarily reported, there exist instances of chronic partial torsion. Tryman (1923) has recorded an example of the latter and considers it a

diagnosable entity; such an opinion is supported by Corner and Sargent (1905), Pratt and Falls (1927) and Grace (1938). In this connection, it is noteworthy that Berger (1923) in a study of 69 patients, found volvulus complete in only 42 per cent. It is possible that there is some relationship between partial cecal torsion and that much disputed entity *cecum mobile*. Finally it is clinically important that partial cecal volvulus may produce symptoms like those of acute appendicitis. Pascalis (1929) states that he has attended several persons with suspected appendicitis who were found at laparotomy to have a twisted right colon; he believes that cecal volvulus must always be considered in the differential diagnosis of diseases presenting signs and symptoms in the right lower quadrant.

DEFINITION

It is not easy to formulate a definition of volvulus of the cecum. As will be seen the abnormal anatomical freedom which permits the development of this disorder varies in degree. Therefore, volvulus, centering about the cecum runs the gamut from a twist of the isolated cecum to torsion involving all of the small intestine and most of the large. The designation "volvulus of the cecum" is misleading; most of the cases so named involve also a variable amount of the ascending colon and terminal ileum. The condition could better be termed "volvulus of the right colon," were not the present name so firmly entrenched. Gelfiller, Moutser and Porcher (1931) have proposed that "volvulus of the cecum be defined as a condition in which torsion is limited to the cecum, ascending colon, and terminal ileum. This forms a satisfactory entity on embryological and anatomical grounds, since the right colon is usually fixed in its upper reaches, no matter how defective may be the peritoneal attachments of the cecum and adjacent bowel. Clinically this definition serves to separate right colic torsion from sigmoidal volvulus, iliac volvulus and total volvulus.

LITERATURE

The first report of a case of cecal volvulus probably that of Rohdanzky in 1841. Critical consideration of the

Contribution from the Northwestern University Medical School, Department of Surgery and Department of Anatomy (No. 5 from the latter). Portions of this paper were presented before the Chicago Surgical Society, April 24, 1941 and before the American Association of Anatomists, April 24, 1941 (Abstract Anat. Rec. 91: 79. No. suppl. No. 7: 34).

*Corner and Sargent (1905) computed a fatality rate of 60 per cent in 37 cases of patients operated upon and not operated upon collected from the literature. Chailant (1931) mortality figure of 6 per cent in 8 cases of patients operated upon and not operated upon. Berger (1923) death rate of 53 per cent in 69 cases of patients operated upon.

Fig. 1 Diagrammatic figures based upon actual specimens recording the range of ileocolic attachment in

125 consecutive adult specimens for convenience types are indicated the percentage occurrence of each type noted

occur in 14 subjects (11.2 per cent). In type IIIa, the line of attachment ascends, leaving the cecum free, this arrangement obtains in 7 or 5.6 per cent. Figure 4 illustrates an example of type IIIa: a hyperdescended cecum hangs free in the true pelvis, with a line of attachment beginning just above the ileocecal junction and ascending colon without adhesion. In 25 instances, 20 per cent, type IV, this line of fixation is situated well above the ileocecal junction, though the cecum is sometimes fixed laterally by a descending line of fusion. In Figure 2 is pictured a cecum that falls into class IV. It is somewhat exceptional in that a redundant cecum, fixed in the iliac fossa, turned backward upon itself to point upward and touch the liver (termed an "erect cecum"). Figure 3 illustrates another example of type IV, in which however there are two extra retaining bands. In type V, 5 subjects, 6.4 per cent, the cecum and much of the ascending colon are free of attachment to the posterior abdominal wall. Figure 6 is an example: there is a completely mobile cecum and ileum as shown by the ease with which it could be retracted medially. The ascend-

ing colon is also without fixation throughout much of its length. Type VI, 6 subjects, 4.8 per cent, illustrates complete freedom of the whole right colon. Such cases have, to a greater or lesser extent, a common ileocecolic mesentery.¹ Figure 8 shows an example of this type, further complicated by a retroperitoneal ileum which occupied the iliac fossa, such an attachment would provide a fulcrum for volvular movement. Figure 9 illustrates another instance of type VI, it demonstrates that embryonic failure in rotation and descent is the basis of malposition, the cecum here occupying the left hypochondrium.

The application of these anatomical observations to the question of cecal volvulus is obvious. Only those right colons free of adherence to the posterior parietes for at least a part of their length are subject to torsion. It is immediately

¹Complete ileocolic mesenteric fusion does not occur as frequently in most series. Reeves (1919) found it in 2 of 125 cadavers, 1.6 per cent. Treves (1886) in 2 of 100, 2 per cent. Wan (1903) in only 1 per cent of 640 cases. Our criteria were perhaps more elastic: since we included all cadavers with a free cecal line, even if the hepatic falciform ligament adherent. All 5 of the 6 cadavers had a retroperitoneal ileum and a very short ileal mesentery, so that actually only 2 of 125 per cent possessed a common mesentery.

while it has been Coughlin's (1927) experience that Jackson's membrane is present only in patients possessing an ascending mesocolon. An embryological explanation of the origin of these abnormal retaining membranes is afforded by assuming persistence of Reid's (1911) "genito-mesenteric fold." However Crotti (1930) would have it that if the cecum remains beneath the liver overlong, it acquires adhesions which persist even after fetal descent has taken place. Such secondary bands, if unsuccessful in immobilizing the cecum, become a menace to its integrity, since they achieve the same result as would local hyperfixation. In fact, the two processes may be akin.

While the failure of fixation is the principal cause of right colic mobility it must be recognized that nonrotation and nondescent may also play a lesser rôle as early noted by Tandler (1897) the nonrotated or partially rotated cecum and the nondescent cecum are particularly likely to remain without effective fixation. The importance of these factors is indicated by the observation of Corner and Sargent (1905) that the left hypochondrium is the most common site of clinical cecal volvulus. Ratford (1920) and Carter (1938) report cases of complete nonrotation (left sided colon) with subsequent cecal volvulus. Bulman (1924) cites an instance of embryonic failure in the midgut torsion (giving an hepatic flexure in contact with the splenic) which suffered a cecal volvulus. Some other accidents in the colon's development may also result in a free cecum. Thus the unique case of Low and Hilderman (1940) in which there was true hyperrotation (400 degrees instead of the usual 270) possessed a *cecum mobile* on a mesentery though there was no volvulus, it would have been anatomically possible. The rare occurrence of reversed rotation of the colon is evidently often followed by volvulus. Cases have been reported in which patients died of their causes (Hunter, 1922; Harvey, 1926) while 3 cases have been recorded in which patients developed a cecal volvulus (Dott, 1933; Donald, 1927; Holman, 1930).

ANATOMICAL OBSERVATIONS

Stimulated by growing surgical interest in the ileocecal region many anatomical studies have been made of the iliac and colic peritoneal relationships, some of them specifically directed toward the problem of cecal mobility. The present authors feel justified in adding another to this list of reports for 3 reasons: first, previous authors have often not examined their patients in detail being content to record some one fea-

ture second many series have been concerned with children rather than adults third, most of the exhaustive studies have been conducted in Europe, there being no comparable works in this country.

The authors have examined 125 normal consecutive adult dissecting-room cadavers. The mesenterial attachments of the cecum, ascending colon, and terminal ileum were critically studied, area of posterior fixation graphically mapped. In the records, however no effort was made to distinguish between primary fixation and secondary attachments, or even between instances of common ileocecolic mesentery and those with a right mesocolon but which lacked continuity with the mesentery of the terminal ileum. A classification was then devised and the specimens were placed in the selected categories. Classification of the variations in the peritoneal attachments of the ileocecal segment incidentally is not clear cut, since in fitting cases into arbitrary types, the succession of almost imperceptible gradations in the extent of fixation must be disregarded. In Figure 1 are presented diagrams illustrating this classification and showing the distribution of 125 specimens among its types; each sketch was prepared from a specimen representative of the class, and, in some instances, demonstrating the scope of divergence within a class. Figures 2 to 9 contain detailed drawings of individual cases.

In type I (see Fig. 1) the cecum is completely or almost completely fixed to the posterior wall, being in some cases retroperitoneal. Seven specimens, 5.6 per cent, fell into this group. Figure 3 shows such a cecum, and illustrates the characteristic tight adhesion. In 4 subjects, 3.2 per cent, the cecum is attached through a third or more of its posterior surface (type Ia). In 20 cadavers, 16 per cent type Ib cecal adherence to the posterior abdominal wall, extending the length of the organ is usually narrow in some instances being a very short mesentery. Type II is made up of specimens having peritoneal attachment at the ileocecal junction with the cecum free there are 2 of these, 1.6 per cent. In 3 bodies 2.4 per cent type IIa, the arrangement is complicated by tight adherence of the terminal ileum to the posterior wall. Figure 8, though not of a specimen belonging to type IIa, illustrates this type of fixation of the terminal small bowel. Cecum with a descending line of fixation beginning just above the ileocecal junction (type III)

*These were American subjects and specimens, mostly males, peritoneal dissection material of the anatomical laboratories of the North western University Medical School. All were prepared for research only, by the phoshoformin technique which leaves no specimens almost perfect as in life. Bodies with indications of some abnormality were reported.

could be manipulated into a position of volvulus in the abdomen of the cadaver. On the other hand, types V and VI are certainly predisposed to torsion of the right colon, all of the examples of these two classes permitted such manipulation. Type V would seem to represent the ideal in predilection, since in members of this group the bowel is mobile and the ascending colon fixed at a single locus which could behave as a stable

point around which the free segment could turn.¹ Three of the eight specimens of type V actually exhibited partial torsion. Figures 4, 7, and 7a illustrate a case in which the right colon had already been so rotated that the ileocecal junction

¹It is significant that many reported cases of clinical volvulus of the cecum were observed to have a band securing the ascending colon and acting as the hub of the twist. Lehmann (1922) reported a case of cecal volvulus in the presence of a free cecum and a retroperitoneal ascending colon and was able to collect 6 other cases from the literature.

Figs. 1-6. Detailed drawings of cecal and related structures from selected specimens. Figs. 1 and 3, type IV

Figs. 4, type IIIa; Figs. 5 and 6 (same specimen), type I; Fig. 6, type V

apparent that types I Ia and Ib are too firmly fixed to permit volvulus. Cecae of types II, IIIa and III also seem too securely moored to permit twisting unless the cecum were to become greatly pouched. Even in the latter event a fixed point of rotation would be a further requisite. In this

particular class IIIa would perhaps be predisposed to volvulus because of the presence of a well anchored ileum. Types IIIa and IV in some instances present ceca that could revolve were concomitant pouching and dilatation to occur. None of the specimens in these two categories

Fig 7

could be manipulated into a position of volvulus in the abdomen of the cadaver. On the other hand, types V and VI are certainly predisposed to torsion of the right colon, all of the examples of these two classes permitted such manipulation. Type V would seem to represent the ideal in predilection, since in members of this group the bowel is mobile and the ascending colon fixed at a single locus which could behave as a stable

point around which the free segment could turn.¹ Three of the eight specimens of type V actually exhibited partial torsion. Figures 4, 7, and 7a already been so rotated that the ileocecal junction

¹It is significant that many reported cases of clinical volvulus of the cecum were observed to have a band forming the ascending colon and acting as the hub of the twist. Lehman (1922) reported a case of cecal volvulus in the presence of a free cecum and a retroperitoneal ascending colon and was able to collect 6 other cases from the literature.

FIG. Hypothetical explanation, recorded in diagrams, of the dependence of the direction of rotation upon the plane of the ileocecal orifice: the direction of force could tend to initiate clockwise turn (B) or counterclockwise movement (C) ere the cecum turned from coronal plane (A).

was on the lateral margin of the large intestine and the ileum passed behind the cecum, as shown by lifting the latter. Treves (1885) and Pernkopf (1928) reporting cases similar regarded them merely as instances of unusual cecal position.

Types V and VI together making up 11.2 per cent of the series, represent the percentage in which the right colon is physically able to undergo twisting. This total perhaps should be added those which, if secondarily pouched, could revolve. If volvulus occurred in members of types V and VI it would be truly congenital volvulus in members of other classes would be in a certain sense acquired.

A comparison of our figures with those of other investigators is given in Table II. It should be noted that these data were collected in various ways (for the possibility of maneuvering the cecum into a position of rotation for the occurrence of right mesocolon, etc.) Some used cadavers others autopsy material or radiographic records; some studies were carried out on children others on adults. The figures in Table II are therefore not altogether comparable. It is significant that the incidence of ascending mesocolon runs over 20 per cent while that of extraordinarily mobile right colon is only 10 to 15 per cent—a fact that would indicate that a right colonic mesentery may be compensated for by secondary anchoring membranes. The present authors figure of 1 per cent of ceca able to form a volvulus compares well with Engel's (1857) 10 per cent, Wandell's (1903) 10.3 per

FIG. Roentgenogram of the authors' case, taken post-operatively after barium enema. The cecum (treader lower left) is greatly dilated; arrows point to the ends of the small intestine within the dilated portion, through the lumen of which the terminal colon and cecum.

cent Kantoe and Schechter's (934) 10.4 per cent Treves (1885) 11 per cent, Harvey's (918) 13 per cent, Piernols (1907) 14 per cent, Alglave (1907) 15 per cent, and well also with Thun's (913) 9 per cent. The higher figures recorded by some workers possibly may be due to the inclusion of infants, or to the failure to regard secondary bands of attachment. All in all it would seem fair to say that some 10 to 15 per cent of adults are anatomically predisposed to cecal volvulus.

In 1905 Kelly and Hurdon called attention to the fact that the terminal ileum may be firmly fixed even retroperitoneal, instead of normally free. Since then others have reported on various features of such cases (Oelachslagel 924 Benzel,

*It should be noted here that anatomical information on postnatal attachments of the ileocecal system are of service in other clinical matters than cecal volvulus. These attachments are of obvious importance in the symptoms of acute appendicitis and of the possible pathologic effect of retroperitonealization of this area as well as in such problems as abnormal locations of the vermiform appendix, internal hernia and distal mesocolon, such as in the case of Lynch (1911) and likewise point to the dependence upon clinical considerations. The best technique in the diagnosis of cecal volvulus is the double contrast method of the upper perspective of abdominal radiology in the early years of life.

TABLE II—MOBILITY OF CECUM AND RIGHT COLON

Author	Date	No.	Mobile No	Per cent	Type of data	Description
Engel	1857	100	10	10	Cecum free	Adults

such a segment is noted by Homans (1921). This particular type resembles those cases in which sigmoid volvulus is due to a similarly redundant sector.

THE MECHANICS OF CECAL VOLVULUS

Much has been written on the mechanics of cecal volvulus, and many classifications have been proposed, of which perhaps the best are those of Treves (1900), Corner and Sargent (1905), Faltin (1902) and McGowan and Dixon (1936). However, it is felt that too much stress should not be laid on classifications and rigid mechanisms. The literature amply demonstrates the simple fact that right colic volvulus can involve a variable amount of bowel, and that it can occur in many ways, depending upon the anatomical relationships and the presence or absence of pathological adhesions. Thus a colon with a common ileoceccocolic mesentery may turn about the superior mesenteric vessels as an axis, or, the opposite extreme, an isolated cecum may twist on itself—sometimes not obstructing the bowel, as in Makkas' (1929) case, in which the point of torsion was distal to the ileocecal junction. A locus of attachment on the ascending colon can act as the point of revolution and hence of obstruction, or a fixed terminal ileum can act in the same manner. If both the ascending colon and the ileum possess adherent areas, the intervening bowel can turn between them, if free, as shown in the patients discussed by Smith (1920) and Kirby (1929). A redundant loop of right colon with a narrow base can turn on itself after the fashion of a sigmoid volvulus, with obstruction of both the afferent and efferent limbs (Homans, 1921). Abnormal membranes or adhesions may further complicate the mechanism of volvulus, as in cases of adherent appendix (Nowland, 1925), of appendix fixed in the left pelvis (Cochrane,

1932, Piotet, 1934, LeVay, 1940). The importance of the fixed ileum in providing a point around which the right colon may swing to form a volvulus is noted in one of the cases of Sweet (1935), abnormalities of ileal attachment are stressed in this regard by McGowan and Dixon (1936). There have been a few studies on the percentage occurrence of fixed ileum, though the figures are at such variance as not to be very helpful (Table III), in these it is not generally indicated whether the cecum was free or fixed.² In our series, 13 subjects, 10.4 per cent, showed stable terminal ileum, whether retroperitoneal or bound down by extra bands, but only 5 of these, 4 per cent, were combined with a free cecum. The figure of 10.4 per cent compares well with the observations of previous authors, except for the low figure of Armstrong (1921) and the high one of Addison (1900).

No example of the rarer conditions (reversed rotation, left sided colon, hyperrotation, etc.), sometimes responsible for mobility of the right colon, was met with in the current study, nor was any case found in which the cecum and hepatic flexure were fixed and the right colon free and redundant between them. Volvulus of

²Armstrong (1921) reported two cases of fixed ileum with mobile cecum. He notes that two similar cases were found in a survey of 50 bodies.

1929) or even to the sacrum (Edwards, 1917). There are other rare and bizarre mechanisms, as for example Wistinghausen's (1919) case in which the terminal ileum wrapped around the ascending colon to form a pedicled cecum that underwent torsion.

The direction of rotation of an ileocecal volvulus cannot be completely accounted for on anatomical grounds. Many assume that the direction of twist is almost always clockwise. However as pointed out by Beeger (1923) and Graham (1926) direction depends upon how the cecum is placed and it is apparent from some descriptions and figures that not all authors have faced the hypothetical timepiece in the same direction. Beeger and Graham feel that the direction should be taken from an imaginary timepiece placed, dial upward, upon the patient's abdomen. Since many of the accounts in the literature are uninterpretable because of this confusion, no attempt has been made to compute the percentage of rotation in one direction or the other. Faltin (1902-1903) found only 15 of 50 analyzed cases had a clockwise twist. Jacobsen (1924) reviewing 24 cases, found 50 per cent clockwise. Von Zoeger-Manteuffel's original idea that the medial attachment of the mesentery accounts for the usual clockwise rotation must be held in abeyance. It seems more plausible, mechanically for a free cecum to roll medialward on its mesentery than for it to turn counter clockwise beneath that structure. However Dixon and Miller (1940) are of the opinion that cases with a common ileocecal mesentery twist in a counterclockwise direction, while the turn is more frequently clockwise if the colon distal to the cecum is fixed. It is possible that the position of the ileocecal junction, dorsal or ventral to a frontal plane through the long axis of the right colon, may be important, since the force of the fecal contents driven against the anterior or posterior wall of the cecum might be sufficient to give the impetus for rotation counterclockwise or clockwise, respectively (Fig. 1).

INCITING ETIOLOGY

Although the anatomical background of cecal volvulus can easily be demonstrated, the fact that there are so few cases of the disease indicates that the inciting etiology deserves careful examination. That the anatomical predisposition is not the sole basis is suggested by a number of facts. Thus, von Thun (1913) found a majority of cases of cecal mobility in children below 5 years yet most clinical volvulus occurs in young adults. As a second point it should be mentioned

that there are cases in old persons who have anomalies obviously present since birth. Third, Bryant (1921) states that there is more marked ptosis of the right colon (and hence presumably greater mobility of the cecum) in females than in males, yet clinical cecal volvulus is recognized to be more frequent in the latter sex.

It seems evident that there are many causes of volvulus. It would be desirable to differentiate between those which merely set up a more favorable mechanical situation and those which actually set the process in motion unfortunately in the present state of our knowledge it is not possible to distinguish between the two. A large number of the causes listed in the literature seem to be of the mechanical variety. Many cases have been reported following events essentially traumatic, among them being exercise, heavy lifting, blows to the abdomen, coughing, jumping, dancing. Pregnancy seems to be an important mechanical cause of volvulus. Dreyer (1911) illustrates the manner in which the rising pregnant uterus displaces a mobile cecum (that such displacement occurs is confirmed by the radiographic studies of Eldering (1932) and Fieth and Ohlsson (1928). Pratt and Falls (1927) however believe that pregnancy causes volvulus not so much by mechanical means as by the abdominal peristalsis accompanying the vomiting of pregnancy. Surgical operations of different sorts have been followed by volvulus, and various kinds of intra-abdominal pathology have been cited as contributory in individual cases. Corner and Sargent (1905) state that the cecum is frequently found in the strangulated or obstructed right inguinal hernia of children and, when distended with gas, is almost always twisted.

There have been many surmises as to the possible etiological roles of such general factors as race, sex, age, country and diet. There is little evidence that cecal volvulus is of greater incidence in any particular race. The case for geographical influence is no stronger. In the early literature many of the victims were German (2 of Bundschuh's 110 collected in 1913). Later however Allipow (1925) collected 39 Russian cases, Jacobsen (1924) analyzed 24 cases from Denmark, and several series of cases were reported from other Scandinavian countries. Podlaha (1926) collected 168 cases from Germany, Finland, Russia, Poland, and Scandinavia. Recently there has been an increase in the number of cases from North America, Central Europe, and France (Table I).

On the basis of circumstantial evidence, diet seems to be the most significant general factor

Pratt and Fallis (1927) and Ohman (1924) note that there was a large increase in the incidence of volvulus in the Baltic states during the Great War, when the diet consisted largely of coarse vegetables. Graham (1926) calls attention to the potato and sour bread diet of Finland and the vegetable diet and heavy eating in czarist Russia. The recent increase in the number of reported cases in America does not seem to have a dietary basis.

Cecal volvulus is conceded to be a disease of young adults. Corner and Sargent (1905) found 50 per cent of cases in the 20 to 40 year group, while Bundschuh (1913) met with 82 of 102 cases under 40 years, and 20 over that age. Faltin (1902) estimated that 71.4 per cent of his cases were less than 41 years and 45.4 per cent in the 17 to 30 year class. This is not in close accord with the anatomical evidence for the age incidence of mobile cecum, von Thun (1913) found that 51 per cent of bodies below the age of 5 had ceca free enough to produce a volvulus, 9 per cent of persons from 5 to 50 and 13 per cent of persons over 50 years of age.

There seems to be a definite sex predilection, males are more often affected with the disorder than are females. Pratt and Fallis (1927), analyzing 150 cases, found males predominating over females in a ratio of 3 to 1, while of Bundschuh's (1913) 110 collected cases, 76 were in men, and of Corner and Sargent's (1905) 57 cases, 42 were in men. Faltin (1902) found that 56 of 79 cases were males. This, again, does not fit in well with the anatomical facts, since it has been generally found that in males the right colon is less free than in females. Thus Harvey (1918) found a right mesocolon in 6 per cent of male infants and in 20.4 per cent of female infants. Wilms (1908) and Klose (1909, 1911) feel that *cecum mobile* is definitely more frequent in the female. Bryant (1921) makes a similar observation. However, Wandel (1903), whose large and carefully studied series demands respect, finds that, as regards ceca free enough to rotate, the proportion is slightly in favor of males.

It is a well known clinical fact that many cases of cecal volvulus occur without assignable cause, particular or general, some begin in the physiological quiet of night. Many cases have a prior history of long standing intestinal complaint. Heavy eating, constipation, and diarrhea have also been noted in cases of volvulus. One must therefore look to physiological maladjustments for the inciting etiology which plays on an anatomical predisposition. True, a mass peristalsis might constitute a true mechanical cause,

but upsets of normal peristalsis must be considered physiological in their inception. That the normally placed and fixed right colon is the site of complicated physiological activities, and that disturbances may easily upset their harmony has been emphasized by Homans (1921), such disturbance perhaps results in unusual amounts of putrefaction, in the formation of gas, misdirected peristalsis—leading in the end to distention, kinking, and volvulus. Perazzo, Zavaleta, and Artuso (1938) think that many of the so called traumatic and mechanical causes really act indirectly by setting up pathological peristalses. Harttung (1922) stresses constipation and anti-peristalsis as the cause of the actual torsion. McConnell and Hardman (1922) find differences between peristalsis in normally and imperfectly fixed right colons. It should be mentioned that some think a rôle is played by the ileocecal valve in the causation of cecal volvulus (Perazzo, Zavaleta, and Artuso, 1938). Amazing as it may seem, the physiology of this structure is only now beginning to be understood (Wakefield and Friedell, 1941).

CASE REPORT

Mrs. M. N., a white female, aged 71 years, entered Passavant Memorial Hospital August 16, 1938, on the service of Dr. Howard B. Carroll.

On the evening of August 14, at 5:30 p.m., she ate some honey dew melon and shortly thereafter experienced abdominal distention. At 9 p.m. she began to have generalized abdominal cramps. She took a half bottle of magnesium citrate, which was followed by six watery stools, which did not, however, relieve the pain or distention. On the morning of August 15 she took another half bottle of citrate of magnesia and later a Seidlitz powder. Orange juice, lemonade, and paregoric were taken, but all were vomited. Pain and distention continued. There were two watery bowel movements during the day. The pain, distention, and vomiting continued up to the time of admission on the 16th.

The past history was not pertinent except for constipation of many years' duration. She avoided fried foods, white sugar, white flour and desserts, and had lost 15 pounds in the past year. "Pills" and mineral oil had been used for constipation for many years.

Physical examination revealed a thin woman, with normal pulse and temperature and a blood pressure of 160-90. The head, neck, and chest were normal. The abdomen was markedly distended, tympanic over the dome, and dull in the flanks. There was no rigidity, but there was generalized tenderness upon palpation. No peristalsis could be seen. The left lower abdomen bulged, and palpation revealed a mass in this locus. The red blood count was 4,580,000, the white blood count, 4,500, the hemoglobin, 14.0 grams. A differential blood count showed 62 per cent polymorphonuclears, 30 per cent lymphocytes, 8 monocytes. The urine contained three plus albumin and some granular casts.

A diagnosis was made of intestinal obstruction, very likely a volvulus. The patient was given intravenous fluids and hot abdominal packs. Her vomiting abated and she passed a fairly comfortable night. There was no stool and she passed no flatus. The distention persisted. On August

7th she as given barium enema. A large mass of barium was seen in the lower abdomen, with an area of constriction in the lower right colon (Fig. 7). The patient was seen by the senior author on the afternoon of August 7 and was operated upon soon after.

When the abdomen was opened, through a right lower abdominal incision, some blood-tinged fluid escaped from the peritoneal cavity. Loops of ileum were found to be distended. The ascending colon was collapsed, but in the lower abdomen and pelvis could be felt a large, distended loop of intestine. The dilated segment, on delivery from the peritoneal cavity was made up of the cecum and the first portion of the ascending colon. There was a 90 degree clockwise twist. The dilated loop was some 6 inches in length, 7 in diameter. Its wall was so thin that the contents of the lumen could be distinguished. The loop was untwisted, catheter implanted, and the cecum emptied of 15 liters of fluid. A larger tube was then implanted for the purpose of cecostomy. There was no evidence of necrosis. The gut was replaced and the abdomen closed. The operation was well tolerated. After operation constant gastric aspiration was applied and also suction to the cecostomy tube.

On the following day the patient condition as excellent, and convalescence went smoothly until the 5th postoperative day when she seemed weaker and demonstrated dependent edema. Her blood chlorides were found to be 400 milligrams per cent and she as given transfusion of 300 cubic centimeters of citrated blood.

On the 6th postoperative day she displayed respiratory embarrassment, and oxygen was administered. Her abdomen became distended, and fluids given by mouth did not pass the pylorus. She gradually became sicker and ran fever up to 102 degrees F. The chest became filled. It rales, and she died on August 27 days after the operation.

At autopsy the cecum was found to be of normal size and adherent to the anterior abdominal wall. There was no evidence of leakage around the cecostomy tube. An acute fibrinous peritonitis with necrosis as demonstrated, judged by the pathologist to have been due to proptosis, ending. There was also an acute bilateral fibrinous pleuritis with hydrothorax, subtotal pulmonary arteritis and other relevant findings such as early portal cirrhosis, enlargement of the spleen, chronic cholecystitis with cholelithiasis and arteriosclerosis.

There are several points of interest in the case. One is the advanced age of the patient though by no means the oldest case on record, this is one of the most aged. Second, is the fact that a pre-operative diagnosis was made on the basis of clinical findings. Third, is the attributability of the fatality to the 2 day delay in seeking medical aid and the additional delay in resorting to surgery. This case serves well to stress the point that volvulus of the cecum, in its usual form, is an acute surgical emergency. The presence of a distended cecum is a constant menace through its thin walls contamination of the peritoneum can easily take place, as occurred in this patient, to prejudice seriously the success of inevitable operation.

The direction of torsion in this case was definitely clockwise in the sense defined by Beerger (1925) and Graham (1926). The anatomical

mobility of the cecum was clearly evident. The loop was filled with fluid, not with gas, as Weinstein (1938) and Homans (1921) have assumed to be the case, because of the colonic anaerobes growing in an oxygen deficient milieu. In the current case however there was a narrow lumen at the site of the twist, which allowed barium introduced into the colon to enter the twisted loop (Fig. 11).

The inciting etiology in this case would seem to be pathological peristalsis, whether before or after the intake of cathartics cannot be stated. The diagnosis was made on clinical grounds, but confirmed by radiological examination. A scout film of the abdomen and a barium enema are of great diagnostic assistance. If a small lumen is present the volvulus can be directly visualized. If torsion is complete the point of obstruction shows up as a cone-shaped, smooth shadow. In such event, the presence nearby of a large dilated loop of bowel suggests cecal volvulus.

Prompt surgical intervention is necessary as emphasized by the case of Valentine and Kinross (1937) in which death occurred in 5 hours. The presence of vascular obstruction sufficient to cause necrosis cannot be determined unless the abdomen is opened. Leakage from the thin walled and distended cecum is a source of constant danger. The procedure to be utilized varies in the hands of individual surgeons. Many operations have been recommended, but, since these patients are usually debilitated, the simplest possible measure should be chosen. Untwisting and cecostomy constitute the conservative procedure in cases in which the gut is viable. Patients having necrotized bowel, the involved sector can be exteriorized. Resection is used but would seem too severe an operation for any patient not in unusually good condition. The situation is quite different with regard to chronic or partial volvulus. In this contingency it is permissible to restore normal peritoneal relationships by some of the cocoplastic procedures.

SUMMARY AND CONCLUSIONS

Over 300 cases of volvulus of the cecum have been reported in the international literature. It therefore follows that cecal torsion is not a mere surgical curiosity but possibility which should be kept in mind in the differential diagnosis of disease presenting in the right lower quadrant of the abdomen, and in the differential diagnosis of intestinal obstruction. The literature pertinent to the subject is briefly outlined.

It is proposed that volvulus of the cecum be defined as torsion limited to the cecum and adja-

cent terminal ileum and ascending colon, as suggested by Gatellier, Moutier and Porcher (1931). It is further proposed that the direction of twist be noted as clockwise or counterclockwise as referred to an hypothetical watch placed dial up on the patient's abdomen, as originally suggested by Beeger (1923) and Graham (1926).

In 125 normal adult cadavers studied consecutively by the present authors it has been demonstrated that in 11.2 per cent the cecum is mobile enough to allow the development of a volvulus. A survey of the literature indicates that 10 to 15 per cent of ceca are free enough to undergo torsion. In the present series 10.4 per cent of terminal ileums were found to be fixed, of these 38.5 per cent were associated with free cecum, and in these cases the attached ileum could serve as a hub were the ileocolic part of the digestive tube to revolve.

The anatomical arrangement which best predisposes to cecal volvulus is believed to be one in which the cecum is free and the ascending colon fixed somewhere along its vertical course. It is noteworthy that many accounts of clinical cases describe a band which binds down the ascending colon. Of 8 instances of this anatomical type encountered in the present authors' series of 125 specimens, 3 displayed some degree of torsion. The mechanism of volvulus varies greatly, but seems to depend chiefly upon the anatomical relationships and upon the position of fixed point or points for twisting.

The inciting etiology of this disease may be purely mechanical, or may be due to as yet incompletely understood physiological faults in the complex functioning of the right colon.

A case of cecal volvulus is reported. A study of this case serves to emphasize the necessity for prompt surgical care, and the importance of early examination by roentgenographic means. The authors suggest that cecostomy or exteriorization is the procedure of choice in acute cases, final selection depending on the viability of the bowel. Resection should be reserved for patients whose condition is very good. Cecoplastic procedures are permissible for chronic or partial volvulus.

HAZARDS OF FIRE AND EXPLOSION OF ANESTHETIC AGENTS

III In the Presence of Diathermy

BARNETT A. GREENE, M.D., Brooklyn, New York

THIS report, the third in a series on the fire and explosion hazard in modern anesthesia, is best viewed as a logical development of our previous reports. It is especially related to the paper on cautery ignition (3), which we recommend for study before reading this report.

The application of high frequency electrical currents to surgery is widespread and increasing, it is practically indispensable in some phases of modern surgery, especially neurological and genitourinary surgery. Therefore, anesthesiologists must accept the presence of electrosurgical apparatus in the operating room and must adapt their methods to this hazard.

Paralleling the increased use of electrical instruments in the presence of anesthetic agents and equipment is the decreased use of open ether and chloroform volatilized with air, and the greater utilization of semiclosed and completely closed methods of administration of ether, ethylene, and cyclopropane, with high concentrations of nitrous oxide or oxygen, or both. While these changes have been of great value in diminishing intraoperative and postoperative morbidity, they have, unfortunately, augmented the likelihood of serious injury to the patient and the surgical team exposed to an anesthetic combustion. It is more important than ever before to prevent anesthetic ignition, especially the entirely preventable types associated with electrical apparatus.

A marked discrepancy and a lack of unanimity in anesthetic practices exist with regard to these dangers. Even in hospitals with otherwise progressive departments of anesthesiology, we have found unsafe techniques in use. Many have adopted inadequate compromises as a result of incomplete understanding of the details of the hazard, e.g., barring ethylene and cyclopropane but allowing ether (17), or forbidding combustible inhalation anesthetics in head and neck electrosurgery but permitting them in surgical diathermy.

Dr. Greene is director of anesthesia, Prospect Heights Hospital, Brooklyn, N.Y.; anesthesiologist, Brooklyn Cancer Institute, Kings County Hospital, chairman, Subcommittee on Anesthetic Hazards, American Society of Anesthetists; diplomate of American Board of Anesthesiology.

employed at more remote points of the body or extremities (5).

It is high time that there be established a universally accepted standard of safe practice of anesthesia with diathermy. We believe that our studies have secured sufficient information to make this possible, and more, to make it convincing.

ELECTRICAL DATA

The basic information about combustible anesthetics has been presented in detail in foregoing reports (3, 4). All that is necessary, we believe, to secure understanding and agreement with our opinions on this type of electrical hazard is a presentation of the electrical aspects of high frequency apparatus as they are related to the possibility of igniting a combustible inhalation anesthetic mixture.

The heat necessary for ignition—182 to 517 degrees C (3) may be considered present whenever a visible or audible spark is produced. For practical purposes, this is a necessary and safe rule even though it might be shown that there are degrees of sparking which cannot ignite anesthetic mixtures (we do not know of any such proof). When the surgical diathermy is employed, sparking or arcing may appear in five zones: (1) at the active electrode during fulguration, coagulation, or cutting; (2) within the cabinet of the apparatus if the machine has a spark-gap or defective insulation; (3) at the foot or hand switch controlling the make and break of the circuit; (4) at the wall plug socket during the make or break of the connection; (5) *this is the one source of sparking usually overlooked*—at many scattered and unpredictable points where a high frequency current or induced current jumps an air gap formed between the patient (charged by the high frequency electricity coursing between the two electrodes) and a grounded conductor or any conductor of sufficient electrical capacity to accept a charge. Such a conductor may be a nearby grounded or ungrounded machine or person.

We must consider each of the five zones in greater detail with regard to explosion protection from the sparks arising in each zone.

rection of regional blocks, spinal anesthesia, rectal basal narcosis, and intravenous barbiturate anesthesia now makes it safe and feasible for a trained anesthetist to administer a noncombustible anesthetic whenever high frequency currents must be employed

Our personal experience is worth citing as typical of the necessary and practicable adjustments in anesthetic methods safe for use in the presence of x-ray and diathermy apparatus. In our early years, we were fortunate in our ignorance to have used, without mishap, ether-oxygen-nitrous oxide and cyclopropane-oxygen for fluoroscopic surgery and surgical diathermy in various parts of the body, ranging from the breast to the cervix. With further education and experience, we have learned to discard these dangerous practices and to substitute noncombustible methods without serious difficulty. An increased use of spinal and other regional blocks, intravenous barbiturates and rectal basal narcotics combined with nitrous oxide-oxygen or regional blocks has enabled us to supply noncombustible anesthesia whenever the surgeon has desired to use the x-ray or diathermy. And at no time were we ever doubtful of the safe control of the depth of the anesthesia. Our most common occasions for changing a combustible inhalation anesthesia to a noncombustible technique have occurred in radical breast and neurological surgery. In both, we have been well pleased by the supplemental use of minimal amounts of intravenous barbiturates injected into the tubing of the infusion usually started with radical breast and neurological surgery. Simultaneously, the combustible agent is removed from the apparatus and "washed out" of the patient. The inhalation apparatus is used to supply nitrous oxide-oxygen with relatively large amounts of oxygen (20 to 25 per cent) and to provide an accurate indicator of the respiratory excursions. We have found this combination of minimum doses of pentothal sodium with optimum oxygen-nitrous oxide the answer to most of our problems of supplying noncombustible anesthesia in the presence of diathermy, when spinal or regional block was impracticable.

CLINICAL DATA

We have found published warnings (7, 8, 16, 18, 19, 22) against the use of diathermy apparatus with inflammable agents as far back as 1924. Through the 16 years, it has been repeated again and again. Yet explosions and deaths have been caused by the practice even up to the present, and the hazard is being repeatedly tempted in very many hospitals, even by some of the largest

We believe that the reasons for this continued violation of safe practice are four, one or more of these accounting for the persistence of the dangerous combination in different institutions: (1) Ignorance—of the physics and chemistry of the subject and therefore of the reality of the hazard, (2) indifference—to the hazard because of past "blind" good luck and because of unawareness of the catastrophes experienced by others, (3) inflexibility—of available methods of anesthesia because of lack of versatility and training in the anesthetist, forcing the use of combustible anesthetics in hazardous circumstances, (4) conflict—of opinion among surgeons, anesthetists, and diathermy manufacturers, fostered by the lack of an official and unequivocal censure of the unsafe practice.

In the literature and in our discussions with many anesthetists and surgeons, we have noted an almost universal disregard or oversight of the "diffuse sparking" tendency of high frequency currents, a fact long known to physicists. We have found only two statements alluding to this feature, but both without explanation. Size (20) has stated "at the present time there does not seem to be any certain way of guarding against miscellaneous sparking from this procedure," i.e., diathermy. The Minister of Health for England and Wales, in a memorandum (14) on the use of electrical apparatus in the presence of an inflammable anesthetic, pointed out that the patient, under an electrical potential while in a surgical diathermy circuit, may allow a spark to jump from himself to the operating table or anesthetic apparatus.

The elimination of the first three of the reasons stated above, for the persistence of the unsafe practice of mixing diathermy with inflammable anesthesia, is entirely dependent on the universal elevation of the standards of education and supervision of anesthesia and anesthetists. Fortunately, this is rapidly, but not rapidly enough, becoming a reality.

Most authorities condemn the practice under discussion, but we have found several writers who have permitted the loophole to remain, through which the erring anesthetist may escape condemnation. These writers, usually on very inadequate grounds, have indicated that ether inhalation is permissible with diathermy. For example, Mock stated "The anesthetic of choice in these cases of goiter is 0.5 per cent procaine hydrochloride used locally. With this anesthetic no precaution need be taken on account of the electrical current. Nitrous oxide may be used without fear of an explosion, and ether can be used. In the lat-

1 The active electrode always produces a spark or arc whether the high frequency current is adjusted for fulguration and coagulation (which are visibly associated with arcing) or for cutting. This knife like action is performed, not by a hot electrode, but by an arc which forms ahead of the electrode and which separates the tissues by volatilizing them (2). The danger arising from the arcing active electrode is as obvious and as localized as that of the hot tipped actual cautery. All the rules suggested in our earlier report (3) on the cautery may be applied here. We refer the reader to this paper for details.

2 The sparks in the cabinet of the apparatus may be caused by the multiple spark-gap frequently used to produce the high frequency oscillating current. This source of sparking is absent in the type of equipment which substitutes radio vacuum tubes for the spark-gap mechanism. Another source of sparks may arise from faulty or worn insulation or loose contacts. All of these internal machine sparks may be rendered innocuous by following the same precautions as have been described for the active electrode or actual cautery. Another method of protection that has been employed is the placing of the machine outside of the operating room and using very long lead-in wires to the electrodes.

3 The sparking at the foot or hand switch is an obvious hazard easily removed by enclosing it in a bag through which it may be operated, similar to the suggestion made for the fluoroscopic foot switch.

4. The plug-socket hazard at the wall connection may be avoided by inserting the plug before the start of anesthesia and removing it only after the anesthesia has ended and the room well ventilated. To prevent accidental disruption of the connection, one should use a locking type of wall socket (21). Of course if the socket is located outside of the operating room, the above precautions are unnecessary.

5 The scattered and unpredictable type of sparking mentioned before in zone 5 cannot be surely and safely prevented as the following consideration explains. Arcs may be produced in the presence of high frequency generators under conditions that would be absolutely safe from any other form of electrical spark. There are two reasons for this. (a) Arcs may be drawn from a high frequency conductor by a grounded conductor or by any conductor of relatively high capacity, e.g. a human body even if it is perfectly insulated. In the case of an insulated body it is continually charged and discharged by electromagnetic induction and if the distance is small this electromag-

netic stream will cause ionization of the air in between to the extent of forming a continuous arc. (b) An otherwise well insulated conductor may acquire an induced high frequency voltage by being near a high frequency conductor. Arcs may then be drawn from it very easily as described in (a). Many substances which are poor conductors or even good insulators to direct current or low frequency alternating current are good conductors of high frequency electricity. All of these special characteristics observed in using high frequency increase in proportion to the frequency and the frequencies employed in surgical diathermy are very high.

This information shows how difficult it is to limit the path of high frequency electricity and the possible points of arcing. Even with the inactive electrode on the sacrum and the active electrode at the urethra the currents are traversing all parts of the patient and are not entirely confined to a narrow path lying between the electrodes. A current diffuses itself more or less throughout the body (11). This device route is followed partly because of the varying electrical resistances of the structures in its path. No matter how far the electrodes may be from the mass, the hazard of arcing in or near the insulation system is a constant threat.

The prevention of this diffuse type of sparking is possible theoretically by connecting the patient to all objects and persons likely to approach him closely. To offset the increased hazard of electric shock introduced by this greatly increased circuit and capacity it would be necessary to add a high resistance barrier between each person and any likely grounding contact. It should be apparent how difficult this would be. Much more so than the Horton system (9) of intercoupling described for the prevention of electrostatic sparking. For in addition to the group connected by the Horton intercoupler (operating table, patient, anesthetic, and anesthetic apparatus) it would be necessary to include in the circuit all of the surgical teams and instruments which might draw a spark from the electrically connected patient and group in the immediate vicinity of the anesthetic inhalation system.

It should be evident why we consider the use of a combustible inhalation anesthetic mixture as entirely unsafe in the presence of electrosurgery anywhere on the patient. Even with precautions theoretically possible but never applied and highly impracticable, the practice is not as safe, more cumbersome, and less practicable than the use of noncombustible anesthetic methods and techniques. The progress of anesthesiology in the di-

to 220 volt current to a metal part that is usually insulated or to the secondary circuit which normally carries only a very small amperage. If "grounding" is in use, the electrical shock and the short-circuit spark are increased. The presence of a megohm resistance, as in the Horton intercoupler, between the "ground" and the person "grounded" eliminates the possibility of shock to those in the intercoupled group but does not prevent short-circuit sparking. The surgeon or a nurse, who are usually not included in the intercoupled group, may still be badly shocked or killed if he or she is standing in leather-soled shoes (which are conductive) on a "grounded" floor.

To prevent short-circuit sparking or electrical shock, it is necessary to check regularly the insulation of the diathermy equipment (in fact, all electrical apparatus on a house current) by means known to every electrician with the aid of a megger. It requires vigilance, circumspection, and repeated inspection to employ safely the modern equipment of surgery. These virtues are rarely used in most operating rooms until after the first accident has been experienced.

CLINICAL DATA

We have recorded 20 cases of fires and explosions ignited by diathermy apparatus. Three cases involving ether-air caused no injury, 8 cases of ether mixed with high concentrations of a source of oxygen (nitrous oxide or/and oxygen) resulted in the death of 2 patients, the serious injury of a third patient and 3 bystanders, and the slight injury of a patient and 2 bystanders. One case of nitrous oxide-oxygen containing an unknown combustible seriously injured the patient. Two cases of ethylene-oxygen caused the death of 1 patient and in another the rupture of the urinary bladder with recovery following repair. Two cases of cyclopropane-oxygen occurred, with the death of 1 patient. There were 3 cases of surgical field fires: alcohol ignited in 2 with the death of 1 patient, and ether ignited in 1 instance with death of the patient.

The igniting spark appeared at the active electrode, where the threat is exactly identical with that presented by the actual cautery tip, in 14 cases. The detailed consideration of this type of obvious hazard would be only a repetition of our discussion of the cautery hazard, to which the reader is referred.

In the remaining cases, the igniting spark occurred in unexpected and unpredictable places in or near the respiratory path of the combustible anesthetics although both the inactive and active

electrodes were deliberately and probably effectively kept out of contact with the gases. In these cases (definitely in 4 cases, and probably in 2 cases) the spark was of the type which is less obvious and more difficult of prevention, namely, the "diffuse sparking" which has been described in paragraph 5 of the electrical data presented in the early part of this paper.

SUMMARY AND CONCLUSION

We have considered in detail the electrical basis of all sparking or arcing during the use of high frequency apparatus. The prevention of all sparks is impossible. The localization of the hazard to one restricted zone, as is possible with the actual cautery, is practically impossible. No matter how far from the mask the electrodes are placed, there is serious danger of spark ignition of a combustible inhalation anesthetic mixture. In view of the relatively narrow field of use of surgical diathermy and because of the practical impossibility of spark prevention during diathermy, we have reached the conclusion that combustible anesthesia is contraindicated by the surgical need for diathermy in any part of the head, neck, body, and extremities.

We have directed attention to the other hazards of surgical diathermy in the operating room, namely, surgical field fires, fulguration-produced explosions of hydrogen in the urinary bladder and electric shock and sparking resulting from short-circuits in defective apparatus.

Our study forces us to conclude with the bald statement:

Anesthetic fires and explosions ignited by diathermy, like those due to x-ray apparatus, are completely preventable only by the use of noncombustible anesthetic methods. Failure to use such methods in the presence of diathermy is an admission of inability to maintain the standards of safe anesthesia which have long been advocated by many authorities, which are here demonstrated as necessary, and which are now practiced in the better departments of anesthesia and surgery.

ter 2 cases, a wet flannel roll is placed just below the lower edge of the mask and further protection against the fumes of the ether reaching the electric spark is provided by a rubber apron placed over the anesthetic frame and held tightly by clips against the skin of the cheeks and chin. If a general anesthetic is necessary rectal ether anesthesia, as in one of my cases, may be used. In all but one of the 15 cases in this series, local anesthesia was used. It is apparent that this author was recommending ether inhalation with electrosurgery of the thyroid gland without ever having used it.

Even the discoverer of the clinical usefulness of ethylene for anesthesia has committed the error of advising a combustible inhalation anesthetic with surgical diathermy. In 1924 Lockhardt and Kretschmer reported their use of ethylene anesthesia in 13 cases of fulguration of the urinary bladder and 1 case of carcinoma that received diathermy. In this article, they stressed the fire and explosion hazard of flame, cautery and electric sparks. Then they described the careful placing of the spark-gap apparatus at a distance from the patient, with the machine cover kept shut and the lead wires to the electrodes drawn through holes drilled through the walls of the cover. Yet they failed to recognize the danger of the sparking active electrode and the greater threat of diffuse sparking from any part of the patient. No explosion occurred even though this was in the days of only semi-open administration of ethylene. This is an excellent example of the fact that failure to cause an explosion by violation of the rules of explosion prevention cannot be used as evidence of the harmlessness of the bad practice. An explosion is the result of the coincidence of many predisposing factors of which the absence of any one may prevent the accident favored by the many other favorable influences.

We have been surprised to find Guedel allowing Ethylene properly managed, may be used in electric fulguration within the bladder if the air bubble above the water is held to minimal size and the fulguration spark is not permitted to reach the bubble. (6)

Kovacs (2) in his authoritative textbook on electrotherapy has contributed to the undeclassiveness of the warning against using diathermy with ether by describing its use in one paragraph, but, in the next, saying, "since however there have been occasional serious accidents resulting from ignition and explosion of ether, for it is better to avoid its use when possible."

Kelly and Ward in their textbook entitled *Electrosurgery* repeatedly advised the use of the

hazardous technique of interrupted open ether anesthesia for oral and other types of surgical diathermy, stating that the risk is slight with proper precautions, i.e., the patient exhales a few times and all ether-soaked materials are removed. While this was their most common method of general anesthesia, probably because of a lack of trained anesthetists, they admitted that rectal anesthesia administered by a trained anesthetist is the method par excellence.

Many manufacturers, in the commercial literature accompanying their diathermy apparatus (17) have warned against the use of ethylene but advised that ether might be used with only the precautions of an ether screen and wet towels. One of the leading manufacturers so poorly understood the ignition possibilities of diathermy that he considered the sparking hazard present only in the spark-gap type of machine and absent in the vacuum tube models.

The precautionary steps necessary to allow the change-over from a combustible anesthetic to a noncombustible one for use with diathermy are the same as are those which have been advised and described for cautery surgery (3) about the head after a combustible inhalation agent has been used.

There are three other varieties of hazard of special interest to the anesthetist when the diathermy is operated in the surgery. (1) The active electrode can ignite an inflammable cleansing or antiseptic fluid painted on the surgical field as it did in 3 cases. In this respect, the cautery and diathermy present the same problems. The field and drapes prepared with an inflammable cleanser or antiseptic should be thoroughly dry before the active electrode is applied, or better yet, a noncombustible fluid should be used. (2) There is a type of accident peculiar to bladder fulguration during which hydrogen may be liberated by the decomposition of the irrigating water within the bladder. The hydrogen rises to the dome of the bladder, mixes with the air bubble, and is subject to explosion whether or not an inflammable anesthetic agent is in use. (6) (3) The last type of danger is that of electrical short-circuiting with the resulting effects of electrical shock and sparking. These are possibilities which are ever present.

If electrical apparatus of any type receiving its source of power from a house current (110-220 volts) The main line of current may reach the operator or patient or by accident or intentionally in circuit with a part of the apparatus which has become live because of a break in the insulation within the machine or a defect in a condenser. This allows a leak of the main line

BACKACHE

THERE is an increasing tendency in this country to ascribe all lame back conditions to a ruptured intervertebral disc resulting in a herniation of its nucleus pulposus into the spinal canal, and when no evidence of such a lesion can be demonstrated by examination or by operation, there is a further tendency to make a diagnosis of a thickened ligamentum flavum. It must be remembered that pain in the back is still pain, and as such is only a symptom of many conditions which may exist in the back itself or regions outside the back, e.g., peptic ulcer, kidney and pelvic lesions, Hodgkin's disease, diseases of the blood (leucemia) and general infections. One of the most prominent and early symptoms of small pox is severe backache.

Low back pain above, or in combination with, radiating pain especially along the course of the sciatic nerve, may be present in a great many instances in which there is not a shred of evidence by x-ray or by myelogram of any local intraspinal lesion. It would be just as

logical to assume that all headaches are due to intracranial lesions. There are no typical physical signs of a herniated nucleus pulposus. Certainly a diminished knee jerk or absent ankle jerk is not pathognomonic, since these alterations may be seen in cases in which there has been a prolonged sciatica from many other causes. Furthermore, the removal of a herniated nucleus pulposus or a thickened ligamentum flavum does not always relieve or cure the lame back.

There are many conditions which may produce this so often distressing and even agonizing symptom, e.g., occupational attitude, sprains, compression fractures, malignancy, arthritic infections, local and general disturbances in the abdominal, pelvic, and retroperitoneal regions, pregnancy, relaxed abdominal walls after pregnancy, mechanical conditions of the extremities such as tilted pelvis, unilateral short leg, foot strain, contracted fascia lata, and bad posture. There is a large group of patients who may have severe pain radiating down the sciatic nerve. This pain may be alternating and the patients may show no clinical signs whatever of low back trouble. They are apt to be fascial, not "muscle bound."

On the other hand, a patient may have the severest of lame backs without any evidence by x-ray or other tests of any abnormality in his vertebral column, and the reverse of this is true, he may exhibit by x-ray marked congenital abnormalities or severe osteoarthritis of the spine and never have a lame back. When a patient does have a lame back in the presence of such abnormalities, why does he ever recover when these remain the same? There is plenty of evidence that recovery does take place and often without a recurrence of

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IT is estimated that 40 to 50 per cent of all disease in man is due to infection. Approximately 250 living agents of animal or vegetable origin are known to produce disease at least 56 different bacteria, 8 spirochetes, 21 ultramicroscopic viruses, 63 molds, yeasts, actinomycetes, and pathogenic fungi, 16 protozoa, 31 helminths, and, about 51 anthropods. Infection involves two living entities—the infectious agent and the host. It is the balance between them which determines the outcome. A clinical understanding of the mechanisms of infection on one hand and of natural resistance and acquired immunity on the other is of fundamental importance in the prophylaxis and treatment of disease. On this thesis, Kolmer and Tuft have developed *Clinical Immunology, Biotherapy and Chemotherapy*,¹ which is composed of two parts.

Part I covers the general aspects of infection, immunity, biotherapy and chemotherapy while Part II is given over to the clinical applications of these principals which concern the diagnosis, prophylaxis, and treatment of disease.

The difficult and often confusing subject of immunology is presented in a clear, concise, orderly manner. A chapter is devoted to each of the following subjects: active immunization and vaccine therapy, passive immunization and serum therapy, bacteriophage therapy, methods of diagnosis and treatment of allergy, blood transfusion therapy, nonspecific protein therapy, and chemotherapy.

In Part II infectious diseases are grouped under suitable chapters, and emphasis is placed upon the immunological aspects of disease and treatment suggested along these lines. Such information is of greatest value to the student of medicine who has a fundamental knowledge of these diseases, as no attempt is made to present a complete clinical picture or to suggest general therapeutic measures. In most instances the authors have adhered to their subject and they have written with unquestioned authority.

The authors should be commended for editing this mass of material and correlating these related subjects in such an agreeable text. There is no other book known to the reviewer which contains such a wealth of material pertaining to the therapy and practice of immunology. Each chapter has a comprehensive summary and, in addition, to each a list of valuable references is appended.

HOWARD B. CARROLL

¹CLINICAL IMMUNOLOGY, BIOTHERAPY AND CHEMOTHERAPY IN THE DIAGNOSIS, PREVENTION AND TREATMENT OF DISEASE. By John A. Kolmer, M.S., M.D., Dr. P.H., Sc.D., LL.D., LL.D., F.A.C.P. and Louis Tuft, M.D. Philadelphia and London: W. B. Saunders Co. 1941.

THE book entitled *Surgical Diseases of the Spinal Cord*² by Elsberg is far too comprehensive to admit a discussion of any one specific feature of its many contents. It is in a sense a source book, yet a book which reads as easily as a good novel, and throughout the book one finds morsels of digression, such as a note on the history of laminectomy in Chapter XX, which enliven and enrich the text for the less intent reader. This work is noteworthy for its solid and conservative honesty, its lack of overstatement, and its easy avoidance of dogmatism. This is true because it is Dr. Elsberg's forthright statement of up to date factual data molded around his profound knowledge of diseases of the spinal cord resulting from his own vast personal experience. To illustrate this point one need but mention his opinions concerning the possible difficulties in the operative exposure of a ruptured intervertebral disc. The author certainly labors under no illusions, and he advocates the application of only solid surgical principles.

The book is beautifully printed. It is well organized as to content, it is well indexed, and the many simple half-tone illustrations enhance its attractiveness. Chapter X, concerning the diagnosis of cord tumors by clinical features at different levels, typifies the uncomplicated, direct, and effective style of the author. While it is definitely Dr. Elsberg's book, the chapters on roentgenology and pathology of diseases of the cord by Drs. Dyke and Wolf are worthy of the prominent place which they are given in the book.

Many contemporary surgeons will agree that Dr. Elsberg represents in relation to disease of the spinal cord that which Dr. Cushing did in relation to intracranial disease. As Cushing's contributions have been as yet but little enlarged and improved upon, even so, in the opinion of this reviewer, the American literature contains no current book surpassing this one in genuine reliability for student and clinician alike.

JOHN MARTIN

TO surmount the difficulties of making clear to beginning medical students the anatomy and function of the nervous pathways is one of the chief goals of every teacher of neuroanatomy. The subject must be presented in a simple fashion if it is to be remembered, and in simplifying it much detail, and possibly some accuracy, must be lost. Rasmussen is perfectly conscious of the shortcomings of a

²SURGICAL DISEASES OF THE SPINAL CORD, MEMBRANES AND NERVE ROOTS, SYMPTOMS, DIAGNOSIS AND TREATMENT. By Charles A. Elsberg, M.D. With chapters by Cornelius Dyke, M.D. and Abner Wolf, M.D. New York: Paul B. Hoeber, Inc. 1941.

satisfactory results began to be reported. Review of the history of colostomy from the time it was first recorded by Aurellanus as having been performed for ileus by Prazagoras, 400 years before Christ, down to the modern type of colostomy would be tedious and time consuming. Suffice it to say that Littré in 1710, through the medium of a child who died of a congenital obstruction of the rectum conceived the idea of a permanent colostomy although it was not until 83 years later that Duret performed a left iliac colostomy for a similar lesion. Another French surgeon Amussat established the principle of colostomy for rectal cancer.

Ward, in 1865 probably was the first to advocate routine lumbar colostomy in all cases of rectal cancer showing that the gradual recognition of this maneuver as an integral part of the treatment was slow in developing due largely to the refusal of the medical profession to accept an artificial anus.

As time went on mortality figures remained high and long range cures continued to result in only a small group of cases. Finally with the development of anesthesia, aseptic surgery and a better understanding of the fundamental principles of surgery as applied in this field it came about that Miles developed the technique which today unquestionably gives sufferers from rectal cancer a better chance of longevity than any other. Because the trend in the treatment of rectal cancer has been toward the Miles operation it is not perhaps amiss to note here that this extremely radical procedure which most master surgeons today recognize as combining the basic fundamentals of surgical attack on cancer of the rectum, is the result of the work of many men.

Czerny in 1883 performed the first one stage perineoabdominal resection of the rectum. Finding it impossible to remove a carcinoma well up in the rectum by the perineal route as planned, he promptly and courageously opened the abdomen and completed the resection transperitoneally.

From this time until the announcement of Miles monumental contribution to the surgery of rectal cancer many procedures have been tried and many modifications of Miles technique have been instituted, and it is a

tribute to Miles, Czerny and others who developed this operation that the trend both in America and on the Continent is definitely in its favor when it is at all applicable with reasonable mortality. The acceptance of colostomy as a step in surgery for rectal cancer is rarely now disputed. It is true that there remain a few surgeons who debate this thesis and who insist on attempting to perform a type of operation which will save the magnificent sphincteric mechanism of nature. To them I would venture the suggestion that a careful scrutiny of the end-results of such procedures is definitely in order and, I hazard the opinion, that comparison of a group of patients operated by this method with a group of patients receiving the advantages of a radical operation which includes colostomy will establish the superiority of the latter maneuver. I would not be understood as wholly condemning sphincter saving operations for indubitably if the cancer has not metastasized but is still local and of a low grade such a procedure may occasionally be indulged in with satisfaction. However I know of no way of actually determining prior to resection whether or not malignant cells have escaped to other parts and organs of the body.

Although radical operative procedures which remove areas of gland bearing tissues in the neighborhood of the original growth are always highly desirable it should be noted that one may not apply a single operative procedure routinely. A surgeon who is capable of performing only one technical maneuver for rectal cancer is not sufficiently versatile to combat the many difficulties which this type of surgery develops. Unquestionably the operation of Mummery which consists of colostomy and posterior resection has a definite field of usefulness in the armamentarium of all surgeons. Moreover I believe an occasional local excision because of reasons other than local conditions may be justified even an occasional segmental resection with anastomosis can be defended. All of which indicates that there are at least two operations, Miles and Mummery's, by which most rectal cancers may be operated upon and that there are several less radical procedures which, if included in

the surgeon's repertoire, will extend the field of operability advantageously

Surgery of the colon proper, necessarily awaited full development until the Listerian era, which followed the discovery of anesthesia and permitted fearless invasion of the peritoneal cavity

In the beginning colostomy as a decompressive measure was about the only operation performed for cancer, but gradually hardy and persistent surgeons doggedly extended the horizon and began attempts at removal of malignant lesions with re-establishment of the gastrointestinal continuity

As far back as 1823, Reybard, successfully resected the sigmoid flexure for cancer and made a primary anastomosis in a young man 29 years of age Progress was slow thereafter, although Thiersch reported a resection of the colon for acute obstruction in 1843 Thirty-seven years later only 10 resections of the large bowel had been recorded and only 3 of these were successful During the nineties, however, more resections were performed successfully because of the development of the principle of exteriorization

The discovery that a mobile segment of bowel harboring a cancer could be brought outside the peritoneal cavity and having the abdominal wall snugly closed around it remain *in situ* for subsequent resection marked an enormous advance in colonic surgery This epoch making discovery decreased mortality figures hugely and gave great impetus to a field hitherto viewed with scant interest

Many names are associated with this type of operation, and heretofore I have thought that Bloch, of Copenhagen, deserved credit for the first account of it published in 1891 However, I am now indebted to Dr John H Gibbon, Jr, of Philadelphia, for some information which had escaped my attention

In a paper before the American Surgical Society in May, 1941, he credits Thomas Bryant as being the first surgeon to bring a loop of bowel containing a carcinoma outside the abdominal cavity and suture the wound around it Zachary Cope refers to Mr Bryant in his article entitled "Extra-abdominal Resection of the Colon"¹ The article by Mr

Bryant was published in *The Proceedings of the Royal Medical and Chirurgical Society* (London, 1882, 9 149), and *The British Medical Journal* (1882, 1 461)

Dr Gibbon also informs me that an American surgeon, J M Barton, of Philadelphia, published an article under the title "Cases of Abdominal Surgery, 13th Case, Resection at Ileocecal Valve for Epithelioma—Recovery" in the *Journal of the American Medical Association* (1888, 10 549), describing a procedure which embodied the exteriorization principle Subsequent to these resections, Bloch, in 1891, published a report of his type of resection

In 1892, Recluse, collaborating with Forgeue, published a description of 2 cases of exteriorization of the bowel without mentioning Bloch's name Paul, of Liverpool, 9 years later, published a modification of Bloch's method, by which he ligated the mesocolon, abutted the two limbs of bowel and decompressed the proximal loop with a glass tube In 1902, Mikulicz spoke of the procedure which he claimed to have performed first in 1886, and for some reason his name has been commonly attached to all exteriorization operations by surgeons in this country As a matter of fact, exteriorization represents the concepts of many surgeons, for a single isolated procedure only occasionally marks the discovery of a principle Even more rarely is the discovery of a principle the work of one man, for research and recorded experiences combine to establish truth and exteriorization may well be said to be an ensemble of principles marking a new era in colonic surgery

While mortality figures were enormously increased by the discovery of this principle, further progress was insured when the recognition of the principle of decompression prior to resection became universal

Present day knowledge of the physiology of obstruction easily explains why a sick, dehydrated, and desiccated patient with an imbalanced blood chemistry is such a high risk for any formidable procedure In consequence, it has come about that a period of preliminary decompression and rehabilitation has become a standardized practice in dealing with large bowel cancer Such a period has for a long time been part of the attack on ob-

Fig. The step in aseptic end-to-side anastomosis between the transverse colon and the terminal ileum. The anastomosis is made first as in a, and then division is made as to a one stage or two stage procedure. b, Shows mobilization of the right colon. This step may now be abandoned and the Miller Abbott tube utilized.

struction from gastroduodenal lesions, obstruction in the urinary tract, and other ailments which cause a profound physiological upset. Applied to lesions of the colon this principle has been no less emphatically advantageous and today it is an unwary surgeon who neglects this very necessary phase of the surgical attack.

When one is confronted with a combination of acute intestinal obstruction and cancer obviously disregard of the malignancy and attack on the acute intestinal obstruction is the proper sequence. How often this principle is modified or reversed in attack on the two ailments combined is an unforgettable error of judgment reflected in mortality statistics. Although cancer of the colon, particularly of the left colon in the vast majority of cases produces some type of intestinal obstruction, acute, subacute, or chronic, one may save in the acute variety always attempt medical decompression and with splendid chances of success. When the obstruction must be relieved surgically a cecostomy without exploration is the procedure of choice. This acute intestinal obstruction while usually due

to malignancy more than occasionally is the result of injudicious administration of opaque media by mouth a procedure to be entirely condemned as not only useless in the diagnosis of colonic lesions, but definitely dangerous in the presence of encircling neoplasms of the left colon.

Recently I have studied a group of cases of cancer of the colon and rectum which occurred in my private practice from February 1, 1933, to February 1, 1940. This group occurred in a series of 605 cases diagnosed as major lesions of the lower gastrointestinal tract. Of these major lesions 418 patients had cancer thus emphasizing the fact that practically 2 out of 3 of the major organic lesions of the colon and rectum are due to cancer. There were diagnosed 178 cases of cancer of the right and left colon 100 males and 78 females 170 were operated upon.

Table I shows the type of operation used for cancer of the colon, the resectability percentages, and the mortality figures. Operative technique and the question of type of operation must vary in the two halves of the colon because of differences in physiology pathology

TABLE I — ANALYSIS OF 170 CASES

and anatomy. As a general principle it is safe to assume that cancer of the right colon may be extirpated most satisfactorily by an ileocolostomy and resection in one or two stages.

Aseptic ileocolostomy between the terminal ileum and the middle of the transverse colon followed immediately or at a later stage by resection is the procedure of choice. My apostasy from an open type of anastomosis dates back 15 years or more when I developed an instrument for performing an aseptic anastomosis. In consequence, I am convinced of its utility in avoiding or at least reducing infection and certainly the simplicity of its performance recommends it to most surgeons. Nevertheless, in the modern management of colon cases and with the new chemotherapeutic agents available to sterilize the bowel, one may be quite justified in doing an open anastomosis if that is deemed preferable. An anastomosis between small and large bowel by whatever technique one chooses to do it is a relatively satisfactory procedure in so far as healing is concerned. The blood supply of the small bowel is copious, and that of the large bowel, while less free, is definitely adequate and usually of a constant pattern. Leakage at the anastomosis line is rare, and

Fig 2 Steps in obstructive resection plus complementary cecostomy. The addition of the cecostomy which required very little time has been a very valuable adjunct.

when resection is done by modern types of technique is almost a unique occurrence.

Exteriorization procedures in the right colon I definitely deprecate for three reasons: (1) infection around the growth secondary to obstruction and ulceration is likely to produce a lethal peritonitis from the efforts at mobilization, (2) few circumstances are more unpleasant to a convalescent patient than a deluge of liquid alvine discharges over the abdominal wall, (3) it takes little extra time to do some type of anastomosis, and a patient who will tolerate an exteriorization will usually tolerate an anastomosis and thereby avoid the unpleasantness of an artificial stoma.

The mortality in the right colon in this small series indicates that a two stage procedure often is advantageous. In reviewing the 5 deaths which occurred following single

stage operation it is not apparent that a different type of technique would have resulted differently. One individual was an elderly person of 70 in good condition and with a freely movable right colonic cancer. She died 14 days after operation. Another individual was a middle age woman of 50, with 2 cancers, one in the rectosigmoid and one in the right colon. An ileocolostomy skeletonizing the right colonic cancer as the first stage of a graded maneuver was performed. She died 3 weeks later of a subphrenic abscess. A third death in this series was due to leakage at the anastomosis.

Nevertheless I believe that there frequently are instances when it is desirable to use ileocolostomy and resection in one stage. More often I think it is desirable to do the operation in two stages. A question of ileostomy for decompression after primary anastomosis and resection seems to be satisfactorily solved at present by the utilization of the Miller Abbott tube. This tube does all that ileostomy can do and even more and avoids the unpleasantness of ileostomy as well as additional surgery.

In the left colon it will be noted that the choice of operation was obstructive resection and cecostomy. Usually the cecostomy is employed as a complement to the resection. Occasionally when a patient has an obstruction it is utilized prior to resection as a decompressive measure. In 50 patients operated upon by this maneuver there were 6 deaths a mortality of 10.1 per cent.

I have been reticent to accept the principle of primary anastomosis in lesions of the left and transverse colon because the mortality in my hands has been higher and I have not been sure that I could do as radical a resection and immediate anastomosis as by resection and delayed union. I have no quarrel with surgeons who choose resection and primary anastomosis and feel sure that it is frequently indicated when the preliminary efforts at decompression have been adequate. On the other hand, I think the crux of the situation lies in the radical removal of mesentery and adjacent gland bearing tissues.

In considering immediate restoration of intestinal continuity economic factors must not

be allowed to influence surgical judgment, nor must the desire to perform an artistic surgical operation be considered favorably against a radical even mutilating type of procedure in dealing with cancer.

In this group of cases the resectability figure was 73 per cent. To improve the horizon of operability and to remove every cancer of the colon possible one must accept border line cases. Surgical removal of 3 out of 4 cancers of the colon accepts this principle as a necessity. The mortality figures in the right colon of 17.5 per cent are too high. On two former occasions I have reported mortality figures of less than 15 per cent for a series of right colonic cancers removed surgically. The latter figures should be accomplished in the hands of most surgeons without difficulty and will be possible, I think, if the graded procedure is accepted in all cases of cancer which are not freely movable or are complicated by local or general conditions. Certainly in order to do a one stage procedure one must select only the most favorable cases for resection. The mortality figures in the left colon were 10.1 per cent, with a resectability figure of 72 per cent.

Table II is an epitome of the entire group.

Many maneuvers permit a wide range in selecting a type of operation for radical extirpation for cancer of the colon and rectum. The cardinal principle of wide removal of the growth and the tissues in immediate juxtaposition to it as well as lymph gland bearing tissues situated more distantly is of course the ideal sought. Any type of operative procedure which gives a high percentage of ultimate cures must take into consideration the lymphatic system's relationship to metastasis.

The brilliant works of David and Gilchrist, of Gabriel, Bussey and Dukes, and of Collier Kay and MacIntyre are monuments to industry for they show beyond peradventure that

Fig 3 The steps in a combined abdominoperineal resection of the rectum in one stage a, Shows mobilization of the growth after ligation of the blood supply is completed. The pelvic dissection is shown completed and the Cope DeMartel clamp applied b, Shows the bowel and growth dropped back into the pelvis, a new floor being formed and the single barrel colostomy made through a stab wound in the groin c, The beginning of the posterior dissection. The rectum is mobilized up to the peritoneal fold and is then removed by this posterior approach

the more glands one inspects the more metastases one finds. Coller and his associates found that 60.8 per cent of all resections of the colon showed glandular involvement if a large number of glands were studied. Isolating an average of 52 glands per specimen, it was found that 59.4 per cent nodes showed malignant involvement, and 41.4 per cent were without metastases. Here again they emphasized a paradox which has long been recognized, namely, that a higher percentage of cancers of the right colon show metastasis than do cancers of the left colon. Actually 62.5 per cent of the cancers of the right colon in their series showed metastasis in comparison with 60 per cent of those of the left colon. Despite these figures more individuals who undergo operations for cancer of the right colon survive at the end of a given period than do those undergoing operations for cancer of the left colon. An explanation of this fact is not forthcoming, but statistics are definite on it.

David and Gilchrist in 1938, had a similar experience in dealing with cancer of the rectum. They found that in 68 per cent of rectal

cancers glandular metastasis could be demonstrated by a careful examination of a large number of glands. This work is supported by statistics from St. Mark's Hospital in London and has been buttressed by all investigators who have taken the pains to make examinations of large numbers of glands. It established beyond any question proof that widespread resection of the mesentery is necessary, consequently, a most important decision in choosing an operation for cancer of the colon comes, first, between graded and single stage procedures, and second, between immediate anastomosis and delayed union. There are surgeons who glibly assert that colonic resection should always be done in one stage, or on the other hand, two stages. Obviously there is a middle ground which is predicated upon the ability of the patient to undergo formidable resection in one operation, and the question of whether or not his condition will be advantageously treated by multiple procedures. Local conditions such as fixation, infection, and obstruction, and general conditions, such as age, obesity and coexisting debilitating disease, decide the selection in the average

case. The final and ultimate decision will come only on exploration and individualization of cases at the operating table. Inevitably one must fit the operation to the patient and not the patient to the operation and such a program demands familiarity with many types of technical procedures.

There were 275 cases of cancer of the rectum 258 of which were operated upon 4 were treated by radium, and 13 refused operation or went elsewhere. In this group there were 175 males and 100 females.

In selecting an operation for cancer of the rectum, it is my confirmed opinion that there are few cases in which it is desirable to ignore the necessity of a colostomy as one of the steps of the operation. There are many reasons if one needs more evidence than the number of involved glands found in resected specimens why colostomy should be routinely employed. Certainly the burden of proof rests on those who would salvage the sphincteric mechanism to show that a comparable percentage of patients will be alive and free from disease in a given period of years. My own experience with the sphincter saving operations has been paralleled by that of many colleagues and may be summed up briefly in the statement that they usually are followed

by recurrence fistula formation or stricture. It must be an extremely small percentage of cases of rectal cancer of low grade which have not metastasized and which are located favorably for local excision and segmental resection. This group in comparison to the whole is relatively insignificant.

Table III indicates the distribution of the rectal cancer cases treated in this series during the designated period. It will be noted that 13 cases were not treated by me. Of the group of 275 three of these were sent to me by colleagues for consultation and subsequently were operated upon by these surgeons. A combined abdominoperitoneal resection of the rectum was successfully performed in each case. The 10 other patients went elsewhere for advice and treatment for various reasons. A few of these people refused operation because of my insistence upon colostomy as a part of the procedure. It has been my plan to hold fast to this principle. Occasionally patients do refuse.

Table IV shows the type of operation, mortality and resectability percentages as well as the applicability of the one stage operation in this series.

It will be noted that the trend in this series was definitely toward the one stage combined abdominoperitoneal resection of Miles. Over a period of 15 years, I have found myself changing from a graded procedure in treating cancer of the rectum to a single stage opera-

tion wherever it is feasible—the reverse of practice in treating cancer of the colon. The advantages and disadvantages of a one stage combined operation are well known. A consideration of end results leaves few arguments necessary to establish the desirability of this radical one stage operation, but if further arguments were needed, the splendid work of David and Gilchrist and our English colleagues should convince the most stubborn that radical resection of a large portion of the mesentery of the sigmoid is definitely essential.

My own operation is useful only occasionally. When it is noted that I have performed it only 7 times in 262 operations its utility in a very small field is definitely established. Mummery's operation, while less radical than Miles, is a very useful procedure and should be applied to the less sturdy risks and to those individuals who for one reason or another are unable to withstand a formidable one stage operation.

The resectability rate in this series was 74.8 per cent. Of 258 patients operated upon, 193 were subjected to resection of one kind or another. The applicability of the one stage resection to the whole group was 70.4 per cent.

This seems to indicate that with proper preliminary preparation one may apply the one stage combined abdominoperineal resection of the rectum not routinely, but at least with great frequency in any given series. The

mortality statistics show that the one stage procedure may be accomplished with a death rate comparable to that of other procedures. In 136 operations there were 9 deaths, a mortality of 6.6 per cent. This compares favorably with the group operated upon by the two stage procedure, 49 Mummery operations being performed with 4 deaths, a mortality of 8 per cent. The total mortality of the whole group was 8.5 per cent, with a resectability rate of 74.8 per cent.

Mortality statistics and curability figures are inextricably bound together and are influenced by many factors. Operability varies in the hands of different surgeons because of many circumstances peculiar to the surgeon and the case. Suffice it to say that it is a well recognized axiom that every effort should be made to extend operability curves which so vitally influence end-result percentages. Standardization of preoperative and postoperative measures as well as flexibility of the operative phase of the attack will no doubt still further reduce hospital casualties, morbidity figures and thereby enhance the satisfactory ultimate outcome. It is widely conceded that prognosis following successful radical extirpative measures for cancer of the lower gastrointestinal tract is satisfactory by present day standards. Nevertheless, the ultimate goal is far from reached and continued effort is essential to amplify efforts to combat successfully this modern scourge by surgical methods.

THE TREATMENT OF PATIENTS WITH SEVERE BURNS

HARVEY S. ALLEN, M.D., F.A.C.S. and SUMNER L. KOCH, M.D., F.A.C.S.,
Chicago, Illinois

THE surgical principles involved in the treatment of burns are often forgotten sometimes ignored in the constant effort to find new and improved methods of treatment. These principles can be expressed very simply by stating the objectives of treatment. They are:

1. To prevent and combat shock.
2. To convert the open contaminated wound into a clean wound.
3. To cover the open wound by the simplest possible dressing that (a) protects it from the constant danger of reinfection, (b) does not fix or destroy any part of the skin or subcutaneous tissue which remains viable when the patient is first seen, (c) provides for drainage of the serum that exudes from the burned surface until it is checked by pressure or the normal process of coagulation, (d) exerts a uniform moderate pressure over the burned area, and (e) can be easily removed if infection develops underneath the dressing or if the burn involves the whole thickness of the skin.
4. To keep the injured part at rest.
5. To secure healing in the minimum period of time and with minimum loss of function.

If these principles are sound they apply whatever the extent, the location or the severity of the burn and the effort to classify burns into first, second and third degree or to distinguish between the treatment of burns of the trunk and burns of the face and extremities may only divert attention from essential factors in the treatment.

So much controversy has arisen and so many conflicting ideas have been expressed concerning the local treatment of burns that we wish to postpone for the moment the discussion of the problem of shock and consider first the principles involved in the local care of the burned area.

CONVERSION OF THE OPEN CONTAMINATED WOUND INTO A CLEAN WOUND

This principle often completely ignored in discussions of burns is of primary importance. To cover a burned area with chemical or coagulating solutions without first using every effort to transform it into a clean wound seems to us an inexcusable disregard of fundamental surgical principles.

If the burned patient is still clothed, adherent and burned clothing is best soaked off in a tub of clean water maintained at a temperature of 100 degrees F. in a room reserved and equipped for the treatment of burned patients. The process is rendered almost painless by giving the patient an adequate dose of morphine immediately after admission. We have not used other analgesics or anesthetics even in children with very extensive burns. The room is kept at a temperature of 80 degrees F. and opening of the doors while treatment is in progress is avoided to prevent currents of air from blowing through the room.

With the burned area free from clothing and debris that can be removed by soaking and the surrounding uninvolved area cleansed with soap and water the patient is lifted upon a table covered with a sterile sheet and cleansing of the burned area begun.

To transform an extensive and contaminated raw surface into a surgically clean wound, and without adding further injury and bacterial contamination requires time, patience, gentleness, plenty of soap suds, and continuous irrigation with sterile water at a temperature of 100 degrees F. Obviously the surgeon, his assistants and the patient must be masked. The surgeon and his assistant wear sterile gowns and gloves. Every effort is made to carry out the same careful technique that one would carry out in performing an abdominal operation.

Grease or ointment which may have been applied over the burned surface can usually

From the Division of Surgery, Northwestern University Medical School, and the Children's Hospital Ward of the Cook County Hospital.

be washed off with soap suds. If not, a fat solvent such as benzene is used.¹ The actual cleansing is accomplished with large "wash cloths" of soft sterile cotton, plain white soap, and sterile water. Green soap, gauze, scrubbing brushes are avoided as causing unnecessary trauma. Blisters are opened with sterile scissors, shreds of epithelium and skin that can be lifted away with forceps are removed. No excision that might cause bleeding is made.

DRESSING OF THE WOUND

With the injured surface cleansed as completely as possible it is smoothly covered with a few layers of fine meshed gauze impregnated with petrolatum. Such gauze is easily prepared in strips 3 inches wide and 12 inches long and sterilized in a porcelain basin provided with a well fitting cover. This dressing does not adhere to the raw surface as does a

¹Johnston of Detroit has found lard an excellent medium for removing oil and grease. Any lard remaining on the skin can be washed away with soap and water.

coagulant crust, it does not fix tissue, and it still permits drainage of serum and exudate into the dressings outside it.

Over the petrolatum gauze are laid a half dozen layers of flat dry sterile gauze, over this a mass of gauze fluff and over the fluff mechanics' waste or sea sponges so as to provide under the retaining bandage a resilient covering that produces an even pressure over the injured extremity or the burned surface but does not cause constriction.

The dressing and compressing sponges are held in place preferably with an elastic bandage such as stockinet. This is particularly advantageous if the burn involves the trunk.

The advantages of pressure over an injured surface have been well stated by Blair:

"The application of most any dressing produces pressure, but he who employs this pressure in a selective, purposeful manner will get bigger returns than he who applies it incidentally or even as a matter of routine.

Fig. 2. Extensive burn with loss of partial thickness of skin. a, On admission. b, after soap and water cleansing and excision of devitalized tissue. c, on discharge from hospital, 4 days after admission. Burned area healed.

There are chiefly four basic things to be gained by the use of properly applied mechanical pressure to wounds:

The elimination of dead spaces.

The control of oozing.

The limitation of venous and lymph stasis.

Limitation of the amount of plastic material that pours into the wound.

The elimination of dead spaces into which constant oozing can take place and the limitation of exudation from the surface of a wound and into the subcutaneous tissues are

important objectives in wound treatment which are too often completely ignored. The surgeon who sees blood escaping rapidly from an open wound instinctively applies pressure to stop the bleeding and conserve vital body fluid. By some curious inconsistency if we cannot see it we may ignore the subcutaneous bleeding that goes on just as definitely after the subcutaneous rupture of blood vessels and continues until it is arrested either by coagulation or by actual compression of the injured blood vessels by the tensed body tissues.

If this subcutaneous bleeding is the "white hemorrhage" that goes on in tissues injured by a flame or scalding water, it needs to be arrested just as promptly as if the blood were escaping from a torn blood vessel. It can be arrested and body fluid saved by the application of pressure over the injured area.

REST FOR THE INJURED PART

The importance of rest for injured tissues has been emphasized with increasing frequency since war and its accompanying disasters have again focused attention on the treatment of severe and multiple compound injuries. The magic of the plaster cast has proved to be due in large part to the uninterrupted and enforced rest of injured tissues which was so important a principle in the creed of Hugh Owen Thomas. It is as important and essential a part in the treatment of severe burns and of other soft tissue injuries as it is in the care of compound fractures.

Fig. 3. Extensive burn with limited areas of sole thickness destruction. a, On admission. b, after removal of primary dressing, 6 days later. c, on discharge from hospital, 60 days after admission. Healing of areas of sole thickness loss could have been hastened by early skin grafting.

Healing of areas of sole thickness loss could have been hastened by early skin grafting.

dressing, c, 13 days later, d, appearance 33 days after admission, shortly before skin grafts were applied

HEALING OF THE BURNED SURFACE

The mechanism of healing after partial or complete destruction of covering skin is sometimes forgotten in the face of the constant emphasis on new methods of treatment which are stressed so strongly by lay writers in *Hygeia*, the *Reader's Digest*, and other nonscientific journals

If there has been loss of only a partial thickness of the skin, in other words, if there still remain epithelial elements—sweat glands and hair follicles—of the deeper portion of the corium rapid re-formation of the covering epithelium takes place (1) if the remaining epithelial elements are not fixed and rendered inert by a coagulating agent, (2) if no infec-

Fig 5 Severe burn with extensive area of whole thickness loss a, After application of pressure dressing and immobilization with splints b after removal of primary dressing, 12 days later, c, appearance 23 days after ad

mission, d appearance on discharge, 53 days after admission, e, appearance on discharge showing some of grafted areas and on dorsum of trunk, healing of areas from which grafts were taken

Fig. 6a.

tion supervenes. (3) If regenerating epithelium is not torn away and destroyed by careless or frequent or too early removal of the protective dressing.

In cases with loss of partial thickness complete regeneration of epithelium takes place in 10, 12, or 14 days and healing of the burned area should be complete when the primary dressing is first removed at the end of 12 or 14 days.

If the burn has resulted in a whole thickness loss of skin no dressing can bring about regeneration of epithelium. Reformation of covering skin can come only by ingrowth from the periphery or as a result of skin grafting. To await spontaneous healing if the denuded surface is more than 2 or 3 square inches in area is only to delay recovery. Moreover, to wait indefinitely for spontaneous separation of a coagulant crust or of the

Fig. 6b.

Fig. 6. Severe burn involving 44 per cent of body surface. This patient received 8 plasma transfusions of 500 cc. each during the first week, and blood transfusions of 500 cc. each during the second week. a, Patient on fifth day under typhoid tent, his burned areas covered with compression dressing. Plasma being given through vein in leg; b, c, after removal of primary dressing on fifteenth day; d, just before application of skin grafts on thirty-sixth day after admission. As surfaces are being dressed, his moist fine-meshed gauze, over which pressure dressing is maintained 7-12 days after admission, 6 days after application of skin grafts; e, 5 days later 57 days after admission.

charred adherent tissue that represents the destroyed surface covering causes serious and unnecessary delay in healing. Cleanly surgical care after the removal of the primary dressing subsequent dressings at regular intervals of 24 or 48 hours with removal of any adherent tissue that can be cut away without causing pain or bleeding and the use of dressings saturated with Dakin's solution all help to hasten separation of the covering tissue destroyed by the original injury and help to counteract the infection that tends to develop in the presence of an open wound and necrotic tissue.

During this stage of treatment our primary objective is to secure a covering of healthy granulations as soon as possible so that skin grafts can be laid over the raw surface. Here again a number of details in treatment are of great importance. They are (1) cleanly

tion supervenes. (3) If regenerating epithelium is not torn away and destroyed by careless or frequent or too early removal of the protective dressing.

In cases with loss of partial thickness complete regeneration of epithelium takes place in 10, 12 or 14 days and healing of the burned area should be complete when the primary dressing is first removed at the end of 12 or 14 days.

If the burn has resulted in a whole thickness loss of skin no dressing can bring about regeneration of epithelium. Reformation of covering skin can come only by ingrowth from the periphery or as a result of skin grafting. To await spontaneous healing if the denuded surface is more than 2 or 3 square inches in area is only to delay recovery. Moreover to wait indefinitely for spontaneous separation of a coagulant crust or of the

Fig. 6b.

Fig. 6. Severe burn involving 44 per cent of body surface. This patient received 8 plasma transfusions of 500 c. each during the first week and blood transfusions of 500 c. each during the second week. Patient on fifth day under oxygen tent. His burned areas covered with compression dressing. Plasma being given through vein in leg. b, c, after removal of primary dressing on sixteenth day d, just before application of skin grafts on thirty-sixth day after admission. raw surfaces are being dressed with moist fine-meshed gauze over which pressure dressing is maintained 142 days after admission, 6 days after application of skin grafts g, 5 days later 57 days after admission.

charred adherent tissue that represents the destroyed surface covering causes serious and unnecessary delay in healing. Cleanly surgical care after the removal of the primary dressing subsequent dressings at regular intervals of 24 or 48 hours with removal of any adherent tissue that can be cut away without causing pain or bleeding and the use of dressings saturated with Dakin's solution, all help to hasten separation of the covering tissue destroyed by the original injury and help to counteract the infection that tends to develop in the presence of an open wound and necrotic tissue.

During this stage of treatment our primary objective is to secure a covering of healthy granulations as soon as possible so that skin grafts can be laid over the raw surface. Here again a number of details in treatment are of great importance. They are (1) cleanly

Fig. 6c.

what the effect of that loss is on blood volume, blood concentration and blood pressure (1, 3, 8) little emphasis has been laid on the importance of arresting the "white hemorrhage" and preventing the shock producing loss of body fluid

It is to prevent this loss that we have emphasized the importance of pressure applied over the entire burned area or around the affected limb as soon as the open contaminated wound has been converted into a clean wound, and, after the application of the pressure dressing, as complete immobilization of the injured area as it is possible to secure

In spite of every effort to prevent loss of body fluids in patients seen late and in those with extensive burns the loss may be sufficiently great to lead to shock and collapse. In such cases prompt replacement constitutes a life saving procedure. Many workers have made helpful contributions to the solution of this problem, and without discussing in detail the studies of Harkins, McClure, and their associates, of Scudder, of Trusler and his associates, of Rhoads, Wolff and Lee we would simply say that we agree with the statement that "plasma transfusion is the most logical type of replacement therapy and that it has given the best clinical results" (14)

To estimate the extent of fluid loss and the need for replacement during the early and critical stage of treatment the hematocrit reading is an easily obtained and dependable guide. The determination made immediately after admission of a patient with a severe burn can be used as a standard against which to check subsequent readings. Significant changes in blood volume may not be reflected immediately in the clinical symptoms, but a slow steady increase in the hematocrit level indicates that hemoconcentration is taking place and that the loss into the tissues should be compensated for by administration of plasma.

In cases seen late thirst, restlessness, and a rapid pulse rate are constant and important signs of fluid loss and indicate the need for prompt administration of plasma in adequate amounts. To give transfusions of whole blood in such cases, as has been frequently pointed out, may add to hemoglobin con-

centration, and to give water alone in large amounts, as Trusler and his associates have emphasized, may lead to "water intoxication"

The administration of oxygen, particularly in patients with burns of the face and chest, is a valuable adjunct to treatment. In patients with burns of the face and chest the inhalation of irritating gases and the resulting congestion and inflammation of the upper respiratory passages may add another handicap and contribute to the development of anoxemia. We have given oxygen as part of the routine treatment in patients with burns about the face and chest and have thought it to be of definite benefit.

Toxemia The formation of a burn toxin as the result of destruction of the superficial body tissues has been considered by many workers to be the determining factor in causing death in patients with severe burns. Wilson and Stewart and their associates at the Edinburgh Royal Infirmary, particularly, have stressed the frequency with which the picture of acute toxemia develops in from 6 to 50 hours after injury in those cases which go on to a fatal termination. They have emphasized the frequent occurrence of jaundice in these cases and the degeneration and necrosis of the liver seen after death. They have injected into healthy animals "edema fluid" from the subcutaneous tissues of burned animals with resulting fatal toxemia and pathological changes similar to those seen after death from severe burns.

We have no definite evidence either to support or refute the theory that a burn toxin results from destruction of superficial body tissues. The few cases we have observed after death have shown acute degenerative changes in all the parenchymatous organs. The pathological change has not been limited to the liver, nor have we seen the extensive liver changes described by Wilson and his associates.

We would like to point out again that the fatal cases cited by Wilson all received a general anesthetic shortly after the injury. To give ether to a patient with impending shock, particularly a child, seems to us a dangerous procedure, which may well predispose to intensification of shock, the hemocon-

Fig. 7. Extensive burned area coagulated with tannic acid applied by members of Fire Department. Severe infection developed under the crusts, and to remove crusts and necrotic tissue control infection, and secure healing required 6 months' time. a, On admission; b, appearance 4 days after application of skin grafts over large raw surfaces.

congestion that results from the temporary loss of the normal outer retaining wall against which the venous channels can be compressed.

As soon as a covering of healthy granulations is secured and the patient a condition permits, the raw surface should be covered as completely as possible with grafts of intermediate thickness. The sooner this can be accomplished the sooner will recovery be achieved and the less will be the disability and the contracture that steadily increase as long as a raw surface remains unhealed.

COMPLICATIONS FOLLOWING BURNS

The complications resulting from burns have aroused almost as much controversy as the question of local treatment. Many papers have been written on the problem of burn shock, toxemia and infection. Without wishing to oversimplify the problem we would simply state our belief that the initial shock is due to pain, fright, and overexertion and is often followed very quickly by secondary shock resulting from loss and shifting of body fluids; that unequivocal evidence has not yet been produced to show that acute toxemia results from the effect of a circulating toxin formed by autolysis of the burned tissue (Wilson); thirdly, that in the cases under our observation infection developing after a burn has been a feared and serious complication only in patients who were admitted to the

hospital 24 or 48 hours after the injury and whose primary treatment often consisted of the application of ointments of some type.

Shock. Most observers are agreed that primary shock can be severe and is not necessarily dependent on the extent of the burned area. Fright, frantic efforts to avoid injury or to escape from a burning building or from underneath crushing wreckage, sudden and powerful muscular exertion far beyond that normally employed—all can lead to sudden collapse that may appear unexplainable to the observer who sees only an injury of limited extent and severity. For this primary shock morphine is the most effective aid, and in our judgment the morphine need not be supplemented by a general anesthetic. It is of significance to us that the workers who have stressed the theory that a burn toxin is responsible for early death in fatal cases have persistently used anesthetics, including ether during the initial process of cleansing and tanning.

Many observers are agreed that secondary shock is due to loss of body fluid from the burned surface and still more important loss of fluid into the subcutaneous tissues. The latter is comparable to the bleeding that occurs into a crushed limb and although a great deal of effort has been expended to determine how rapidly the loss can take place, how large a percentage of the available body fluid can escape into the subcutaneous tissues, and

MORTALITY RECORD

	Method of treatment	No of cases	No of deaths	Percentage of mortality
1934-1936	Tannic acid	395	39	10
1937 (10 mos)	Tannic acid and silver nitrate (Hedin)	82	6	7.3
1939	Nonadherent dressing with pressure	137	8	5.8
1940		164	6	3.65
1941		185	5	2.7

If we can accomplish these objectives and others of equal importance by a simpler method than the application of tannic acid it means that we are making progress, and not clinging to an outmoded method—even though that method represented a definite advance fifteen years ago.

Under a régime such as that outlined above the results obtained in patients with severe burns in the Children's Surgical Ward of the Cook County Hospital have steadily improved. The accompanying table indicates the mortality record only.

As evidence of the severity of the injuries treated is the fact that of the 19 patients who died as a result of burns in the years 1939-1941, 10 died during the first 24 hours, and 3 during the second 24 hours after admission. Of 6 patients who died later, 3 were transferred from other hospitals, and in these cases the control of infection was an outstanding problem.

In addition to the cases of severe burns were many patients who were not admitted to the hospital or remained in the hospital less than 24 hours. These patients were treated by the same method, and in this group of cases there were no deaths.

Other workers have obtained equally satisfactory results with the method of treatment described. Siler of Cincinnati showed a colored motion picture at Boston in November, 1941, which graphically illustrated the essential details of treatment—wound cleansing, the application of a nonadherent dressing, compression and continued rest, and which showed the excellent results obtained by the application of these principles to the treatment of burns at the Cincinnati General Hospital.

Space does not permit extended discussion of the improved results that have followed

as far as time expended for nursing care, time required to prepare the raw surfaces for skin grafting, and duration of hospital stay are concerned. Nor can one dismiss the subject without emphasizing the constant co-operation on the part of the nursing and resident staff that is essential for good results. The entire nursing staff of the Children's Surgical Ward, the surgical residents,—Lt Clayton Brock now at Camp Shelby, Mississippi, Lt William Requarth, now with Submarine Squadron 4 at Pearl Harbor, and Drs Frederick Leese and W A Yemm of the present resident staff—have all given their constant, whole hearted co-operation to secure the best possible treatment for these seriously injured patients. Without their help it would have been quite impossible to secure the results that have been obtained.

A final word should be added concerning the management of burned patients under emergency conditions. Some of you will say that one cannot possibly carry out the treatment suggested under war conditions or when numerous casualties confront the surgeon.

It is our belief that under such conditions, as well as with patients who come to the surgeon late, or who have received prolonged "first aid" treatment under unfavorable conditions, the sulfonamides can be used to great advantage. An ointment containing a sulfonamide, for example, such as has been successfully used by Allen, Owens, and Dragstedt, can be rapidly spread over the burned surface, covered with a sterile dressing and a compression bandage. The ointment should be applied with a clean spatula and by a masked orderly or nurse. In other words, even under emergency conditions there can be no excuse for not protecting the open wound from contamination with organisms from uncovered mouths and noses.

Patients so treated could be transported to field hospital or casualty clearing station where the treatment outlined in the preceding pages would be carried out. It might well be emphasized again that after cleansing is completed and a pressure dressing applied the patient is left undisturbed for from 10 to 14 days unless some complication arises. If transportation of the patient becomes neces-

centration stressed by Underhill, and the resulting anoxemia which has been stressed by McClure and others as a grave threat to the injured patient.

Infection For years past infection has hung over the head of the burned patient like a veritable sword of Damocles, threatening life and destroying tissue. No one who has had the responsibility of caring for severely burned patients can erase from his mind the picture of the anxious feverish child with an extensive severely infected raw surface anticipating with constant dread the daily ordeal of change of dressings.

The doctor who asked "Is it true that every patient with an extensive burn eventually develops a blood stream infection?" was simply voicing what has been more or less generally accepted as the inevitable accompaniment of an extensive burn.

To some the statement that infection is the result of careless or unthinking treatment may sound as heretical as Holmes' indictment of the medical profession concerning the responsibility for puerperal infection. Holmes did not know what has since been demonstrated that of almost equal importance with infected hands and contaminated clothing as sources of contagion are the mouth and nose of carriers of virulent streptococci and staphylococci. Here a admirable studies have brought laboratory explanation of the often repeated clinical observation that in most instances the greatest menace to the patient is not the object that causes the open wound not infection that may have been present on the patient's clothing or on his skin but infection that comes from the open mouth and uncovered nose of excited and voluble bystanders, of enthusiastic first aid workers, too often of the doctor and nurse who are caring for the patient without masking themselves and with out making certain that their hands and their surgical instruments are free from pathogenic bacteria.

When we recall the fact so forcefully stressed in a recent editorial by Mason that a burn is in all its essentials a large open wound and when we consider the elaborate precautions every surgeon constantly takes in the operating room to prevent infection of even a small

open wound we cannot but wonder at the inconsistency of failing to take the same precautions in preventing infection of a wound far more extensive than the largest wounds which the surgeon ordinarily sees in the operating room.

If one were to ask the junior medical student why the surgeon and everyone else in the operating room is carefully capped and masked he would have a ready answer. If we were to ask him why in the initial treatment of a patient with an extensive burn, or during the change of dressings in the days following injury such precautions are seldom taken what would he say?

To express it as concisely as possible it is our belief (1) that the most important source of infection of a burned surface is from the open mouth and uncovered nose of individuals working over the injured patient (2) that infection can be prevented in almost every case if the patient is seen promptly after injury and if he has not received extensive or prolonged "first aid" treatment (3) that the simplest and safest method of converting an open contaminated wound into a clean wound is by gentle, thorough cleansing with plain white soap and sterile water applied with gloved hands under eyes that are alert and mouth and nose that are carefully masked and (4) that it is neither logical or wise to substitute for a safe and tested method an elaborate time consuming procedure which involves the use of powerful chemicals concerning whose possibilities for harm we are still in doubt.

To say that the application of a coagulant over a burned surface is not the ideal or most desirable type of dressing in no way detracts from Davidson's splendid contribution to the problem of burn treatment. Davidson taught us two important facts that if a burned surface is covered promptly with an occlusive dressing the constant danger of infection of the large open wound is eliminated and secondly that the prompt application of a dressing which checks the constant loss of serum from the burned surface diminishes the loss of vital blood plasma.

¹Cases of self-induced poisoning and fatality resulting from the application of ichthammum to the face have been reported by Pickrell, have been reported.

INVERT SUGAR AS A SUBSTITUTE FOR GLUCOSE IN INTRAVENOUS THERAPY

S E KERR, Ph D, Newark, Delaware, and R J PAULY, Ph D, Beirut, Republic of Lebanon

INABILITY to secure glucose because of blockade and interruption of commerce by the war resulted in the trial of invert sugar for intravenous therapy, with satisfactory results. The following report on the method of preparation of invert sugar solutions from ordinary cane sugar and the results observed will be of especial interest wherever hospitals are isolated from their usual sources of supply.

During the last world war (1914-1918) Mayer and Guerbet used invert sugar prepared from sucrose for intravenous injections, because of difficulty in obtaining pure glucose, which at that time was frequently contaminated with lead and arsenic. They stated that the physiological and therapeutic actions of the invert sugar preparation were identical with those of glucose. Even though glucose of satisfactory quality was available soon after the war, the use of invert sugar rather than glucose continued in Germany at least up to 1930 (9). Invert sugar solutions for intravenous use were placed on the market in Germany under the proprietary name of "calorose" (10, 12), and methods for making non-proprietary substitutes for "calorose" were published by Danish pharmacists in 1930 (7). Cousin and Fagon in 1937, finding difficulty in securing pure glucose in the French colonies, turned to the use of invert sugar, using a modified form of the method of Mayer and Guerbet. In the American literature we have found no references to the use of invert sugar for therapeutic purposes.

The earlier methods recommended for the preparation of invert sugar solutions for parenteral use depended upon the hydrolysis of sucrose with phosphoric acid (3) with subsequent removal of phosphate as the calcium salt by interaction with calcium carbonate, or

with tartaric (12) or hydrochloric acid (7), the acids being subsequently neutralized with sodium carbonate. Hansen, Shou, and Tonnensen used small amounts of hydrochloric acid as the hydrolytic agent with no attempt at neutralization, producing solutions with a pH of about 3.

We have adopted a method recommended for the preparation of invert sugar solutions for use in the so called Boeseken titration (1). In this procedure a hot concentrated solution of sucrose is hydrolyzed rapidly with hydrochloric acid, which is then exactly neutralized with an equivalent amount of sodium hydroxide. The resulting solution diluted to a concentration of 5 per cent (calculated as hexose) is a clear, colorless liquid with a pH between 4.5 and 6.0, containing not more than 0.01 per cent of sodium chloride and 0.05 per cent of unhydrolyzed sucrose.

REAGENTS

Freshly distilled water (not over 12 hours old) should be used in the preparation of all reagents, as well as for solution of the invert sugar. It is well known that reactions following intravenous injections of saline or glucose are most frequently due to the use of distilled water in which "pyrogenic" bacteria have grown.

Hydrochloric acid Prepare a solution approximately normal in strength by a 1 to 10 dilution of concentrated (38 per cent) hydrochloric acid.

Sodium hydroxide It is essential that this be of exactly the same normality as the hydrochloric acid. Adjust the concentration of a 5 per cent solution until 25 cubic centimeters of the hydrochloric acid solution are exactly neutralized by the same volume of the sodium hydroxide solution. Keep in a paraffined bottle provided with a siphon and a soda-lime tube to prevent contamination with silica and carbon dioxide.

From the Biochemical Research Foundation, Newark, Delaware and the Departments of Biological Chemistry and of Pharmacology, American University of Beirut, Beirut, Republic of Lebanon.

sary it can be accomplished with minimum difficulty and without change or interruption of treatment. In other words, the simplicity of both the initial treatment and the post operative care should commend such a method if it is based on sound surgical principles.

*Results expressed in milligrams of sugar per 100 cubic centimeters of blood.

†Number of minutes after beginning the infusion

sugar was at this time in most cases considerably below the fasting level—a phenomenon also observed when only glucose is injected

The small amount of unhydrolyzed sucrose in the invert sugar solutions is promptly excreted in the urine. Excretion of reducing sugar varies between 0.6 and 1.1 grams during infusion

ADVANTAGES OF LEVULOSE

Since invert sugar is half glucose and half levulose, any question regarding justification for its use must involve the intermediary metabolism of the levulose fraction. The review by Deuel as well as other literature supplies ample evidence that levulose is readily converted to glucose and glycogen in the body. It is easily oxidized and causes a prompt rise in the respiratory quotient and in heat production. There is considerable evidence which suggests that levulose is more readily utilized in diabetes mellitus than glucose.

SUMMARY AND CONCLUSIONS

No unfavorable reactions were observed in 2,349 cases following intravenous injection of

invert sugar prepared by acid hydrolysis of commercial sucrose. The levulose fraction disappears rapidly from the blood stream, 18 milligrams per 100 cubic centimeters being the highest value observed at the end of an infusion. The results confirm the experience of others that when glucose is not available invert sugar is a satisfactory substitute for intravenous therapy.

Indicator For adjustment of hydrogen ion concentration a convenient indicator is made by mixing equal parts of methyl orange (0.1 per cent in 50 per cent alcohol) and brom-cresol-purple (0.04 per cent in water). This indicator when used in the proportion of 4 drops per 5 cubic centimeters of solution, gives a yellow color between pH 4.4 and 5.8 (a range suitable for intravenous injection). Below pH 4.4 the indicator gives a reddish color and above 7.0 a purplish color.

Hydrogen-ion concentration standards Although the hydrogen ion concentration may be adjusted to within the proper range by merely observing the color given by the indicator as herein noted, it is advantageous to have known standards for reference. Nine standards between pH 4.0 and 7.2 with intervals of 0.4 are sufficient. Directions for the preparation of these may be found in any biochemical manual (e.g. Cole). Measure 5 cubic centimeters of each standard into test tubes and add to each 4 drops of the indicator.

METHOD OF PREPARATION OF INVERT SUGAR SOLUTION

Twenty liters of sterile invert sugar solution may be prepared by the following procedure. Dissolve 960 grams of sucrose (commercial granulated table sugar) in 300 cubic centimeters of freshly distilled water in a 2 liter Erlenmeyer flask with the aid of heat and with continuous rotation of the flask to avoid caramelization then bring to the boiling point and boil for a minute or two until clear. With a pipette add exactly 25 cubic centimeters of normal hydrochloric acid and mix the contents of the flask by rotation for 1 minute. Immediately neutralize while mixing, by adding 300 cubic centimeters of water containing exactly 25 cubic centimeters of the sodium hydroxide solution. The solution should have no more than a light yellow color. The volume is about 1500 cubic centimeters and contains the correct amount of invert sugar to make 20 liters of 5 per cent solution (glucose equivalent).

The stock solution is filtered while still warm through four thicknesses of muslin and then through one thickness of filter paper.

Adjustment of hydrogen-ion concentration Dilute 3 cubic centimeters of the concentrated preparation to 40 cubic centimeters and mix. To 5 cubic centimeters of this diluted solution add 4 drops of the indicator and compare with the pH standards. If the pH is not within the range 4 to 6.8 (a yellow color indicates 4.4-5.8) titrate 15 cubic centimeters of the concentrated sugar solution with 0.01 normal sodium hydroxide (or hydrochloric acid if it is too alkaline) using 12 drops of indicator and end the titration at a pH between 4 and 5. To the main solution (1500 cubic centimeters) add a quantity of normal sodium hydroxide (or hydrochloric acid) equal to this titration and mix. Again dilute 3 cubic centimeters to 40 and test the pH.

The stock solution is finally diluted to 20 liters with freshly distilled water within 48 hours, measured into flasks or ampuls and sterilized by autoclaving at 120 degrees C. for 30 minutes. Each flask is inspected for fiber particles before autoclaving and refiltered if necessary.

RESULTS

In a period of 5 months when glucose was not available (November 21, 1940 to April 18, 1941) 2,349 flasks of invert sugar were used for parenteral therapy in the hospitals of the American University of Beirut. Not a single reaction was observed. Previous to this period (November 1, 1939 to October 31, 1940) three reactions occurred in the treatment of 6,180 cases with glucose solutions.

Determinations of total reducing sugar and of levulose in blood were made during and after intravenous injections of invert sugar in normal subjects. The method of Herbert was used for levulose, and that of Shaffer and Somogyi for total reducing sugar both determinations being carried out on a zinc hydroxide filtrate of the same blood specimen. The results, presented in Table I, show that the rise of blood levulose is much less than that of glucose the maximum value observed for levulose being 18 milligrams per 100 cubic centimeters at the termination of an infusion of 500 cubic centimeters of 10 per cent invert sugar. Half an hour after the end of the infusion, blood levulose varied from 5 to 9 milligrams per 100 cubic centimeters while total reducing

TABLE I — CURE RATES REPORTED FOR CANCER OF THE OVARY

	Total cases	Per cent cure
Schaefer	74	16.2
Stuebler and Brandess	122	24.5
Schleyer	126	9.5
Wintz	87	17.2
Norris and Murphv	93	53.8

Schroeder	56	32.1
Heyman	134	32.1
Lynch	62	35.5
Meigs	147	16.0
Pemberton	114	32.0
Walter Bachman and Harris	63 (No x ray) 61 (x ray)	6.3 29.0

than the adenocarcinomas, they nevertheless do frequently metastasize and cause the patient's death. These tumors should, therefore, be included in any series of cases of cancer of the ovary although tables should be so constructed that the part they play in the final figure for the whole series is apparent.

Adenocarcinomas of the ovary In the largest group, the papillary serous and pseudomucinous adenocarcinomas, 88 in number, there was a 5 year cure rate of 15.9 per cent. The cure rate among the 25 pseudomucinous tumors was 5 or 20 per cent, among the 63 serous adenocarcinomas, 9 or 14.3 per cent.

Granulosa cell tumors Of the 16 cases of granulosa cell tumors, 11.6 per cent of the

TABLE II — RESULTS IN RELATION TO EXTENT OF DISEASE

	Total cases	Per cent frequency	Per cent cured
Complete surgical removal	44	31.0	45.5
Partial removal	50	36.2	4.0
Exploration only	29	21.0	0.0
Recurrent cancer	15	10.0	0.0
Total	138	100.0	15.2

series, there were 5 definite 5 year cures and 7 cases in which the patient died or in which metastasis was present when the patient was last observed. The exclusion of the granulosa cell tumors from the entire series would lower the 5 year cure rate to 13.9 per cent, an insignificant change.

Other special tumors The dysgerminoma is represented in this series by 2 patients, both of whom died of their disease shortly after treatment. There were 2 patients with squamous cancer developing in a dermoid cyst, both of whom also died within a few months of their operation. Four cases classified as mesonephroma (Schiller) resulted in 1 cure and 3 deaths from recurrence.

Melastatic tumors There were 4 ovarian carcinomas with endometrial cancer in which there was a doubt as to the primary site of the tumor. In this group there was one 5 year cure. In another patient classified with the granulosa cell tumors, there was an independent primary cancer of the endometrium.

In 12 cases originally classed as cancer of the ovary, histological review suggested that the tumor might have originated in the stomach or large intestine. All of these patients

TABLE III — FREQUENCY AND RESULTS IN INDIVIDUAL TYPES

	Cases	Frequency	Cures	Per cent cured
Papillary serous adenocarcinoma	63	45.6	9	14.3
Pseudomucinous adenocarcinoma	25	18.1	5	20.0
Granulosa cell tumor	16	11.6	5	31.3

FACTORS INFLUENCING THE END RESULTS IN CARCINOMA OF THE OVARY

Report of a Series of 138 Patients Treated from 1910 to 1935

HOWARD C. TAYLOR, Jr. M.D. F.A.C.S., and ARTHUR V. GREELEY M.D. F.A.C.S.,
New York, New York

REPORTS on the results of the treatment of ovarian cancer have exhibited a range from below 10 to over 50 per cent of 3 to 5 year cures (Table I). This wide variation is evidently the result of other factors beside the relative merits of therapy as applied by the reporting clinics and must almost certainly be ascribed to different methods of classification or the statistical handling of the case material.

The calculation of any 5 year cure rate is carried out principally to make possible the selection of the best of several methods of therapy or to demonstrate the need of some special procedure, such as postoperative radiation. Statistics on malignant ovarian tumors have failed in this purpose because of the heterogeneous character of the group and the differences of opinion as to how it should be reported.

In the present article this problem will be examined in the light of a series of patients treated at the Roosevelt Hospital. At the same time the end results for these cases will be presented and the effects of radiation therapy reported.

For this work 198 cases of ovarian tumor have been reviewed, including 138 cancers of the ovary and 60 papillary cystadenomas. The series includes all cases belonging to these categories, the patients being admitted to the gynecologic service from 1910 to 1935.

The "absolute" 5 year cure rate among the 138 malignant cases has been placed at 15.9 per cent, when all cases are considered and the lost cases are counted as dead. This figure is approximately that recently reported by Meigs (6) in his review of cases at the Massachusetts General Hospital, but is much lower than the recent figures of Pemberton or of Walter et al.

The principal factors which may vary the actual end-results, as well as the figures as reported, will now be considered. These are four in number: the gross extent of the disease, the histological type of tumor, the histological grade of the tumor, and the use of radiation therapy.

GROSS EXTENT OF DISEASE (TABLE II)

It is well recognized that the gross extent of the ovarian carcinoma at the time the operation is undertaken is the most important single consideration in prognosis. If one defines an operable case as one in which all cancer was apparently removed, the operability of this series was 31.9 per cent. The known cures in this operable group were 45.5 per cent, while if the many cases untraced for the necessary 5 years, but free of disease when last seen, be excluded, the 5 year cure rate in the operable group becomes 58.8 per cent. The other side of the picture is as gloomy as this is encouraging: for of the 94 cases in which malignant tissue was left behind at the conclusion of the operation or which were recurrent, only 2 have survived the 5 year period.

TYPES OF OVARIAN TUMOR (TABLE III)

The cancers of the ovary are distinguished by the diversity of their cells of origin, and evidence has been presented in the literature to show that certain of the special types, such as the granulosa cell tumors and dysgerminomas, have a relatively favorable prognosis. For this reason some writers on this subject have considered it wise to exclude these special tumors from series of cases of ovarian cancer on which 5 year end results are reported. To make this exclusion seems to us to render the record incomplete, for although the special types are probably in general less malignant

Read before meeting of the American Radiology Society at Cleveland, Ohio, June 2, 1941.

Fig 5 Pseudomucinous cystadenoma Originally diagnosed as malignant Five year cure (SD2724)

Fig 6 Pseudomucinous cystadenocarcinoma Malignancy doubtful Five year cure (SC9376)

In a series of cystadenomas and adenocarcinomas of the ovary, the morphological transition from the benign to the malignant takes place almost imperceptibly. No pathologist has had the experience to place the line of division exactly. The uncertainty of histological diagnosis in this group of tumors is exemplified by 6 cases.

The following papillary serous tumors are only a part of those about which there was disagreement.

C F (No 2,649, Fig 1) An unmarried woman of 35 years was operated upon at the Roosevelt Hospital on July 24, 1913. Bilateral cysts of the ovary with multiple intestinal implants were discovered and, although a complete hysterectomy with removal of both adnexa was performed, neoplastic tissue remained in the abdomen. In spite of these findings the patient was quite well 13½ years after her operation. A pathological diagnosis (B-3,867) of pap-

illary cystadenoma was made, and this diagnosis was confirmed by the patient's course.

H L (No 20,489, Figs 2 and 3) A married woman of 35 years had a right oophorectomy on January 12, 1933, for a small cyst, discovered after operation to be filled with papillary material. On the basis of slides (SD7,852) a diagnosis of "papillary cystfibroadenoma (benign)" was made (Fig 2). Two years later she was operated upon again and found to have a solid tumor in the right side of the pelvis and metastatic nodules in the abdominal wall and omentum. The diagnosis (SD1,949) was now changed to papillary cystadenocarcinoma (Fig 3).

H W (No 13,388, Fig 4) A married woman of 34 years was admitted to the hospital June 19, 1920. At operation an apparently inoperable condition was found and a diagnosis was made of papillary cystadenocarcinoma. The disease did not progress, however, and the uterus and adnexa were successfully removed 18 months later. A histological diagnosis was then made of papillary cystadenoma (SA9,775). She remained well for 3 years after which ascites appeared. Seven years after the beginning of her

Fig 7 Pseudomucinous cystadenocarcinoma Originally diagnosed as benign Died in 13 months (C3181)

Fig 8 Papillary serous cystadenoma Benign type Ten year cure (SB6723)

Fig. 1. Papillary serous cystadenoma. Clinically diagnosed as malignant. Ten year cure (B-3567)

Fig. 2. Papillary serous cystadenocarcinoma. Originally diagnosed as benign. Recurrence in 7 years (SC7851)

are dead. The exclusion of these 12 cases would raise the original 5 year cure rate to 17.4 per cent.

Unclassified cases The histological material was either lacking or unsatisfactory in 10 cases among which there was 1 cure.

It is noteworthy that the exclusion of any of these rather small groups has very little effect on the 5 year cure rate of 15.2 per cent that has been noted for the series as a whole

HISTOLOGICAL DEGREE OF MALIGNANCY (TABLE IV)

Although it has been repeatedly stated that 'grading' has no bearing on the results of treatment in ovarian cancer most reports indicate that there is a relatively favorable outlook for the more differentiated papillary adenocarcinomas of the ovary (Pemberton

Lynch, Meigs, 6) Other writers, who speak of malignant degeneration in papillary cystadenomas are apparently referring to the same group (Stuebler and Brandess). Still other writers use the term papillary cystadenoma for tumors that have from the clinical standpoint a malignant course (Moench). It seems best to us to designate these differentiated types, which are capable at times of recurring and killing the patient, as grade 1 adenocarcinoma of the ovary.

If the recognition and segregation of this type may be termed "grading" then the grade of malignancy in ovarian cancer is of enormous prognostic significance. The classification of 88 cases of ovarian adenocarcinoma, Table IV indicates only 2 cures, among 53 undifferentiated types whereas among 36 so called grade 1 cases there were 12 cures.

Fig. 3. Infiltrating carcinoma in recurrence from tumor of Figure 1 (SD1949)

Fig. 4. Papillary serous cystadenocarcinoma. Originally diagnosed as benign. Died after 7 years (S 19771)

Fig 5 Pseudomucinous cystadenoma Originally diagnosed as malignant Five year cure (SD2724)

Fig 6 Pseudomucinous cystadenocarcinoma Malignancy doubtful Five year cure (SC9376)

In a series of cystadenomas and adenocarcinomas of the ovary, the morphological transition from the benign to the malignant takes place almost imperceptibly. No pathologist has had the experience to place the line of division exactly. The uncertainty of histological diagnosis in this group of tumors is exemplified by 6 cases.

The following papillary serous tumors are only a part of those about which there was disagreement.

C F (No 2,649, Fig 1) An unmarried woman of 35 years was operated upon at the Roosevelt Hospital on July 24, 1913. Bilateral cysts of the ovary with multiple intestinal implants were discovered and, although a complete hysterectomy with removal of both adnexa was performed, neoplastic tissue remained in the abdomen. In spite of these findings the patient was quite well 13½ years after her operation. A pathological diagnosis (B-3,867) of pap-

illary cystadenoma was made, and this diagnosis was confirmed by the patient's course.

H L (No 20,489, Figs 2 and 3) A married woman of 35 years had a right oophorectomy on January 12, 1933, for a small cyst, discovered after operation to be filled with papillary material. On the basis of slides (SD7,852) a diagnosis of "papillary cystfibroadenoma (benign)" was made (Fig 2). Two years later she was operated upon again and found to have a solid tumor in the right side of the pelvis and metastatic nodules in the abdominal wall and omentum. The diagnosis (SD1,949) was now changed to papillary cystadenocarcinoma (Fig 3).

H W (No 13,388, Fig 4) A married woman of 34 years was admitted to the hospital June 19, 1920. At operation an apparently inoperable condition was found and a diagnosis was made of papillary cystadenocarcinoma. The disease did not progress, however, and the uterus and adnexa were successfully removed 18 months later. A histological diagnosis was then made of papillary cystadenoma (SA9,775). She remained well for 3 years after which ascites appeared. Seven years after the beginning of her

Fig 7 Pseudomucinous cystadenocarcinoma Originally diagnosed as benign Died in 13 months (C3181)

Fig 8 Papillary serous cystadenoma Benign type Ten year cure (SB6723)

Fig. 9. Papillary serous cystadenofibroma. Benign type (SE266)

disease an exploratory operation was performed again and in spite of an identical histological structure, the diagnosis was changed back to papillary cystadenocarcinoma. Ten years after the onset of her disease she died.

The pseudomucinous tumors offer similar problems, as can be seen from the following 3 cases.

31 R (No C 354,63 Fig. 5) A single woman of 5 years was operated upon on December 6, 1935. A large cystic tumor was found and a right salpingo-oophorectomy was performed. An original diagnosis of carcinoma (S.D. 724) was made but this opinion was reversed after outside consultation and the case is now carried in our records as benign. She is free of recurrence after 5 years.

C.C. (V) 54 (Fig. 6) A married woman of 3 years was operated upon in the fourth month of her pregnancy and a right salpingo-oophorectomy was undertaken. The patient was delivered of normal child at term and has since remained well. Slides (S.C. 9,376) were submitted to four pathologists who examined them independently. They regarded the condition as benign and two as malignant. On account of the recognized authority of one pathologist who called this cancer, the case has been carried in our carcinoma series although it is our belief that almost all tumors of this type will be cured.

31 P (No 5,63 Fig. 7) A married woman of 60 years was operated upon on November 9, 1935 and a large multilocular cyst of the right ovary was found. The operation consisted in complete hysterectomy and bilateral salpingo-oophorectomy. Metastasis was present and diagnosis of papillary cystadenoma was made (C3 8). Nevertheless, the tumor rapidly recurred, causing the patient's death in 3 months. The diagnosis was accordingly changed to adenocarcinoma.

There are then 2 possible changes in our histological classification of cases which would

Fig. 10. Pseudomucinous cystadenoma. Benign type (SD3544)

fundamentally affect our own reported cure rates. (a) Certain of the cases classed as papillary adenocarcinoma might have been benign. Actually 12 of the 14 cured cases of adenocarcinoma were regarded as well differentiated and classed as grade 1. (b) On the other hand some of the 60 papillary cystadenomas were perhaps malignant. There are no known recurrences in this group. Nevertheless, 4 were noted to have had peritoneal implants at the time of their operation and 6 were labelled carcinoma by the first pathologist. In all at least 26 of the 60 papillary cystadenomas were somewhat doubtful (Table V).

It is interesting to note what an effect changes in the classification of these two categories, those here regarded as grade 1 adenocarcinomas and a doubtfully benign or actively proliferating papillary cystadenomas, would have on the reportable cure rates of the Roosevelt Hospital cases. The exclusion of 12 cured grade 1 cases would have reduced our 5 year rate in the cystadenocarcinoma group

to 2.6 per cent, in the entire series of ovarian cancer to 7.9 per cent. On the other hand, if the 26 "borderline" cystadenomas had been added to the cures, the 5 year cure rate of the adenocarcinomas would have been 35 per cent, the cure rate for the entire series, 29.2 per cent. A range of 8 to 35 per cent of 5 year cures in ovarian "cancer" is about what may be found in the literature.

Difference of opinion as to what histological features justify the classification of some of these borderline tumors as benign or malignant, is probably the most important variable governing the reported figures on cures of ovarian cancer. A slight change in conception of the morphological criteria of malignancy in the cystic tumors of the ovary appears to us largely to explain the change in our own figures from the 8.3 cure rate of our 1934 report to the 15.2 per cent noted in the present article.

RADIATION THERAPY

Postoperative x-ray treatment of ovarian cancer was begun at the Roosevelt Hospital in 1928. For the first 3 years the therapy consisted as a rule, in a single high voltage treatment given to each of four fields, but insufficient in amount to produce a skin erythema. From 1931 to 1933 the commonest plan of therapy was based upon four pelvic fields, each receiving 670 r in one dose, the factors being 200 kilovolts, 50 centimeters target-skin distance, 1 millimeter aluminum and 0.5 millimeter of copper filtration, 5 milliamperes of current, for 70 minutes, with fields of 20 by 20 centimeters. From 1933 to the present various plans to give divided dosage have been employed, the commonest being the use of four fields, each receiving five exposures of 300 to 360 r at each treatment. The factors employed for delivery of these treatments were usually 200 kilovolts, 50 centimeters distance, 2 millimeters of aluminum and 0.75 millimeter of copper filtration, 25 milliamperes of current, for 9 minutes with fields of 15 by 15 centimeters. In the tabulation of these cases, those which received 650 r or more per port in a single treatment or a series of small treatments totaling 1500 r or more have been classed as receiving "ade-

Graph 1 Effect of x-ray therapy on survival in cases of ovarian cancer

quate" radiation and are to be distinguished from those receiving incomplete x-ray courses or small doses of radium in the uterus or vaginal vault.

Among the 82 patients receiving no radiation there were 5 year cures in 12, 14.8 per cent, among the 26 patients receiving "adequate" radiation therapy, there were 5 year cures in 9, 34.6 per cent, and among the 30 patients receiving incomplete radiation there was 5 year cure in only 1, 3.3 per cent. It is noteworthy that all but 2 of the radiation cures are in the relatively differentiated type in which cure frequently results simply from surgery. In 2 cases alone, those in which some carcinoma remained after the conclusion of the operation, x-ray appears to have been the essential factor in producing a cure.

A better method perhaps of studying the effects of x-ray is in the construction of a curve for survival rate (Graph 1). The curve is based on 82 cases, in which patients survived their operation by at least 1 month and in which the exact month of patient's death because of cancer is known. The curve of survival for the patients receiving "adequate" x-ray is consistently higher than the basic curve for the nonradiated cases but is of essentially the same shape. It should be

noted further that had the deaths within the first 3 months been eliminated the two curves would have been almost exactly superimposed. The very low survival curve of the cases receiving "inadequate" radiation is probably an example of the range of variation which may be expected in building curves on small samples of cases, but might be due to the fact that it includes a number of patients who were too sick to complete their treatment. It does not appear to us that radiation, as given at the Roosevelt Hospital, has materially affected the average duration of life in cases of ovarian cancer.

Strikingly beneficial effects from x-ray therapy in ovarian cancer have been reported from many sources (Harris and Payne Heyman, Montgomery and Farrell, Schinz and Zuppinger, Schroeder Wintz, and Walter Bachman and Harris). Yet the best cure rates reported after postoperative x-ray therapy still lie within the limits of the best figures reported for cases not treated by radiation. Furthermore few if any reports based on contrasted series treated in the same institution have eliminated the possibility of the favorable selection of patients assigned to radiation. It does seem probable to us that in an occasional case as cited in this series, the x-ray is the essential factor in producing a 5 year cure but it appears unlikely that postoperative x-ray can be expected to transform a cure rate of 6.3 per cent to 29.0 per cent as indicated in the recent paper of Walter Bachman and Harris.

SUMMARY AND CONCLUSIONS

1. The reporting of statistics on ovarian carcinoma, on account of the heterogeneous character of the disease requires the listing of special types with their individual end results as well as figures for the whole. The special types, such as granulosa cell tumors and dysgerminomas, should be placed in special categories. The adenocarcinomas should be graded and at least those capable of different interpretation by different pathologists considered as a group. In this respect it is necessary to include a note on the papillary cystadenomas treated in the hospital during the same period since if this group is very

small it is probable that some have been erroneously classed with the cancer cases. Tumors possibly primary outside of the ovary should not be disregarded simply because the primary ovarian character cannot be absolutely established.

2. In the present series of 138 cases of ovarian cancer the absolute 5 year cure rate is reported as 13.2 per cent. The factor which most affected prognosis was the gross stage of the disease at the time of operation. Of next importance was the histological grade of the tumor at least in the sense that the differentiated tumors of perhaps doubtful malignancy had a very much better prognosis than the others.

3. Postoperative x-ray therapy was apparently responsible for the 5 year cure of 2 cases, in which recurrence was otherwise certain but the effect of x-ray on the percentage of 5 year cures and on survival curves was less than has been frequently claimed.

FRACTURES OF THE FOREARM

Some Technical Procedures

ARTHUR L. MURPHY, M.D., F.A.C.S., Halifax, Nova Scotia

REDUCTION, retention, and restoration of function are the basic principles of fracture therapy. The techniques developed from these broad themes are legion. In their little details lies ultimate success or failure. Perhaps in no other branch of surgery do trifles loom as great. Our methods of dealing with two common forearm fractures do not infringe on basic principles; they have helped with trifles.

In the ubiquitous Colles' fracture, the great postreduction problem is circulatory obstruction. Originally I splinted these fractures with circular plaster, attempting to make the cast thin enough that, when split on the ulnar side, it would yield to the swelling wrist. Good in theory, the figure of eight windings around wrist and hand made an unavoidably rigid plaster. Forcing its cut edges apart was difficult and sometimes resulted in a loss of the reduction. The simple dorsal or ventral plaster mold did not give the desired stability. Hence, the spiral mold.

The mold (Figs 1, 2, 3) is made of one to two 3 inch by 3 yard bandages. The crinoline-impregnated type is most satisfactory, giving greater strength per ounce. The mold is rolled dry, the distal end is cut obliquely to make a narrow strip across the palm. It is dipped in water, and applied without padding—this is essential. Beginning on the palm, embracing the hypothenar eminence, its distal edge follows the proximal crease of the palm till it passes between thumb and index finger. The angulated edge (made by cutting the end of the mold) is radial, and ends just distal to the radial styloid, so that the full width of the plaster covers the site of the fracture. The mold is continued around the arm to end just distal to the medial epicondyle of the humerus.

The mold is held in place by a wet gauze bandage, the palmar strip being shaped well to fit the palmar arch.

In most cases swelling of the hand will be so slight as to demand no interference. The patient may be sent home without fear of an ischemia developing over night. If swelling does become troublesome it must be relieved. The gauze bandage is cut along the lateral border of the hypothenar eminence, the plaster and injured wrist are supported firmly on their dorsum, the palmar strip of plaster is levered free from its hypothenar end, and then restrapped less tightly. The fracture area has not been disturbed.

After 10 to 14 days the spiral mold is replaced by a simple dorsal mold with the hand in dorsiflexion.

It may be observed in Figures 2 and 3 that the hand is not in the position of flexion too often shown as the correct one for holding a Colles' fracture in reduction. Originally described by Cotton, the technique of reduction has grown to a beautiful example of surgical mechanics. The first movement is pronation. Through the leverage of the hand and carpal ligaments this forces the distal, radial fragment downward, ventrally. The second movement of ulnar deviation, by traction on the radial-carpal ligaments, opens the

Fig 1. Fragment *P* serves to reinforce the mold over the wrist joint at *P*₁.

noted further that had the deaths within the first 3 months been eliminated the two curves would have been almost exactly superimposed. The very low survival curve of the cases receiving "inadequate radiation is probably an example of the range of variation which may be expected in building curves on small samples of cases but might be due to the fact that it includes a number of patients who were too sick to complete their treatments. It does not appear to us that radiation as given at the Roosevelt Hospital has materially affected the average duration of life in cases of ovarian cancer.

Strikingly beneficial effects from x ray therapy in ovarian cancer have been reported from many sources (Harris and Payne, Heyman, Montgomery and Farrell, Schinz and Zuppmann, Schroeder, Wintz, and Walter, Bachman and Harris). Yet the best cure rates reported after postoperative x ray therapy still lie within the limits of the best figures reported for cases not treated by radiation. Furthermore few if any reports based on contrasted series treated in the same institution have eliminated the possibility of the favorable selection of patients assigned to radiation. It does seem probable to us that in an occasional case as cited in this series the x ray is the essential factor in producing a 5 year cure but it appears unlikely that postoperative x ray can be expected to transform a cure rate of 6.3 per cent to 20.0 per cent as indicated in the recent paper of Walter, Bachman and Harris.

SUMMARY AND CONCLUSIONS

1. The reporting of statistics on ovarian carcinoma, on account of the heterogeneous character of the disease requires the listing of special types with their individual end results as well as figures for the whole. The special types, such as granulosa cell tumors and dysgerminomas should be placed in special categories. The adenocarcinomas should be graded and at least those capable of different interpretation by different pathologists considered as a group. In this respect it is necessary to include a note on the papillary cystadenomas treated in the hospital during the same period since if this group is very

small it is probable that some have been erroneously classed with the cancer cases. Tumors possibly primary outside of the ovary should not be disregarded simply because the primary ovarian character cannot be absolutely established.

2. In the present series of 138 cases of ovarian cancer the absolute 5 year cure rate is reported as 15.2 per cent. The factor which most affected prognosis was the gross stage of the disease at the time of operation. Of next importance was the histological grade of the tumor at least in the sense that the differentiated tumors of perhaps doubtful malignancy had a very much better prognosis than the others.

3. Postoperative x ray therapy was apparently responsible for the 5 year cure of 2 cases, in which recurrence was otherwise certain, but the effect of x ray on the percentage of 5 year cures and on survival curves was less than has been frequently claimed.

FRACTURES OF THE FOREARM

Some Technical Procedures

ARTHUR L. MURPHY, M.D., F.A.C.S., Halifax, Nova Scotia

REDUCTION, retention, and restoration of function are the basic principles of fracture therapy. The techniques developed from these broad themes are legion. In their little details lies ultimate success or failure. Perhaps in no other branch of surgery do trifles loom as great. Our methods of dealing with two common forearm fractures do not infringe on basic principles; they have helped with trifles.

In the ubiquitous Colles' fracture, the great postreduction problem is circulatory obstruction. Originally I splinted these fractures with circular plaster, attempting to make the cast thin enough that, when split on the ulnar side, it would yield to the swelling wrist. Good in theory, the figure of eight windings around wrist and hand made an unavoidably rigid plaster. Forcing its cut edges apart was difficult and sometimes resulted in a loss of the reduction. The simple dorsal or ventral plaster mold did not give the desired stability. Hence, the spiral mold.

The mold (Figs. 1, 2, 3) is made of one to two 3 inch by 3 yard bandages. The crinoline-impregnated type is most satisfactory, giving greater strength per ounce. The mold is rolled dry, the distal end is cut obliquely to make a narrow strip across the palm. It is dipped in water, and applied without padding—this is essential. Beginning on the palm, embracing the hypothenar eminence, its distal edge follows the proximal crease of the palm till it passes between thumb and index finger. The angulated edge (made by cutting the end of the mold) is radial, and ends just distal to the radial styloid, so that the full width of the plaster covers the site of the fracture. The mold is continued around the arm to end just distal to the medial epicondyle of the humerus.

The mold is held in place by a wet gauze bandage, the palmar strip being shaped well to fit the palmar arch.

In most cases swelling of the hand will be so slight as to demand no interference. The patient may be sent home without fear of an ischemia developing over night. If swelling does become troublesome it must be relieved. The gauze bandage is cut along the lateral border of the hypothenar eminence, the plaster and injured wrist are supported firmly on their dorsum, the palmar strip of plaster is levered free from its hypothenar end, and then restrapped less tightly. The fracture area has not been disturbed.

After 10 to 14 days the spiral mold is replaced by a simple dorsal mold with the hand in dorsiflexion.

It may be observed in Figures 2 and 3 that the hand is not in the position of flexion too often shown as the correct one for holding a Colles' fracture in reduction. Originally described by Cotton, the technique of reduction has grown to a beautiful example of surgical mechanics. The first movement is pronation. Through the leverage of the hand and carpal ligaments this forces the distal, radial fragment downward, ventrally. The second movement of ulnar deviation, by traction on the radial-carpal ligaments, opens the

Fig. 1. Fragment P serves to reinforce the mold over the wrist joint at P₁.

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 5.

Figs. 2, 3, 4, 5 are posed by lateres, as the mold has been applied. The fractured arm must be bandaged on. Ob-

viously the Kirschner wire in Figure 5 does not pierce the phalanx.

space into which it descends. It also corrects the lateral displacement. The third movement flexion, in this position is limited to about 25 degrees. It simply locks the distal fragment in place and helps to correct the dorsal tilt of its articulating surface.

The spiral mold was devised originally to overcome a problem met in treating fractures of the phalanges and metacarpals particularly Bennett's fracture at the base of the first metacarpal. Abduction of the thumb rarely gives a satisfactory reduction without traction. In using a wire, projecting from a plaster arm cuff to take the traction through an elastic band to the Kirschner wire in the proximal phalanx, we found that the cuff (pushed tight by countertraction) often

caused circulatory obstruction in the arm. The spiral mold (Figs. 4 and 5) bandaged with wet gauze grips without squeezing. The extension along the dorsum of the thumb splint as well as giving a base for traction.

Absence of padding under these molds is essential. It permits the myriad hairs of arm and hand to serve as anchors. I have given up in all plaster work, the use of sheet wadding. When padding is necessary over bony points, and on plaster margins, sadder's felt or sponge rubber serves best. If no padding be needed none is used. A smoothly molded plaster is kinder to the skin than the undulating vagaries of sheet wadding.

The apparatus for reducing fractures of the radius and ulna is presented with distinct reservations. These fractures of both bones may be divided, therapeutically into two broad groups: those which respond to closed manipulation and those which do not. It is desirable that the first group be as large as possible. The use of good local or deep general anesthesia, manipulation under the fluoroscope, prolonged traction to tire spastic forearm muscles—these will increase its numbers. A certain proportion of cases must fall into the operative class.

In between are those that respond to skeletal traction. Let us add to their number a group of cases we have all met—the old, ill-treated, ununited fractures of radius and ulna,

Fig. 6. The patient holds the arm unsupported, in abduction. The apparatus is not here.

Fig 7 $\Lambda 1$, Kirschner wire through the proximal end of the ulna, at right angles to $\Lambda 2$ through the distal ends of radius and ulna T_1, T_2, T_3, T_4 , turnbuckles

in which powerful flexor muscles have contracted and overcome the extensors to produce marked angulation at the site of the fracture—an angulation that must be corrected before good operative work can be done. It was in such cases that our turnbuckle apparatus (Fig 6) was first used. We have since used it in selected, fresh fractures, with good results.

Kirschner wires are used according to the common technique. One is drilled through the proximal end of the ulna, one through the distal ends of radius and ulna. These wires are at right angles to one another when the hand is midway between pronation and supination. (This is not only the position of optimum function, it is the position of best muscular balance and the one in which radius and ulna are most nearly parallel.)

On the Kirschner wires are mounted four turnbuckles (Fig 7, T_1, T_2, T_3, T_4). Thus they form four triangles of force, two with their bases on the radius-ulna wire, two with their bases on the olecranon wire. Manipulation of the fractured bones is possible in all planes. They are held stable in any position without further splinting.

The apparatus and its application in detail. Four $3\frac{1}{2}$ inch turnbuckles are used. These have a range between contraction and expansion, of $2\frac{1}{2}$ inches. Three sets of right hand threaded ends are made for each turnbuckle— $2\frac{1}{2}$ inch, $4\frac{1}{2}$ inch, $6\frac{1}{2}$ inch (Fig 8), giving for the set a continuous range from 5 to $11\frac{1}{2}$ inches, to fit children and adults. Channels are cut to the Kirschner wire openings in the right hand threaded ends to permit changing sizes, without opening the stirrup. This is rarely necessary. The right hand threaded ends are offset three-quarters of an inch to allow for the curve of the arm. On two of the

Fig 8 R, R' — $2\frac{1}{2}$ inch right hand threaded end for turnbuckles $4\frac{1}{2}$ inch and $6\frac{1}{2}$ inch pieces are identical, but lengthened at Λ . $L1$, Left hand threaded ends for turnbuckles T_3 and T_4 . $L2$, Left hand threaded ends for turnbuckles T_1 and T_2 . S , Stop, with setscrew, for Kirschner wire

turnbuckles, for T_1 and T_2 , Figure 7, the left hand threaded ends are also offset $\frac{3}{4}$ inch, and are $\frac{3}{4}$ inch longer, to compensate for the added length of their diagonal direction. Four stops with set screws are provided to prevent the Kirschner wires from slipping in the bone if unequal stress be put on them.

The Kirschner wires are drilled through distal radius and ulna, and through the proximal ulna. Sterile, saddle's felt "washers" are mounted on each side of each wire, against the skin. The stops are set on the wires. The turnbuckles follow, the wires are drawn taut in stirrups. The proximal stirrup can be slung to the posterior surface of the upper arm by adhesive. The distal rests best on the dorsum of the forearm. The turnbuckles are now adjusted to reduce the fracture. Obviously, to correct bony angulation, lengthening of one turnbuckle will necessitate simultaneous lengthening of one other, and shortening of the remaining two. Thus, if there be an ulnar convexity, lengthening of T_1 and T_2 must be accompanied by shortening of T_3 and T_4 . Uniform traction is applied by making equal stress on all four. As with any form of screw traction, the danger of over extension must be guarded against. Fluoroscopic control of manipulations is desirable.

With a satisfactory reduction confirmed by x-ray examination, arm and apparatus may be supported in an ordinary sling. When the patient is in bed the arm should be supported on the chest by pads, otherwise there is danger of pressure on the medial stop on the

Fig. 6. Case 1. December 8, 1940

olecranon wire pushing it against the skin. The patient is allowed active movements of wrist and elbow (the latter is limited to 25 degrees). These movements are painless and seem to cause no abnormal mobility at the fracture line. Despite this apparently complete immobilization, I have not depended on the apparatus alone for splinting beyond the first two weeks. Perhaps this is an unnecessary precaution. I do not yet know. At the end of that time, turnbuckles are removed and plaster applied from the insertion of the deltoid to the proximal crease of the palm, incorporating the wires.

If desired plaster may be applied immediately following reduction. In this event it is better to use the large Kirschner stirrups, to facilitate the application of the plaster beneath the turnbuckles.

Three cases in which the use of the turnbuckles was particularly indicated

CASE 1 (Victoria General Hospital, No. 26394, Fig. 6) The patient, aged 43 years, was admitted with fracture of radius and ulna in the middle third. Both fractures were oblique. The radius showed very slight displacement, the ulnar fragments were overriding with angulation. The elbow joint was the seat of an osteoarthritis. To lessen the immobilization time of the elbow reduction was made with the turnbuckle apparatus and movements of elbow and wrist were permitted, for weeks. X-ray examination at this time showed early callus formation. A plaster was then applied from deltoid insertion to the proximal crease of the palm, incorporating the wires. The turnbuckle apparatus was removed.

CASE 2 (Victoria General Hospital, No. 26363) The patient, male, aged 26 years, was admitted with fracture of the radius and ulna in the upper and middle third of forearm standing union as fibrous. Flexor contraction had resulted in 70 degrees angulation

Fig. 9. Case 2, February 5, 1941

lation at the site of the fracture (Fig. 9). Manual traction and massage were given (without result). December 9, 1940, the turnbuckle apparatus was applied. Adjustments were made to stretch the contracted muscles, the turnbuckles being given few turns every 2 or 3 days. February 5, 1941, the angulation was almost completely corrected (Fig. 9). The arm was prepared for operation to freshen the bone ends and fix them internally. After operation the apparatus was reapplied to prevent recurrence of contraction.

CASE 3 (Halifax Infirmary No. 15030) The patient, male, aged 5 years, had an ununited fracture of the radius and ulna in their middle thirds. There was 5 degrees of ulnar convexity at the site. Operation was performed. The bones appeared healthy, the ends were freshened, perforated with multiple drill holes, and wired. The bones were held straight with little effort. Incisions were closed and plaster cast was applied over right dressing. X-ray films taken at the end of 3 weeks showed good callus formation, but return of the angulation, although the cast had not been disturbed. The cast was removed. Kirschner wires and the turnbuckle apparatus were applied, the angulation was corrected and so held till firm bony union.

SUMMARY

Presented as useful adjuncts to fracture therapy are

1. A spiral plaster mold for fractures of the lower end of the radius, the metacarpals and phalanges, which grips and immobilizes the part without causing circulatory interference.
2. An apparatus for reduction of fractures of radius and ulna which consists of four special turnbuckles mounted on Kirschner wires through distal radius and ulna, and through proximal ulna, so as to give control of the fragments in all planes.

THORACOSCOPY AND PNEUMOLYSIS

Observations on One Hundred Consecutive Cases

LOUIS CARP, M D, F A C S, and BORRIS A KORNBLITH, M D, F A C S,
New York, New York

RIVERSIDE HOSPITAL is one of the New York city municipal institutions for the tuberculous in which far advanced cases constituted about 72 per cent of the admissions during the past 5 years. During this same period 69 per cent of the patients were colored. In most of the cases pneumothorax therapy had been initiated elsewhere. In many instances thoracoscopy and pneumolysis were carried out as a last resort in patients with bilateral disease in the hope that some clinical improvement might be produced by cutting adhesions to help in the collapse of a cavity and the conversion of sputum. It is apparent, therefore, that we have had the more unfavorable type of material for these procedures. No patient was operated upon except after consultation with the medical service, directed by Dr. Max Taschman, and such specialty services as were indicated. We shall report our observations and follow-up notes on our first 100 consecutive patients who had thoracoscopy or pneumolysis.

TECHNIQUE

The instrument About 95 per cent of the pneumolyses were performed with the Moore apparatus, by the use of thoracoscopy through one opening into the pneumothorax cavity and by division of the adhesions through another opening with an electrode which carried coagulating and cutting currents. The Coryllos instrument with its actual cautery was used for the remainder of the cases. All instruments are tested carefully before operation to make sure that the light bulb, cable connections, and current are in working order. On a number of occasions, unnecessary

bleeding was produced by a defective current as a result of improper electrical connections. A blurred field of vision may result from a moist ocular, from insufficient current, from a cold light bulb or observation lens or their moistening by blood or intrathoracic fluid. Appropriate measures correct all of these conditions.

The position of the patient In most instances the patient was placed on his back with a pillow beneath the shoulders. The head was hyperextended and turned to the side opposite the operative field. The hand on the side of the operative field was placed beneath the head. There was no hesitation in sitting the patient up or turning the trunk if such positions produced a better view of the adhesions and easier intrathoracic manipulation.

Anesthesia Local novocain anesthesia was used exclusively with especial care to infiltrate the parietal pleura.

Thoracoscopy openings In over 90 per cent of the cases, openings into the second interspace in the midclavicular line and the third interspace in the midaxillary line were found adequate for thoracoscopy and pneumolysis. When indicated, openings were made in any other part of the chest wall. Stab wounds through the intercostal space permitted the snug introduction of the trocar and cannula. In this way postoperative emphysema of the chest wall and adjacent tissues was minimized or prevented, especially if the edges of the stab wound were tightly approximated by deep suture.

Division of adhesions Pneumolysis requires patience and meticulous care and any attempt at hurry may produce a disastrous complication or incomplete therapy. The ideal time for cutting adhesions seemed to be as early as possible, when the mediastinum was already stabilized by the pneumothorax and when

b

Fig. Successful collapse of cavity following pneumolysis. Colored female aged 25 years, duration of symptoms 6 months, duration of pneumothorax 3 months. a, Unilateral pulmonary tuberculosis with cavity 3 centimeters in diameter in right upper lobe. Note faint streaks interpreted as string adhesions running from the upper lobe toward the first rib. Thoracoscopy showed thick columnar adhesion which fanned out to the apex of the thoracic cage. Pneumolysis. b, Roentgenogram 27 days after operation to show beginning collapse of the cavity aided by continued pneumothorax refills. Note spread of disease in the hilar region of the contralateral lung. This as temporary. c, Roentgenogram 9 months after operation to show complete collapse of the cavity. The apical cavity converted 4 months after operation. A 20 months follow-up shows involvement of the contralateral lung and partial expansion of the right upper lobe which contains cavity. Sputum as positive.

this was adequate for intrathoracic visualization and instrumental manipulation. Whenever possible we attempted to cut adhesion near the chest wall. At this point there is less danger of injury to lung and adjacent anatomical structures and usually there is less bleeding. At times enucleation of the adhesion from the chest wall was advisable. At other times partial pneumolysis was performed under the following conditions: technical difficulty, too lengthy an operation or a desire to stretch an incompletely divided adhesion by increased intrathoracic pressure

so that its complete division at a later date would be easier. Pneumolysis in stages was performed in 9 of our cases. In 5 of these there were 2 procedures and in 4 there were 3.

Postoperative care. Patients were kept in bed and given fluids for 24 hours with codeine for sedation and to diminish the cough reflex. Pneumothorax refills were continued within the first 24 hours after operation.

THE ADHESION

Location. We tried to correlate the locations of adhesions by roentgenogram and

2a

2b

2c

Fig 2 Partial pneumolysis with subsequent bilateral pulmonary fibrosis and conversion of sputum. Colored female, aged 24 years, duration of symptoms, 6 months, duration of pneumothorax 3 months. a, Bilateral pulmonary tuberculosis, with cavity 3 centimeters in diameter in the right upper lobe. Note what was interpreted as massive apical adhesions and string adhesions running toward the second rib. Thoracoscopy showed thirteen string adhesions. Partial pneumolysis. Patient developed a right hydrothorax promptly and contralateral spontaneous pneumothorax 10 days after operation. b, Roentgenogram 3 weeks after operation to show partial collapse of the right upper lobe and fluid in the right pleural cavity. The sputum was converted at this time. c, Roentgenogram 15 months after operation to show re expansion of the lung and bilateral fibrosis. The patient is symptomatically improved and the result is probably not attributable to the original operative procedure.

thoracoscopy. In about 90 per cent of the cases this correlation showed that the roentgenogram was only partially accurate, but it usually served as a guide for the position of the main adhesions. Usually, thoracoscopy showed more adhesions than indicated by

roentgenogram and very often the roentgenogram could not predict their direction. As a rule, mediastinal adhesions could not be visualized in the chest film.

Character and shape In the majority of the cases these could not be foretold by roent-

Fig. 3a.

Fig. 3b.

Fig. 3c.

Fig. 3d.

genogram. The interpretation of what appeared to be a string adhesion in the film very often proved to be a thick spool plicated or quadrangular adhesion. In other instances what looked like a divisible adhesion on the roentgenogram proved to be indivisible because of its character shape, or anatomical position or because of a complete synchia between the lung and chest wall. On the con-

trary what looked like an indivisible adhesion on the roentgenogram was often divisible. We have learned therefore that it is generally advisable to use thoracoscopy in order to determine the pathological state in the pneumothorax cavity and to decide at the time of operation whether pneumolysis is feasible. Adhesions, according to shape, conformed to the following descriptions in their order of fre-

Fig 3 Three stage pneumolysis with collapse of large cavity and conversion of sputum. Colored female, aged 30 years, duration of symptoms, 3 months, duration of pneumothorax, 2 months. a, Unilateral pulmonary tuberculosis with left apical cavity 4 centimeters in diameter and what was interpreted to be a cord adhesion running toward the first rib and massive adhesions between the upper lobe and the mediastinum. Partial pneumolysis with division of one cord adhesion. b, Roentgenogram 6 days later to show the cavity still suspended by what appeared to be a cord adhesion. Thoracoscopy 2 months after the first operation showed tubercles on the surface of the lung. Pneumolysis of two more adhesions. c, Roentgenogram 1 month later to show what appeared to be a cord adhesion running from the apex of the cavity to the mediastinum and another adhesion running from the lateral border of the cavity to the first interspace. The cavity has dropped and there is a small amount of fluid in the pleural cavity. Pneumolysis of these adhesions 8 days later. This was the third operative procedure. d, Roentgenogram 6 days later and 4 months after the first operation to show complete division of the restraining adhesions with release of the upper lobe and re expansion of the left lower lobe. e, Roentgenogram 15 months later and 18 months after the first operation to show collapse of the cavity. The sputum was converted 6 months after the last operation.

quency (Table I) string, fan, cord, spool, synechia, pyramidal, quadrangular, band

OBSERVATIONS FROM STATISTICAL ANALYSIS

The following represents some of the more important observations resulting from analysis of our statistical data.

Among 100 consecutive cases that came to operation there were 32 complete pneumolyses, 43 partial pneumolyses and 25 thoracoscopies (Table II). By complete pneumolysis we mean the division of all visible restraining adhesions. By partial pneumolysis we mean an incomplete division of one or more adhesions, or the complete division of a fraction of the total number of adhesions visualized. The average age for the entire series was 29 years, the youngest patient was 14 and the oldest 53 years. Thirty per cent were males and 70 per cent females. Eighty-nine per cent were of the colored race and 11 per cent were white. The average duration of symptoms on admission to the hospital was 11.28 months. At the time of operation, the average duration of the disease was 18 months and the average duration of the pneumothorax was 7½ months. On admission, the sputum was positive for tubercle bacilli in all of the patients. At the time of operation the sputum was positive in 88 per

cent of the cases with evidence of cavitation in all. Cavities had an average diameter of 3.5 centimeters. Seventy-six per cent of the patients had bilateral disease and in the remaining 24 per cent it was unilateral (Table III). The average estimated extent of the pneumothorax was about 60 per cent, the smallest 30 per cent, and the largest 90 per cent. Two hundred and ninety-seven adhesions were seen at operation, and 60 per cent of these were divisible. Besides adhesions, thoracoscopy demonstrated the aorta, the subclavian and innominate vessels, the beating heart and the pericardium, the phrenic and vagus nerves, fibrin bodies, purulent and nonpurulent fluid, tubercles and fibrinous exudate on the visceral pleura, and the diaphragm (Table IV).

In the 32 patients who had complete pneumolysis, the sputum was converted and the cavity closed in 62 per cent. In 4 per cent the sputum was converted but the cavity remained open. The cavities collapsed in an average time of 36 days and the sputum was converted in an average time of 60 days. In the 43 cases which had a partial pneumolysis, the sputum was converted and the cavity closed in 30 per cent. The cavities collapsed in an average time of 64 days and the sputum was converted in an average time of 75 days.

TABLE I.—THORACOSCOPIC TYPES OF ADHESIONS

	Complete pneumothorax	Partial pneumothorax	Thoracoscopy only	Grand total	
				No.	Per cent

Pyramidal				14	
Columnar					
Quadrilateral					
Band					3
Spontaneous				20	7
Total	26	65	41	292	100

In the 25 cases which had thoracoscopy, the sputum was converted and the cavity closed in 36 per cent. The cavities collapsed in an average time of 110 days and the sputum was converted in an average time of 90 days. The reasons for these last results after thoracoscopy were increased pressures from fluid or pneumothorax, spontaneous rupture of adhesions, pleuropneumonia, and spontaneous fibrosis and recession of the disease. It becomes apparent therefore that the length of time for the closure of cavities and conversion of sputum increases in the procedures in the following order: complete pneumothorax, partial pneumothorax and thoracoscopy. We have

TABLE III.—DISTRIBUTION OF PULMONARY LESIONS

also noted that conversion of sputum usually occurs about 1 month after the collapse of the cavity.

Seventy-one per cent of all the cases had complications which were similar in all 3 procedures. At first glance this percentage seems unusually high, but we have included cases with innocuous hydrothorax which constituted almost half of all the complications. These in their order of frequency were hydrothorax (innocuous), spread of infection to the contralateral lung, tuberculous empyema, spontaneous pneumothorax, hemoptysis, hemothorax, and pleurocutaneous fistula.

Tuberculous empyema occurred in 19 per cent of the entire series and mixed infection in 3 per cent. Only 2 of the entire group occurred directly after operation. Seven of

the 22 empyemas followed thoracoscopy (Table V)

There were 7 cases of spontaneous pneumothorax and they predominated after complete pneumolysis. This complication arose early only once after the operative procedure (Tables IV and V). Postoperative emphysema was not troublesome.

The average follow-up time was 10 months in all the cases the longest period being 28 months the shortest 1 month.

The early and late death rate in the entire group was 27 per cent, and it was practically identical in complete or partial pneumolysis and in thoracoscopy. The causes of death in their order of frequency were

Shortest period			60	
Longest period	120	150	30	120
Sputum converted				
Average period	60		90	75
Shortest period		30	60	
Longest period	70	60	80	120

This occurred early in our experience. Another death occurred 2 months after operation from hemothorax with empyema which developed 6 days after operation. There was no bleeding at the time of operation. A third patient died from spontaneous pneumothorax 10 days after operation. Of the 27 patients with bilateral disease 24 died from causes not due to operation, in an average time of 9 months (Table VI).

Before operation, 12 patients had a negative sputum despite cavitation with adhesions. It seemed advisable to cut these adhesions. One patient developed a contralateral spread of the disease with a hydropneumothorax. Nine months later the sputum became positive and a tuberculous empyema developed on the side operated upon. Another patient had a persistently negative sputum for 6 months after pneumolysis. This patient died of a spontaneous pneumothorax on the contralateral side.

Tubercles without accompanying exudate could be visualized beneath the visceral pleura in 15 per cent of the cases. Over a follow up period of from 4 to 28 months 2 of these patients developed pleural fluid which contained tubercle bacilli. In 1 case the fluid appeared 11 months after partial pneumolysis and in the other patient it appeared 5 weeks after thoracoscopy. Aspiration therapy helped in the disappearance of the fluid in both cases. We believe, therefore, that tubercles on the surface of the lung do not contraindicate pneumolysis, unless they are subject to injury by the electrode.

SUMMARY

1. Our observations are based on complete or partial pneumolysis or thoracoscopy in our first 100 consecutive cases of pulmonary tuberculosis among whom 76 per cent were classified as far advanced and 89 per cent were of the colored race.

2. In most of the patients pneumothorax therapy had been initiated elsewhere so that the average duration of this therapy was 7½ months before operation. This period is far too long if more successful results are to be obtained. Restraining adhesions should be cut as soon as the pneumothorax has stabilized the mediastinum and when it is adequate for visualization and intrathoracic manipulation of instruments.

3. The roentgenogram of the chest served only as a guide for the approximate location, shape, and potential divisibility of adhesions, but it did not predict these with any degree of accuracy.

4. Thoracoscopy and electrode openings were usually found to be adequate when made in the second intercostal space in the midclavicular line and in the third intercostal space in the midaxillary line.

5. Thoracoscopy is advisable to determine the pathological state in the pneumothorax cavity and also the feasibility of pneumolysis. Thoracoscopic findings are enumerated.

6. The presence of subpleural tubercles does not necessarily mean that they will rupture into the pleural cavity. They do not therefore contraindicate pneumolysis, unless tubercles present in adhesions are subject to direct injury by the electrode.

7. The complications after all three procedures are enumerated, with special reference to tuberculous empyema.

8. Comparative statistics indicate that complete pneumolysis was followed by conversion of sputum and closure of cavities in about two-thirds of the procedures and that partial pneumolysis or thoracoscopy accomplished the same results in about one-third of the procedures. The length of time for closure of cavities and the conversion of sputum increased in these procedures in the following order: complete pneumolysis, partial pneumolysis and thoracoscopy. The

version of sputum occurred about 1 month after the collapse of the cavity

9 In our entire series of 100 cases, 40 patients had a favorable outcome following all the procedures. The cavities closed, the sputum was converted and there was symptomatic improvement. The average follow-up time was 10 months.

10 If it is generally accepted that 90 per cent of patients with cavitation and restraining adhesions will die without operative intervention, then our statistics indicate that even in far advanced cases partial or complete pneumolysis reduces the mortality considerably.

11 There was a 3 per cent operative mortality and the causes of death are given. The

remaining 24 per cent, all of whom had bilateral disease, died from causes not attributed to operation, in an average time of 9 months.

CONTINUOUS—SERIAL FRACTIONAL CONTROLLABLE, INTERMITTENT—SPINAL ANESTHESIA

With Observation on 1000 Cases

WILLIAM T. LEMMON, M.D. and GEORGE W. PASCHAL, Jr., M.D.
Philadelphia, Pennsylvania

SINCE April 10, 1939, when we gave the first continuous spinal anesthetic, we have administered more than 1,250 entirely satisfactory anesthetics by this method. In this paper we are giving some of our observations and a statistical report on 1,000 cases.

In this series of cases we have used novocain (procaine hydrochloride) as the anesthetic agent. Our choice of this drug has been deliberate since it is the least toxic of all drugs used in producing anesthesia by injection into the subarachnoid space. By the method of spinal anesthesia we employ, we are able to give just sufficient dosage to produce anesthesia to the desired level and degree. This anesthesia is maintained as long as necessary by adding subsequent small doses as they are needed. We have thereby changed the method of spinal anesthesia from the "single dose" to the "fractional dose" technique which now places spinal anesthesia in the same category with other anesthetics administered by the continuous or fractional dose method such as intravenous anesthesia, ether, cyclopropane, nitrous oxide, etc.

Safety and controllability are the two things we desire most in spinal anesthesia. Sise has pointed out that the first 30 minutes of spinal anesthesia are the most dangerous. It is during this period that deaths and complications are most likely to occur and especially is this true when a single large dose of a toxic drug is administered. We believe that by giving much smaller initial doses of the drug it

should increase the safety. When the needle is left in the subarachnoid space the drug can be rapidly recovered by withdrawing a sufficient quantity (5 to 10 cubic centimeters) of cerebrospinal fluid if untoward toxic symptoms develop, especially in those patients who are very sensitive to the drug. The toxic symptoms seen following injection of a drug into the subarachnoid space are not due to the drug that is fixed in the lipid elements of the sensory and motor synapses producing anesthesia but are due to the absorption of the drug from the cerebrospinal fluid into the systemic (venous) circulation. (This factor will be further emphasized when we deal with spinal anesthesia used in thoracic surgical procedures.) The respiratory center is the most vulnerable to attack. When and if toxic symptoms of an alarming character develop, the first thing to do is to withdraw rapidly the cerebrospinal fluid containing the toxic agent. The greatest concentration of the drug is in the vicinity of the point of the needle. The nerves promptly recover from the anesthesia. This observation was first made accidentally when a turned stopcock on the syringe permitted an unintentional escape of cerebrospinal fluid into the syringe with a subsequent loss of anesthesia. This phenomenon has since been confirmed on numerous occasions. Spinal anesthesia is maintained by the drug that is present in the cerebrospinal fluid and when the concentration of this drug falls below a definite level the anesthesia promptly wears off. After anesthesia is established it takes relatively small doses to maintain the anesthesia for any desired length of time. If we are doing serious technical operative procedures and it is important to maintain complete relaxation at all times, we give an additional dose of 50

From Surgical Division A, Jefferson Medical College and Hospital, Philadelphia.

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, November 4, 1941, Boston, and at the Panel Discussion on Continuous Spinal Anesthesia on November 5, 1941.

milligrams of novocain (5 per cent) solution at the expiration of every 30 minutes. Otherwise, we wait for the initial or previous dose to show signs of wearing off before we give an additional injection.

With a single exception anesthesia was produced to the desired level and degree and the operation was completed under spinal anesthesia. The exception here referred to was a case in which the right middle and lower lobes were being removed for bronchogenic carcinoma and while sensory anesthesia was present up to the level of the hyoid bone, a persistent cough, induced by the incidental tugging on the bronchus, could not be controlled. In this instance cyclopropane was used for this part of the operation. In no other case was a supplementary anesthetic necessary. There were no anesthetic fatalities and no neurological complications. Toxic symptoms were promptly controlled by withdrawal of the drug by rapid aspiration of spinal fluid (3 to 10 cubic centimeters) and by giving inhalations of oxygen.

Some of the disadvantages of the single dose method of spinal anesthesia are (1) failure of the drug to "take" or produce anesthesia to the desired level or degree, (2) the action of the drug wearing off before the operation is completed, and, (3) toxic symptoms or even sudden death following the intraspinal administration of a large dose of a toxic drug. In this series of cases we have eliminated these disadvantages by using this new method of spinal anesthesia.

From the clinical and experimental standpoints, it is generally accepted that procaine hydrochloride is the least toxic of all drugs used to produce spinal anesthesia. Its action is also of the shortest duration. The drugs employed in producing spinal anesthesia, which have a more prolonged action, are also found to be more toxic. There is no reason why any drug or combination of drugs used in producing spinal anesthesia cannot be used by the "fractional" dose or continuous method. It should be more safe to use them by this method than by the single dose technique since the patient would be exposed to smaller amounts of the drug, and because the drug could be recovered by aspiration of a suffi-

cient amount of spinal fluid containing it, should alarming symptoms develop and make this action necessary.

Novocain produces anesthesia promptly when introduced, in sufficient quantity, into the subarachnoid space. We have observed that it takes approximately 90 seconds to relieve pain completely and produce muscular relaxation when it is given in subsequent injections. We feel that each patient is a case unto himself and that each has an individual response to novocain. We have observed a case in which the anesthetic action of novocain disappeared every 15 minutes while doses of 100 milligrams each were being used. We have had anesthesia with 50 milligrams of novocain last for an operation that required 1 hour and 45 minutes. Subsequent injections of 50 milligrams each last approximately 30 minutes, producing both motor relaxation and sensory block. By injecting small doses of novocain (15 to 20 mgm) into the subarachnoid space we have been able to produce sensory block (anesthesia) without causing motor paralysis. In the case of an elderly woman with a strangulated hernia we produced satisfactory anesthesia with 30 milligrams. We are of the opinion that by using this method of anesthesia it is possible to lower the morbidity and mortality rates, especially in serious and prolonged surgical procedures.

TECHNIQUE

Equipment Figure 1 illustrates the equipment used.

Administration. In continuous spinal anesthesia we employ a short acting agent, procaine hydrochloride, which is injected in fractional doses as needed during operation. The patient is placed on a specially designed mattress and a very flexible, special alloy lumbar puncture needle remains in place in the subarachnoid space. This needle is connected to a syringe by means of a 30 inch piece of rubber tubing which is provided with Luer Lok connections at both ends.

The rubber covered mattress is 5 inches thick, 18 inches wide and 6 feet long (see 1 in Fig 1). It has a cut-out area 7 inches in length that comes under the lumbar spine when the patient is supine. There is a break in the center of the mattress, so that the part which supports the legs may be detached for perineal operations. Provision has also been made to break the lower part of the mattress to allow the feet to be dropped when a deep Trendelenburg position is desired (Fig 1 1c and 1d). If an abdominal operation follows the perineal operation, the patient may be pulled back into position and the lower half of the mattress replaced and made secure with straps and buckles (Fig 1 1b).

The spinal puncture is made with the patient in the left lateral decubitus position so that his back is toward the side of the mattress with the gap in it. The malleable special alloy needles are made in 3 sizes No. 17 No. 18, and No. 19 gauge. We prefer No. 18 gauge needles. The site selected for spinal puncture depends upon the site of operation—the second or third for upper abdominal procedures,

Fig 2 A diagrammatic drawing demonstrating the position of the patient and the continuous spinal apparatus in place 1, 2, 3, and 4, Represent incisions for the surgical procedures in these areas

the third or fourth for lower abdominal operations, and the fourth or fifth for operations on the perineum, rectum, and lower extremities. A Sise introducer is used to puncture the skin, and, on withdrawal leaves a track for the soft malleable special alloy needle to traverse. When the cerebrospinal fluid escapes from the hub of the needle, a 10 cubic centimeter Luer-Lok syringe is connected with it, and enough fluid is withdrawn to make up a 5 per cent solution. We have 300 and 500 milligram ampuls of novocain. For estimated short operations we use 300 milligrams of novocain, dissolved in 6 cubic centimeters of cerebrospinal fluid. For long operations we dissolve 500 milligrams novocain in 10 cubic centimeters of spinal fluid. The syringe is disconnected and the needle is plugged to prevent a loss of spinal fluid. Generally, 500 milligrams of novocain is dissolved in 10 cubic centimeters of spinal fluid to make a 5 per cent solution, which contains 50 milligrams per cubic centimeter. The syringe with the stopcock attached is connected to one end of the 30 inches of thick walled, small bore, rubber

tubing. The stopcock is opened and 2 cubic centimeters of the mixture is forced into the tubing, thus displacing the air and completely filling the tube. Then the stopcock is closed. The Luer-Lok connection at the opposite end of the tubing is securely connected to the needle which was left in the spine. The stopcock is opened and 2 to 3 cubic centimeters of the mixture is introduced into the subarachnoid space and the stopcock is closed.

With the needle left in place, the patient is gently turned on his back so that the needle points downward in the center of the gap in the pad. It should not touch the table or mattress at any time. The patient should be kept in 5 degree Trendelenburg position during the induction period. When the height of anesthesia is tested and the desired level is not obtained in 10 minutes an additional injection, usually of 1 cubic centimeter is made. The height of the anesthesia can be extended and controlled by the following means: position of patient, volumetric dilution of anesthetic agent (barbotage), rate of injection, and total dosage of drug.

Fig. 3 The patient lying face down and the spinal needle bent to the side and secured with adhesive. This position used for such operations as excision of the coccyx, and anal operations. The lower drawing shows the lower half of the pad removed and the patient in lithotomy position.

Once anesthesia is obtained, it is easily prolonged by small fractional injections when needed, and we have a setup comparable to the one existing when ether is given by the open drop method or when pentothal sodium is given by the fractional dose intravenous technique. As the anesthesia begins to wear off it is so indicated by the fact that the intestines become less contracted, the abdominal muscles grow more tense, and the patient complains of abdominal discomfort or pain. Just as we would add more ether under similar circumstances to produce relaxation during inhalation anesthesia, when this occurs during continuous spinal anesthesia we give a small additional dose of novocain usually 50 milligrams. We have noted that it takes approximately 90 seconds for this added dose to exert its full effect. We now give these additional

doses, in longer operative procedures, at fairly regular anticipated intervals (usually every 30 to 40 minutes) and are provided with uninterrupted ideal operating conditions throughout the operation.

Preoperative medication. We consider the preoperative medication to be of great importance. On the evening before operation the patient receives 3 grains of nembutal. Three hours before operation the patient is given a second dose of 3 grains of nembutal by mouth. One hour before operation a hypodermic of $\frac{1}{4}$ grain morphine and $\frac{1}{100}$ grain of scopolamine is given. If the sedation is not sufficient, $\frac{1}{4}$ grain of morphine is given intravenously or hypodermically as often as is necessary during the operation. By using proper sedation the patients are spared the unpleasant memories sometimes accompanying

such an experience Most of them sleep throughout the operative period and afterward for many hours

During long and difficult procedures an intravenous injection of 10 per cent glucose solution is given via a vein in the leg These patients also receive a blood transfusion at the end of operation if it is indicated We make an effort to prevent and combat shock rather than wait until its onset before treatment is begun

ANALYSIS OF CASES

We are presenting a report on the first 1,000 cases in which this method has been used The operations in this series include 970 below the abdominal diaphragm and 30 above it In only a single case of the latter group was there a supplementary anesthetic used and that in a case of uncontrolled cough during the course of a pulmonary lobectomy In this case cyclopropane was used during the stage in which tugging on the bronchus precipitated the cough Sensory anesthesia in this case was at the level of the hyoid bone In all of the other cases the operation was begun and finished under spinal anesthesia, and no general or other anesthetizing agent was used

Age The average age for this group was 37.2 years The oldest patient was 83 years old and the youngest was 7 years of age We did an appendectomy on the latter and a leg amputation on the former Younger children do not give satisfactory co-operation to permit the extensive use of spinal anesthesia in that age group (under 7 years)

Length of operation The average length of the operations in this series was 50.4 minutes A total gastrectomy required 215 minutes (3 hours and 35 minutes) The shortest procedure took only about 2 minutes for the incision and drainage of an abscess One of our colleagues reported using this method to produce satisfactory anesthesia during the entire course of a gastrectomy requiring 6 hours

Dosage For these 1,000 cases the average total dose of novocain was 219.9 milligrams In the operations done above the diaphragm the dosage was much larger than the general average, being 445 milligrams This high figure influences the total percentage considerably for it is seen that in the remaining 970

cases the average total dosage was only 181 milligrams of novocain The average number of injections was 2.4 It is interesting to compare the average total dose of the first 500 cases which was 242 milligrams with that of the second 500 cases which was 198 milligrams We feel that this reduction in amount of total dose is due to our increased experience The largest dose given to any one patient was 2,200 milligrams This patient had had an earlier operation in which she required 1,800 milligrams of novocain to produce anesthesia This would indicate an individual tolerance and points out, too, that the dose in any given case is *enough* The smallest dose was 20 milligrams of novocain for amputation of a toe

We have used various dilutions from 1 per cent to 10 per cent solutions of novocain We have obtained best results from using a 5 per cent solution of novocain At times we have used previously prepared solutions of novocain in distilled water and while anesthesia was obtained the results were not always as satisfactory as when the solutions of novocain crystals in spinal fluid were used In thoracic surgical procedures we generally employ a dilution of 1 to 3 per cent This will be discussed more completely in a later paper

Effect on blood pressure The average systolic blood pressure at the beginning of operation for this series was 125.9 millimeters of mercury The average systolic pressure at the end of operation was 113.9 millimeters of mercury This indicates that there was an average fall in systolic blood pressure of only 12 points The blood pressure was recorded every 5 minutes of the operation It was noted that soon after the patient received the preliminary injection of ephedrine sulfate and novocain used to anesthetize the skin and support the blood pressure, there was a general elevation of the blood pressure but after the operation was in progress, the pressure had a tendency to become constant or to fall below that at the onset The average high blood pressure was 129.9 The average low was 103.4 A woman operated upon for a strangulated hernia had a blood pressure of 240 at the beginning and 170 at the end of operation She received 150 milligrams of novocain in 2

injections. In several instances the blood pressure fell to a systolic of 40 millimeters of mercury. We rarely use vasoconstrictors in these conditions but have found that venoclysis or blood transfusion affords the best relief. Most of these patients leave the operating room in good condition. They have a dry skin and a full pulse of good quality.

Morbidity Headache. This is a difficult thing to understand and hard to explain. In cases of the most simple nature we have had this complaint. Some patients subjected to longer operations had no subsequent headache. Our incidence of headache after spinal anesthesia is 2.8 per cent which approximately corresponds to the incidence seen by the former angle injection method. We call attention to the fact that we had 150 consecutive cases in which there were no postoperative headaches. In most instances this complaint is relieved by the use of aspirin or by lowering the head of the patient.

Urinary difficulty. There is no greater incidence of urinary retention with this method than with the ordinary method of spinal anesthesia. Our incidence of urinary retention was 3.4 per cent. In some of our plastic or pelvic operations we inserted an indwelling catheter for the first few postoperative days so that these patients do not enter into our statistics.

Pulmonary. There were 34 cases of pulmonary complications, 19 of these were bronchopneumonia, 9 were lobar pneumonia, 4 were atelectasis, and 2 were pulmonary embolism.

Nervous. There were no motor or sensory disturbances, no cranial nerve palsies or other neurological phenomena. A number of these patients have been observed for more than 3 years.

Mortality. There were 47 deaths among this series of 1,000 cases, making the gross mortality of 4.7 per cent. The average time that elapsed between operation and death was 6.9 days. In none of these deaths do we believe that the anesthesia was a contributing factor. Of the 47 who died 24 were suffering with malignant growths. There were 9 deaths from diffuse peritonitis. Among the remaining factors causing death were pulmonary, cardiac, and

renal conditions. From several others using this method we are informed of something more than 1,000 additional cases in which continuous spinal anesthesia was used. These added to our series make a known total of more than 2,000 cases. There has not been a death reported from the use of continuous spinal anesthesia.

Table I is an outline of the 1,000 cases in this series.

SUMMARY

1 We are reporting 2,000 surgical cases in which operation was done under continuous spinal anesthesia.

2 We have discussed the technique employed in the use of this method and have presented some of the important observations in this series.

3 We wish to emphasize the safety and controllability of this method.

4. We feel that the morbidity and mortality can be lowered by the use of continuous spinal anesthesia.

TOTAL VERSUS SUBTOTAL HYSTERECTOMY FOR BENIGN CONDITIONS

D A McKINNON, Jr, M D, and VIRGIL S COUNSELLER, M D, F A C S,
Rochester, Minnesota

FOR years the question of whether the cervix should be removed along with the fundus in performance of supravaginal hysterectomy has created much discussion. Even among those surgeons who advocate total hysterectomy the technique in performing this operation is noticeably variable and each method has its own adherents who hold certain fixed opinions as to the results.

This paper is based on a group of 2,684 cases observed consecutively at the Mayo Clinic from 1935 to 1939, inclusive, in which operation was performed for benign conditions of the uterus. In 1,920 cases the surgical procedure was total hysterectomy and in 764, subtotal hysterectomy. Further subdivision was made into several classes, the patients who had similar physical hazards—obesity, anemia, and so forth—were placed in separate groups and these groups were analyzed for the occurrence of complications that arose in each. The object of the study was to detect any relation of cause and effect that may exist between certain physical hazards or the type of operation and the nature of post-operative complication. The most reliable figures are those that were obtained after elimination of all cases in which any type of physical disability had been present. In the remaining cases the surgical risk was minimized by the excellent condition of the patients, so that in this group the only known variable was the type of operation performed. Of these 1,497 patients there were 1,034 who had total hysterectomy and 463 who had subtotal hysterectomy.

EVALUATION OF THE TWO TYPES OF OPERATION

The basic reason for different opinions as to the best type of operation when hysterectomy

is considered is founded on the possible development of disease in the retained cervical stump subsequent to subtotal hysterectomy. It is true that in some hands few complications occur in the cervical stump after subtotal hysterectomy, whereas in other hands a long list of pathological changes takes place, making removal of the residual stump at the time of operation the procedure of choice. As to the occurrence of carcinoma in the retained cervical stump, we have little to add. During the 5 year period (1935 to 1939 inclusive) in which the two types of operation were performed in the groups cited, carcinoma of the cervix did not arise in any of the 764 cases in which subtotal hysterectomy was performed. Follow-up reports were not received from the patients during the 18 months previous to the writing of this paper and the future cannot be foretold, however, from insurance tables it is known that 25 per cent of deaths among women are due to carcinoma of the uterus. The ratio of carcinoma of the cervix to carcinoma of the uterus in cases treated at the Mayo Clinic is roughly 3:1. It is apparent that in all probability carcinoma will develop in the retained cervical stump in approximately 2 per cent of the cases in this group.

Black reported several groups of patients who had carcinoma of the cervix. From 21 per cent to 81 per cent of the carcinomas had developed in retained cervical stumps after subtotal hysterectomy. Although these figures do not afford a clue to the actual incidence of carcinoma arising in the stump, they do present forcefully the fact that malignant change occurs in the retained cervical stump subsequent to subtotal hysterectomy. Benign tumors so rarely arise in the cervical stump that the possibility of their development hardly justifies removal of the stump on this basis. Among 1,800 cases in which subtotal hysterectomy was performed Hays observed

From the Division of Surgery, The Mayo Foundation and The Mayo Clinic.

only 2 cases of benign tumors of the cervical stump following the operation.

Rosenow and Benedict (3) in work on certain types of intia, demonstrated definitely that the cervix is a persistent focus of infection. It has been shown also that a causal relationship exists between infection of the cervix and Hunner's ulcer. Although it cannot be stated that in every case of tritis or of Hunner's ulcer the disease is due to an infected cervical stump it is known that this relationship can exist and that in certain cases remarkable cures have been obtained by excision of the infected cervix.

We believe that every patient presenting a diseased cervix in association with other uterine conditions requiring hysterectomy should have a total hysterectomy. This belief is based on the fact that 95 per cent of carcinomas of the cervix arise from erosion and chronic cervicitis. Cauterization of the cervix does not as a rule remove all gland-bearing tissue, nor does it remove the epithelium from the portio vaginalis which is frequently the primary focus of cervical cancer. Therefore, as a substitute for total hysterectomy application of cautery to cervix is a poor second.

Surgical results To determine which type of operation was more satisfactory from the surgical standpoint we noted all of the cases in which surgical procedure on the cervix or in the vaginal vault was required subsequent to subtotal hysterectomy or to total hysterectomy. In 2 cases in which subtotal hysterectomy had been carried out prolapse developed which required excision of the cervical stump and a plastic vaginal operation. Prolapse of the vaginal vault did not occur in any case in the group in which total hysterectomy had been performed. The type of secondary procedure most commonly required on the cervical stump was the application of cautery for chronic cervicitis. The secondary procedure most commonly employed among the group in which total hysterectomy had been done was removal of a vaginal polyp. In most instances situated at the point where the vaginal wall was everted at the time of the primary surgical operation. In the group of patients mentioned earlier who presented the lowest surgical risk the incidence of secondary

surgical procedures after subtotal hysterectomy was almost twice as high as after total hysterectomy (Table I).

Among the 1,920 patients who had been subjected to total hysterectomy it was surprising that during the 5 year period of observation prolapse of the vaginal vault did not occur. Further to investigate this point we examined the records of all cases in which operation for vaginal prolapse had been performed during the same 5 year period (1935 to 1939 inclusive). In only 1 case had total hysterectomy been performed there were 23 cases of prolapsed cervical stump. The interesting point about these cases is that in the majority nearly 10 years elapsed between the original operation and the return for the secondary procedure. On this basis, vaginal prolapse among the group reported in this paper will not become evident for several years. This time element seems reasonable when the normal atrophy relaxation, and obesity that occur among most women from 40 to 60 years of age are considered. In 20 per cent of the cases of prolapsed cervical stump, the prolapse was evident before surgical intervention and recurred shortly afterward. The results in this small group emphasize the advisability of performing an associated vaginal plastic operation in such cases if relaxation is present at time the uterus is removed.

Postoperative complications Among the group of patients who were excellent subjects for operation the complications were classified as follows: (1) postoperative intestinal obstruction, (2) postoperative hernias, (3) poorly healed wounds, (4) parotitis and (5) pulmonary complications. The incidence of each type of complication was about the same after total hysterectomy as after subtotal hysterectomy. There was not any statistically significant difference in incidence of these complications among 1,497 cases in which the only known variable was the type of hysterectomy performed.

The one outstanding exception to the incidence of postoperative complications was observed after total hysterectomy. In 8 cases of 1,034 in which total hysterectomy was performed there developed postoperative bleeding that required active treatment for control. In

TABLE I—INCIDENCE OF SECONDARY PROCEDURES CASES OF LEAST RISK

Procedure	Cases	Second operation required	Per cent
Total hysterectomy	1034	12	1.2
Subtotal hysterectomy	463	11	2.38
Total	1497	23	1.5

practically every case the bleeding was from the everted vaginal mucosa. In the 463 cases in which subtotal hysterectomy was performed postoperative hemorrhage did not take place. The vaginal wall is not cut in carrying out subtotal hysterectomy, consequently, the possibility of hemorrhage from this site does not arise.

In a previous paper (4) we stated that the incidence of pulmonary emboli is higher after subtotal hysterectomy than after total hysterectomy. The explanation of this difference probably is related to the engorgement of the lymphatic channels from the retained cervical stump and to the associated secondary thrombosis in the veins of the broad ligament. Similarly, we demonstrated (4) that the incidence of thrombophlebitis is higher after subtotal than after total hysterectomy.

On the other hand we showed (4) that the incidence of urinary complications following total hysterectomy is higher than that following subtotal hysterectomy. This variation is due to the fact that the dissection of the bladder required in total hysterectomy is wider than in subtotal hysterectomy and therefore causes greater trauma and possibly more damage to sympathetic nerve fibers, resulting in temporary urinary retention which necessitates catheterization for relief. The incidence of vesical infection is parallel to the number of catheterizations, and consequently is higher after total hysterectomy than after the subtotal procedure.

In an earlier paper we demonstrated (4) that the mortality rate in the presence of pelvic infection following total hysterectomy is much higher than following subtotal hysterectomy. The reason for this apparent fact is not definitely known.

Type of convalescence. Much has been said regarding convalescence after total or subtotal hysterectomy. The question of which type of operation carries the least postopera-

TABLE II—DIFFERENCE IN MORTALITY RATES ENTIRE GROUP

Procedure	Cases	Hospital deaths	Per cent
Total hysterectomy	1920	15	0.78
Subtotal hysterectomy	764	8	1.04
Entire group	2684	23	0.85

tive reaction has been argued in both directions. In order to satisfy our own minds on these points we selected 458 consecutive uncomplicated cases in which hysterectomy had been performed during a single year. Three hundred and forty-eight of the patients had total hysterectomy and 110 had subtotal hysterectomy. In each case record was kept as to (1) the highest peak of fever reached postoperatively, (2) the number of days the temperature remained at 100 degrees F (37.8° C) or was higher, and (3) the length of the patient's stay in the hospital. In each regard there was a slight, though definite, difference in favor of subtotal hysterectomy. For any given number of the patients who had total hysterectomy, the fever reached a peak from 0.5 to 0.75 degrees F higher than for the same number who had subtotal hysterectomy. In regard to the duration of fever higher than 100 degrees F (37.8° C) recordings in comparable groups revealed that in the cases in which total hysterectomy was done there was roughly a half day more of fever than when subtotal hysterectomy was performed. The postoperative stay in hospital was a third of a day longer for patients who had total hysterectomy than for those who had subtotal.

The number of cases here presented seems adequate to afford a definite deduction as to the postoperative reaction of patients to these two types of operation. Beyond question, in comparable cases the operation of total abdominal hysterectomy is associated with a sharper and more prolonged reaction than is subtotal hysterectomy.

Mortality. The foregoing statement suggests that the mortality rate should be higher in the group of patients who are subjected to total hysterectomy. An analysis of the hospital deaths, however, does not substantiate this assumption. Table II demonstrates that the mortality rate following total hysterectomy is 0.26 per cent lower than that following

TABLE III.—DIFFERENCE IN MORTALITY RATES CASES OF LEAST RISK

Procedure	Cases	Hospital deaths	Per cent
Total hysterectomy	34		8
Subtotal hysterectomy	493	4	85

subtotal hysterectomy. This figure takes on more significance when it is seen that the mortality rate for the entire group is only 0.85 per cent. When only the patients who were excellent subjects for operation are considered, the difference is even more pronounced. Table III indicated a mortality rate 0.68 per cent lower for the group in which total hysterectomy was performed.

Peritonitis remains the cause of death most commonly encountered. Thirteen of the 23 hospital deaths were due to this complication. Four deaths were caused by pulmonary emboli, 2 by bronchopneumonia and 1 each by (1) acute nephritis, (2) shock (3) atelectasis, and (4) postoperative hemorrhage.

Nine of the 23 deaths from peritonitis occurred in the group of patients who had total hysterectomy. The remaining 4 followed subtotal hysterectomy. The incidence was practically the same for the two types of procedure, 9 in 1,920, or 0.46 per cent, for the former type and 4 in 764, or 0.52 per cent for the latter.

From these figures it would seem that neither operation offers a difference in the possibility of subsequent development of fatal peritonitis. However as we demonstrated previously among those patients who present evidence of infection at the time of surgical intervention the mortality rate is definitely higher following total hysterectomy than following subtotal hysterectomy. For this group of patients, therefore, the operation of choice is subtotal hysterectomy.

SUMMARY

In a review of 2,684 consecutive cases in which abdominal hysterectomy was performed for benign conditions, analysis was made of the postoperative complications and of the results obtained. Of the 2,684 patients, 1,920

were subjected to total hysterectomy and 764 to subtotal hysterectomy.

Total abdominal hysterectomy is favored by the following considerations: (1) The cervix as a possible source of subsequent malignant change is eliminated. (2) The cervix as a focus of infection is removed completely. (3) A more stable vaginal vault is obtained and secondary operations are obviated. (4) The incidence of postoperative pulmonary emboli and postoperative thrombophlebitis is lower. (5) The mortality rate is lower.

Subtotal hysterectomy also is favored by various considerations: (1) The postoperative reaction of the patient is less marked. (2) The incidence of urinary complication is lower. (3) There is not any danger of secondary hemorrhage from the vaginal vault. (4) In cases in which infection is present at the time of surgical intervention the mortality rate is lower.

CONCLUSIONS

Comparison of the postoperative complications and the results in the two groups of cases furnished the basis for our conclusions.

1. The elimination of the cervix as a source of subsequent trouble and the lower mortality rate associated with its removal far outweigh any known complication that may arise after total abdominal hysterectomy.

2. Except for cases in which infection is present at the time of operation, total hysterectomy apparently is the operation of choice when surgical removal of the uterus for benign conditions is indicated.

3. The secondary hemorrhage from the vaginal vault and the increased urinary complications which follow total hysterectomy usually respond satisfactorily to appropriate treatment.

A STUDY OF THE MECHANICS OF BILE FLOW

III Responses to Pharmacological Stimuli

DONALD D KOZOLL, M D , and H NECHELES, M D , Ph D , Chicago, Illinois

IN an earlier paper (12) we have described the method of simultaneously observing the effects of those structures we considered most important in controlling the flow of bile. In that communication we also reported our observations on the influence of physiological intravenous solutions upon these structures. In a subsequent report (13) we described the effects of instillation of various solutions into the duodenum. In the present paper we wish to present the results of stimulating the gall bladder, sphincter of Oddi, and the duodenum with pharmacological agents introduced intravenously. The experimental technique is identical to that used in the two reports mentioned.

Adrenalin was injected intravenously fourteen times into 12 dogs, 0.1 cubic centimeter of a 1:1000 solution was the usual dose. The variability in the response of the gall bladder to adrenalin has been recognized in the literature and our results on the effect of adrenalin on the sphincter and duodenum, in addition, illustrate a similar variable effect. In a number of animals the response of the sphincter was diphasic, i.e., an initial decrease of its tone was followed by a secondary rise. In the duodenum the effect was one of a transitory inhibition of activity and decrease in tonus, followed by a rise in tonus and motility concomitant to the secondary rise in sphincteric resistance. The degree of response varied among different dogs, and in some the only effect seen was the rise in sphincteric and duodenal tone. In the latter group the gall bladder showed a relaxation but no change in motility. In one animal the drop in sphincteric resistance far exceeded the subsequent rise above normal and at the same time the gall

bladder contracted instead of relaxing as was more commonly observed. Lueth (15) has drawn attention to the fact that the effect of adrenalin on the sphincter varies with dosage.

The use of another member of the adrenalin group, epinine (0.2 c.c. of a 1:100 solution intravenously) gave similar variable results (Fig. 3). With this latter drug the gall bladder showed contractions more frequently than with adrenalin. Ephedrine gave responses in no respect different from those of adrenalin and epinine.

Propadrine hydrochloride injected intravenously in 20 milligram doses gave similar but less marked results in the individual animal. The characteristic rise in blood pressure following intravenous injections of medium doses of adrenalin and epinine was usually followed by a subsequent drop below normal, this secondary drop was absent in the case of ephedrine and propadrine.

The effect of adrenalin was diminished but not abolished by a previous injection of trasentin or of atropine. It may be of significance that the same animal usually responded in a uniform manner to any of these adrenergic drugs used. This would imply that another explanation of the variable responses to injections of sympathomimetic drugs may lie in the individual response to stimulation of the autonomic system.

Houssay and Rubio found that the sympathomimetic drugs relaxed the isolated, perfused gall bladder, adrenalin being more effective than ephedrine. After atropine, these drugs still had the same effect. Other literature is quite contradictory. Some (1) describe contraction of the gall bladder on direct application of adrenalin. Some describe a diphasic (1) or triphasic (27) response with large intravenous doses. Necheles found contraction of the gall bladder in normal unanesthetized dogs (19).

From the Department of Gastro Intestinal Research, Michael Reese Hospital.

A preliminary report was read at the meetings of the American Physiological Society, April 19, 1941, Chicago.

Dr. Kozoll, Bernard Portis Research Fellow in Surgery.

Fig. 1. At 1 prostigmine, given intravenously produced an initial simultaneous spasm of the sphincter and duodenum. Subsequently duodenal tone rose steadily while sphincter tone remained practically normal. At 25 and 26 repeated intravenous doses of acetylcholine, produced slight immediate effects. Thereafter, diphasic relaxation and contractions of the sphincter occurred, independent of unsustained tonic contraction of the duodenum. At 3, papaverine, 1 showed simultaneous rise in the tone of the sphincter and duodenum, however the sphincter relaxed while elevated duodenal tone persisted. The gall bladder showed an immediate small relaxation. Codeine produced simultaneous immediate spasm of sphincter and duodenum.

Fig. 2. At secretin-cholecystokinin preparation, 1 produced marked tonic contraction of the gall bladder which persisted for approximately 30 minutes. An increase in duodenal tone and motility occurred simultaneously, but sphincter pressure was hardly affected. At 25 and 26, acetylcholine, given intravenously produced relatively small changes in duodenum and sphincter. At 3, intravenous prostigmine, produced marked recurring simultaneous spasms of sphincter and duodenum. Gall bladder showed only respiratory effect. At 4, units of padutin produced moderate spasm of sphincter no particular change in duodenum, and small contraction of the gall bladder.

Acetylcholine was injected in 5 animals in doses varying from 5 to 50 gamma intravenously. In only one instance was there a significant effect. In this case there was a marked lowering of intraductal pressure associated with recurrent episodes of duodenal spasm. The gall bladder showed no response. In all

other cases the response was relatively insignificant, except when a dose as large as 50 gamma was given. However when the injection of acetylcholine was preceded by prostigmine (Fig. 1) it was usually effective in eliciting moderate rises in intraductal pressure and duodenal motility. Lueth (15) described in-

Fig 3 At 1, a recurrent diphasic response of the sphincter of epine given intravenously, was seen. Note, that a fall of sphincter pressure was followed by a rise above normal. An elevated sphincter pressure persisted even when the duodenum had relaxed from its recurrent spastic contractions. The gall bladder showed a marked prolonged tonic contraction. This animal responded in a similar manner to adrenalin and propantholol. At 2, intravenous prostigmine, produced several recurring sphincter spasms which preceded and persisted long after the duodenum had relaxed from a prolonged spasm. Gall bladder showed no significant changes. At 3, intravenous codeine, produced a marked immediate spasm of sphincter and duodenum. No effect on gall bladder.

creases in sphincter pressure and duodenal tone due to acetylcholine. Sandbloom, Voetglin, and Ivy attribute any gall-bladder contractions with this drug to changes in liver volume.

Prostigmine in 0.2 to 0.25 milligram doses intravenously was effective in every case of 12 animals in producing a marked sphincteric and duodenal spasm and usually no effect on the gall bladder (Figs 1 and 3). Under the influence of prostigmine, we have frequently seen the sphincter relax in the midst of a prolonged duodenal spasm, and vice versa (Figs 1 and 3). We have had occasion to refer to this independent activity of these two structures under other conditions in our previous publications (12, 13). No significant increase in the tonus or motility of the gall bladder was observed. In one atropinized animal prostigmine was completely without effect (Fig 4). Our results with this drug are compatible with the reports of others using physostigmine (3, 5, 14).

Pilocarpine 0.5 to 1 milligram intravenously, produced marked gall-bladder contractions

and a simultaneous rise in sphincteric pressure and duodenal tone in every one of the 8 cases in which it was used (Fig 6). A 25 milligram dose of traserutin abruptly abolished the tonic contraction of the gall bladder produced by pilocarpine in one dog. The ability of pilocarpine to contract the gall bladder is generally recognized (3, 11, 14, 22, 27, 29), but its inability to evacuate the gall bladder is attributed to the sphincteric spasm which occurs at the same time (5, 9, 29).

Five milligrams of a secretin-cholecystokinin preparation was injected intravenously 8 times in 7 animals. In each instance an immediate tonic contraction of the gall bladder and duodenum followed (Fig 2). This is in agreement with previous work (2, 8, 10, 26). After an interval of several minutes an increase in sphincteric resistance occurred, during this interval we believe effective gall-bladder evacuation can occur (Fig 2). The tonic contraction of the gall bladder was considerable and persisted for 20 or more minutes, long after duodenal or sphincter spasm had subsided. The dose of secretin-cholecys-

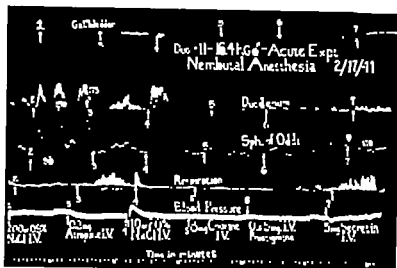

Fig. 4. The effect of tropine on spasm producing agents. At normal saline, gives intravenously produced recurrent increases in sphincter tone, concurrent with duodenal activity. At 3, intravenous atropine, inhibited both of these responses. At 4, intravenous hypertonic saline, produced its usual spastic effect on the sphincter and duodenum. At 5, intravenous codeine, was completely without its usual effect. At 6, intravenous proglumine, as likewise ineffective. At 7, secretin-cholecystokinetic preparation produced marked tonic contraction of the gall bladder without duodenal and sphincter response probably due to the atropinization.

Fig. 5. At intravenous papaverine produced precipitous drop in sphincter pressure previously produced by normal saline, with gradual return to previous levels. The duodenum was inhibited and the gall bladder relaxed somewhat. At intravenous traseptin was followed by an immediate drop in sphincter pressure while duodenal tone and motility were at first unaffected. Gall-bladder tone dropped slightly. The sphincter pressure was maintained at low level, while later duodenal activity was inhibited for shorter period of time. Gradually there was return to previous state of activity.

tokinin used had no significant effect upon blood pressure. Previous administration of

atropine or traseptin had little or no influence on the effects of this drug (Figs. 4 and 6)

The response of the sphincter and duodenum to papaverine in 8 to 15 milligram doses, intravenously, showed considerable variation. In 5 of 10 cases there was an initial relaxation followed by a subsequent rise to or above normal (Fig 5), in others, spasm of sphincter and duodenum were a dominant effect (Fig 1). In every instance that papaverine had an effect on the gall bladder, it was one of moderate relaxation (Figs 1 and 5). Papaverine produced relaxation of a tonic contraction of the gall bladder produced by cholecystokinin in 2 dogs. This relaxing effect of papaverine on the gall bladder has been observed by others (9, 18).

Four to 8 milligrams of codeine produced marked increases in sphincteric tone and duodenal peristalsis in every case in which it was employed (Figs 1 and 3). The effect was immediate and did not appear to influence the gall bladder. Previous injections of atropine and traserutin reduced or abolished the effect of codeine (Figs 4 and 6). The literature is replete with accounts of the spastic effect of opiates on all smooth muscle (7, 23, 24). Although no specific information is available on the influence of codeine on the gall bladder, a closely related alkaloid morphine is thought to be without really significant effect (8, 14, 17, 27).

Atropine, 0.2 to 0.3 milligram intravenously abolished the tonus rhythm of the sphincter as well as duodenal motility. The depressant action of atropine on intestinal activity is well known (6, 15, 24). The small doses employed of this drug did not actually lower intramural pressure, but rather inhibited the occurrence of spasms. The same doses of the drug were without effect on the gall bladder other than a slight decrease in tonus rhythm.

Various agents, of known ability to produce spasms of the sphincter and duodenum, were given after atropinization with the following results. Atropine was ineffective in abolishing the spasm of the sphincter and duodenum produced by gastric juice introduced into the duodenum, of intravenous adrenalin, and of intravenous hypertonic saline (Fig 4). The effect of prostigmine (Fig 4) and of normal saline intravenously (Fig 4) was abolished and the effect of codeine (Fig 4) was either

Fig 6 At 1, intravenous pilocarpine produced an immediate tonic contraction of the gall bladder of about 20 minutes duration. Simultaneously a moderate increase in the tonus of the duodenum ensued with a similar response of the sphincter after more of an interval than is usual. At 2, intravenous traserutin, a synthetic antispasmodic, produced a significant relaxation of all three structures. Intraduodenal instillation of a mixture of egg yolk and cream at 3 produces a contraction of all three structures despite the previous antispasmodic medication. Likewise, another injection of traserutin at 4, did not influence the effect of a secretin-cholecystokinin preparation injected intravenously at 5.

reduced or completely inhibited. Secretin was capable of producing a moderate gall-bladder contraction following atropinization. Ivy (9) reported that the effect of cholecystokinin on the gall bladder was not prevented by atropine. We were not able to confirm the relaxation of the gall bladder with atropine noted by many workers (9, 10, 11, 14, 16), although we occasionally saw a decreased tonus rhythm, however, we used relatively small doses of atropine.

Traserutin A had similar effects as atropine, in doses of 10 to 25 milligrams intravenously (Figs 5 and 6). As with atropine, the effects of adrenergic drugs were not influenced, nor was hypertonic saline, intraduodenal instillation of gastric juice, or egg yolk, or secretin-cholecystokinin. Traserutin relaxed a tonic contraction of the gall bladder induced by pilocarpine in one dog. The new traserutin A preparation which was used did not seem to have such pronounced effects on relaxation of the gall bladder as traserutin was reported to have had (21).

Pituitrin was administered intravenously to 3 animals, and in all 3 a moderate gall-bladder contraction occurred before a moderate rise in sphincter pressure and duodenal spasm, the latter followed after an interval of several

minutes. The contraction of the gall bladder following intravenous surgical pituitrin does not compare with that produced by cholecystokinin or pilocarpine. An initial decrease preceding the rise of tone of the sphincter and duodenum described by some (5-15) was not seen. Gall bladder contraction with pituitrin has been described by others (8).

Decholin 0.5 to 1 cubic centimeter was injected intravenously into 4 dogs, with varying results. There was no characteristic response of the sphincter or duodenum, but the gall bladder relaxed in 3 of the 4 animals used. The use of this drug was associated with a marked increase—about 50 per cent—in the flow of bile collected from the hepatic ducts.

A urinary extract with vasodilator properties, padutin, was investigated. The drug had variable effects on the sphincter and duodenum in a normal state of tone but appeared to relieve a state of spasm of the sphincter produced by other measures.

Nitroglycerin and amyl nitrite also produced temporary relaxation of the sphincter from a spastic state. Theophylline had no significant effects.

Experiments on human subjects. Patients that had been subjected to cholecystectomy and common duct drainage were utilized after biliary drainage had been established and the patient recovered from the operation. Similar to the procedure of Doubilet and Colp and Walters et al the common duct was perfused with saline solution and connected to an oil-carbon tetrachloride manometer which accurately indicated the resistance of the sphincter of Oddi to the flow of perfusion. Various drugs were administered by injection, orally or admixed to the perfusion fluid. It is beyond the scope and extent of this paper to discuss these results in detail, and they will be reported separately (20) but it may be stated that a number of observations on the dog reported, were corroborated on the human.

ANALYSIS OF STUDY

The most important factor in the emptying of the gall bladder ought to be that of reciprocal innervation of the gall bladder on the one side and sphincter and duodenum on the other. This process has been described as

contraction of the gall bladder with simultaneous relaxation of the sphincter of Oddi and duodenum. Whether such a reflex exists or not, it is apparent that emptying of the gall bladder can occur only if during contraction of this organ the sphincter and duodenum do not remain contracted all the time. In other words if there is no orderly reciprocal innervation there must be at least temporary periods of relaxation of sphincter and duodenum during contractions of the gall bladder in order to permit a more or less effective emptying of that organ. We have analyzed these possibilities in our experiments and therefore can answer the above question. The gall bladder may empty either by reciprocal innervation or by contraction of the gall bladder during temporary relaxation of both sphincter and duodenum either waves of duodenal contractions pass over the sphincter leaving it open during the intervals between waves, or the rhythmic opening and closing of the sphincter continues and emptying occurs in these animals with a more or less quiet duodenum or third, both of these possibilities are combined. The occurrence of these combinations can be studied from the illustrations. For instance in Figures 2-4 and 6 following the administration of secretin-cholecystokinin, a marked gall-bladder contraction occurred, which persisted for 20 or more minutes. Although waves of moderate duodenal contraction are immediately induced, sphincter pressure remains low enough for a long enough interval against which the gall bladder could effectively evacuate.

The experiments here reported demonstrate that emptying of bile through the sphincter of Oddi and the emptying mechanism of the gall bladder depend on a number of processes, the timing and intensity of which are the determining factors. It is also demonstrated that reciprocal innervation of gall bladder and of the duodenum and sphincter of Oddi may occur but it is not a necessary assumption for the emptying reflex of the gall bladder. It is further evident that a combination of drugs may offer great possibilities for the eventual substitution of the fat meal usually employed in cholecystography. Experiments to answer this question are in progress.

SUMMARY

- 1 The response of the sphincter of Oddi to drug stimulation can be independent of duodenal activity
- 2 The emptying mechanism of the gall bladder and the flow of bile through the sphincter of Oddi depend upon a number of processes, the timing and intensity of which are the determining factors
- 3 Reciprocal innervation of the gall bladder, the sphincter of Oddi, and the duodenum may possibly occur, but it is not a necessary assumption for the emptying reflex of the gall bladder
- 4 Adrenergic drugs which were employed in this study consisted of epinephrine, epinine, ephedrine, and propradrine, all members of this series produced such variable results that they appeared to offer little clinical application
- 5 Cholinergic drugs employed were acetylcholine, prostigmine, and pilocarpine. All of these produce contractions of the sphincter and duodenum, of varying degree, and also contractions of the gall bladder in the case of pilocarpine
- 6 Codeine produced subtetanic contractions of the sphincter of Oddi and the duodenum without affecting the gall bladder
- 7 Secretin-cholecystokinin produced the most effective contractions for evacuation of the gall bladder, but no reciprocal mechanism was evident
- 8 The most effective spasmolytic drugs in our hands were found to be atropine and traseratin
- 9 The possibility of a combination of drugs which would produce effective gall-bladder evacuation against a relaxed sphincter of Oddi is suggested as an eventual substitute for the fat meal usually employed in cholecystography

Fig 1 The lumen is dilated throughout. Mucosal and submucosal layers show atrophy.¹

6, appendices showing no evidence of obstruction

Group 1 presents a uniformly dilated lumen (Fig 1) from the proximal end to the tip. The changes in the mucosa and submucosa were variable. In some these were quite marked, showing thinning, diminution in number and length of glands with loss of submucosal lymphoid tissue. The muscle layers were thinned. In specimens in which atrophy of the layers was present, the mucosa always presented the most marked change.

In other specimens the wall was thick with hyperplastic lymph follicles having an oblong shape, the long axis being parallel with the circumference of the lumen (Fig 2).

In Group 2 the proximal segments were dilated. Then there was a variable sized lumen to the tip. This variation usually occurred in the midthird (Fig 3). The lumen was small, slit-like, the mucosa appearing normal and the lymphoid tissue abundant.

¹The photographs are mounted so that the upper left segment is the base of the appendix and the lower right segment is the tip.

Fig 3 The lumen is dilated in the 2 proximal segments, slit like in the third and fourth segments, and increasingly distended in the fifth, sixth, seventh, and eighth segments. Lymphoid hyperplasia is present throughout.

Fig 2 The lumen is dilated throughout the first 5 segments. There is hyperplasia of the lymphoid tissue. The germinal centers are elongated, their long axis parallel to the circumference of the lumen.

Then two or three sections might be encountered with areas of luminal dilatation and mucosal thinning.

Group 3 showed evidence of a variable sized lumen along the appendix (Fig 4). The first segments showed a narrow lumen. Then the lumen was uniformly dilated to the tip, or it would show several points of narrowing with interdilatation.

Group 4 showed a uniformly small lumen (Fig 5) with the submucosa markedly thickened due to a large amount of fibrous tissue in the submucosa. The mucosal glands, although decreased in number, were normal in size.

Group 5 showed partial or complete obliteration of the lumen (Fig 6). The primary change was replacement of mucosa and submucosa by a fibrous core, and one showed a neurofibroma. No conclusive evidence of pre-existing inflammation was seen.

Fig 4 The lumen is small in the 2 proximal segments with a markedly thickened wall. There is distention in the 2 distal segments. Abundant lymphoid tissue is present in the 3 terminal segments.

Fig. 5. The lumen is narrow throughout, slit like in the third segment. The wall is greatly thickened due to the increase in fibrous tissue in the submucosa.

Fig. 6. The lumen is replaced by fibrous core except in the proximal segment.

Group 6 showed no structural variations from the normal.

When the lumen was dilated either uniformly or irregularly with definite atrophic changes in the layers of the wall (groups 1, 2 and 3) it was thought that these changes were caused by accumulation of fecal material in the lumen with resultant increased intraluminary pressure, this accumulation being due to obstruction or atony of the appendix.

Group 4 showed no atrophic changes but did show a marked variation in the lumen, sufficient to obstruct partially the interchange of fecal material with the caecum.

The appearance of group 5 suggested that it might be an early phase of obliteration of the lumen as seen in group 6.

Groups 2 and 3 show histological evidence of partial obstruction in the wall due to focal lymphoid hyperplasia. We are uncertain whether this is a primary state or whether acute kinks, due to congenital bands, might have prevented the lumen from distending at these points thus preventing any pressure changes from intraluminary pressure.

Group 1 showed no site of obstruction but definite evidence of increased intraluminary pressure. It was believed that an obstruction could occur at the appendiceocecal junction since the appendix enters the cecum at an acute angle in most cases. When the angle is acute the mucosal fold at the opening (valve of Gerlach) is more prominent.

In these sections it was noted that in specimens in which the lumen was dilated if lymphoid follicles were present they were oblong in shape and the long axis of the

follicle was parallel to the circumference of the lumen. This was not true if the lumen was not dilated.

Comparing these groups, obstruction occurred in 18 of 38 or 47 per cent, noninflamed specimens removed surgically in 36 of 52 or 69 per cent, inflamed specimens removed surgically and in 15 of 49 or 30.6 per cent specimens removed at autopsy.

In groups 1, 2 and 3 of the noninflamed specimens we believe that dilatation of the proximal segments indicates obstruction at the appendiceocecal junction. When there was evidence of obstruction along the appendix at one or more points, the structural variation was a comparative one. While the lymphoid tissue was comparatively abundant and hyperplastic in relation to adjacent dilated segments, actually the mucosa and lymphoid tissue in many cases were normal. We therefore, believed that extrinsic bands with acute kinks rather than true focal lymphoid hyperplasia may have been responsible for this picture.

We are not prepared to say whether lymphoid hyperplasia *per se* may produce appendiceal obstruction.

By this method of pathological examination we are of the opinion that the pathologist can make a diagnosis of appendiceal obstruction.

The third group of appendices studied consisted of 25 appendiceocecal regions removed from stillborn infants and newborn babies which had died. A representative group is shown in drawings (Fig. 7) illustrating the marked variations in position and the presence

Fig 7 Drawing of 16 consecutive specimens removed at necropsy. Numbers 1, 3, 6, 7, and 11 show both an anterior and posterior view.

of numerous congenital bands causing distortion of the appendix. The appendix was free of bands in only 7 cases. The variations seen here represent almost every type encountered surgically and are presented to emphasize the extreme distortion at birth.

The role of obstruction in the etiology of acute appendicitis has long been recognized (5, 7, 11, 12, 13, 14, 15, 16). However, when one peruses the literature on "chronic appendicitis," evaluation becomes extremely difficult because there is no uniform classification which is followed by the clinician and the pathologist.

The term "chronic appendicitis" as generally used has ceased to be a disease entity but rather a 'catch all' for those cases not showing active inflammation.

In the pathological department at Bellevue Hospital the following classification has been used:

1. Inflammatory
 - acute
 - chronic
 - nonspecific
 - specific
2. Non-inflammatory
 - obstructed with
 - lymphoid hyperplasia
 - sclerosis
 - atrophy etc
 - nonobstructed
 - lymphoid hyperplasia
 - sclerosis
 - atrophy etc
3. Neoplastic
 - benign
 - carcinoid
 - neurofibroma etc
 - malignant—carcinoma etc

The term chronic appendicitis is used only when signs of active chronic inflammation are

present. This represents less than 5 per cent of all appendices examined.

Many explanations have been given for the cause of pain in the noninflamed appendix. Barrs, in 1918, reported 7 cases of appendiceal disease in children all cured by appendectomy in which the pathological diagnosis was lymphoid hyperplasia.

Symmers reported 20 cases with similar pathological changes and symptoms simulating those of mild appendicitis with cures following appendectomy.

Follow up records show that between 50 and 80 per cent of the patients in this general group operated upon are cured or markedly improved yet both surgeon and pathologist have been unable to distinguish the offending appendices from those which did not give symptoms.

Since histological evidence of disease is lacking one is forced to turn to disturbances in function for an explanation of the symptoms.

In *Human Physiology* by Flint, 1892 this statement appears: "The function of the appendix is unknown." Certain recent physiological textbooks fail to mention the organ. Dufor (10) in 1890 advanced the theory that the appendix plays a great part in provoking a desire for defecation independent of other reflexes involved in the act. Adams and McCrae (10) in 1914 stated: "It is the appendix that is the hydrostatic agent initiating peristalsis in the large gut." These views have not been widely accepted and Flint's statement still stands: "The function of the appendix is unknown."

Although no useful function has been established, we do know that it functions as part of the large bowel that it is capable of filling and emptying and that the peristaltic action is similar to that of the large bowel (13).

Anatomically the appendix vermiformis must be considered as an undeveloped cecum. Embryologically the appendix is a retrogressive organ having a relatively higher development in the fetus than in the infant, and must be considered merely as the distal portion of the cecum (7).

Differentiation between cecum and appendix starts about the seventh week and con-

tinues to birth when the comparative diameters are 1:4. At 8 years it is 1:6 or 7 and in the adult the ratio is 1:8 or more. One would, therefore, consider comparative retrogression not complete until puberty (7).

The relative location of the appendix is the most variable of any organ in the peritoneal cavity. The location depends on the point of origin from the cecum and varies, first according to the direction of the cecal pouch, and second according to the presence of peritoneal bands which permit following complete rotation of the large bowel.

The appendix is found free of congenital peritoneal bands and entering the cecum at a right angle in about one-third of the cases. The angle at which the appendix enters the cecum varies between 10 and 90 degrees.

The clinical syndrome with which the obstructed appendix is associated is well known. Pain in the right lower quadrant is the one constant symptom steady or intermittent, frequently associated with anorexia, nausea, and occasional vomiting. The patients are frequently constipated. The only constant sign is tenderness in the right lower quadrant centering over McBurney's point usually associated with skin hyperesthesia (8). Evidence of active inflammation is lacking. The temperature is normal and the blood count not elevated.

Can the appendix give these symptoms and signs without showing any evidence of inflammation? We believe it can, and does.

It has been shown (8) that distention of the lumen of a normal appendix will give epigastric pain, nausea and pain in the right lower quadrant associated with persistent skin hyperesthesia. This was done through appendicostomies. Therefore it is reasonable to assume that increased intraluminal pressure due to natural causes can give the same clinical symptoms and signs.

The appendix is a tube, blind at one end and lined with intestinal mucosa capable of secretion and absorption. It opens into the cecum. Intestinal contents reach the cecum in a fluid state, some entering the appendix. Dehydration occurs, and any variation in the diameter of the lumen will favor stasis and accumulation of fecal material. This process

we believe, will cause distention of the lumen with resultant changes in the mucosa which can be demonstrated histologically by the method of examination herein described.

Anatomically, three methods of obstruction are possible: (1) kinking at the appendicocolic junction, (2) kinking along the length of the appendix due to peritoneal bands, and (3) intra-appendiceal stenosis due to lymphoid hyperplasia or fibrosis.

The point of origin of the appendix from the cecum varies according to the direction of the cecal pouch, and the appendicocolic angle is dependent on the position and development of the peritoneal bands which, in turn, depend on the ultimate position of the large bowel.

Intrinsic obstruction occurs due to variations in the thickness and structure of the wall with consequent encroachment on the lumen.

The first two causes of obstruction, namely, an acute appendicocolic angle and kinking due to peritoneal bands, will be seen only by the surgeon, and in writing up the operation, these details are frequently omitted. Consequently, this information does not reach the pathologist. However, the third cause, namely, intrinsic obstruction, can be seen by the pathologist, but unless the specimen is studied carefully, evidence for intrinsic obstruction may not be recognized.

SUMMARY AND CONCLUSIONS

1. Histological criteria for diagnosing appendiceal obstruction are submitted.

2. Appendiceal obstruction was demonstrated in 18 of 28, or 64 per cent, noninflamed specimens removed surgically, in 36 of 52, or 69 per cent, inflamed specimens removed sur-

gically, and in 15 of 49, or 30.6 per cent specimens removed at autopsy.

3. This obstruction is believed to be mechanical rather than inflammatory. The etiological factors for obstruction are present at birth.

4. An obstructed appendix may give symptoms without the presence of inflammation.

5. An obstructed appendix definitely predisposes to acute appendicitis.

6. Appendiceal obstruction may exist without giving signs or symptoms.

SUBACUTE STREPTOCOCCUS VIRIDANS SEPTICEMIA CURED BY EXCISION OF AN INFECTED TRAUMATIC ARTERIOVENOUS ANEURYSM

ARTHUR S W TOUROFF M D F A C S HERMAN LANDE, M D and
IRVING KROOP M D New York, New York

THE rarity of coexisting acquired arteriovenous aneurysm and subacute *Streptococcus viridans* septicemia, is indicated by the fact that up to the present time only 10 such cases have been recorded in the literature. For purposes of classification they may be divided into two main groups.

The first group consists of cases in which the septicemia precedes, and is responsible for the formation of the aneurysm. Such a sequence sometimes is observed in subacute bacterial endocarditis, of which mycotic arteriovenous aneurysm may be a late complication. Cases have been reported by Masbrenier, Simmonds, Libman and Floyd.

The second group consists of cases in which arteriovenous aneurysm is the primary condition and subacute bacterial septicemia the complication. Primary arteriovenous aneurysms (and fistulas) may be either congenital or acquired. Among the better known congenital arteriovenous communications (fistulas) may be mentioned patent ductus arteriosus, patent interauricular septum, and patent interventricular septum. Acquired primary arteriovenous communications (aneurysms) are exclusively traumatic in origin and most commonly are due to gunshot or stab wounds.

Should a patient with an arteriovenous communication of either the congenital or acquired variety develop a transient bacteremia from some extraneous source organisms may lodge upon the intimal lining of the arteriovenous lesion. Under such circumstances, vegetations may develop locally, thus there is established a new infective focus from which organisms are shed into the blood

stream more or less continuously. When these organisms are of low virulence the patient suffers from a condition termed subacute bacterial septicemia." The organism most commonly involved in the latter is the *Streptococcus viridans*.

The frequency with which subacute *Streptococcus viridans* infection develops at the site of congenital arteriovenous communications, especially those located within the heart is well known and many such cases have been collected by Abbott. The superimposition of similar infection upon acquired arteriovenous communications (aneurysms) although observed less commonly has been reported by Bretschneider, Wala, Gravier, Porter and Williams, Hamman and Rienhoff and Leaman. When subacute *Streptococcus viridans* infection develops at the site of an acquired or congenital arteriovenous communication and organisms continue to be shed into the blood stream, new infective lesions may develop at distant points. One of the most common sites for such secondary localization is upon the endocardium and cardiac valves. When this occurs, the fresh cardiac lesions constitute additional infective foci which themselves are capable of perpetuating the sepsis.

Although arteriovenous communication existing in combination with subacute *Streptococcus viridans* septicemia formerly was considered to be of interest only to the pathologist and internist it recently has attracted the attention of the surgeon also. This interest was initiated in 1935 by the report of Hamman and Rienhoff of the first case in which cure of subacute *Streptococcus viridans* septicemia followed excision of an infected, acquired

From the Convalescent Service, the General Service of Dr. Harold Neufeld and the Medical Service of Dr. George Baehr, The Mount Sinai Hospital, New York.

The first surgical cure of subacute *Streptococcus viridans* septicemia superimposed upon "congenital arteriovenous" (patent ductus arteriosus) reported by Tauxel's work in 1936.

arteriovenous aneurysm of the right external iliac artery and vein. These authors emphasized that surgical excision of an infected arteriovenous aneurysm is futile in cases in which vegetations coexist in the heart. For under such circumstances, even though the aneurysm is removed completely, the cardiac vegetations will continue to act as a focus for perpetuation of the sepsis. Thus, operation is contraindicated in cases of mycotic arteriovenous aneurysm occurring as a complication of subacute bacterial endocarditis. For the same reason, operative treatment also is contraindicated in cases of infected, primary arteriovenous aneurysm in which the cardiac valves have become involved secondarily. Accordingly, the only cases which remain amenable to surgical treatment are those of infected, primary arteriovenous aneurysm in which infection has remained confined exclusively to the local site. Under the latter circumstances, local excision of the aneurysm may result in cure.

Since the report of Hamman and Rienhoff, no other instance of cure of subacute Streptococcus viridans septicemia following excision of an infected arteriovenous aneurysm has been recorded in the literature. It therefore appears warranted to report a second successful case in detail.

REPORT OF CASE

R W, a native born white male aged 26 years, single and a clerk, was admitted to the consultation service of The Mount Sinai Hospital on February 2, 1941, because of fever, malaise, and progressive weakness of approximately 1½ years' duration. During childhood he had had measles, pertussis, and scarlet fever, without sequelae. The surgical history included a bilateral inguinal hernioplasty performed at the age of 5, and a tonsillectomy performed at the age of 7 years.

On entering high school at the age of 14, he was examined by a physician and, because of "frail constitution," was advised to abstain from strenuous athletics. No evidence of any cardiac abnormality was present at the time. Despite the advice of his physician, he participated actively in athletics, including bicycle riding, running, and swimming, without manifesting unusual distress or shortness of breath.

At the age of 17 years—9 years before the present admission—the patient suffered an accidental through and through gunshot wound of the left thigh. Although bleeding was profuse, he responded well to

treatment and was discharged from a local hospital, symptom free and with the wounds practically healed, at the end of 1 week. Shortly thereafter, he became aware of a peculiar "buzzing sensation" in the thigh. Because this was not associated with other obvious abnormalities, he considered it to be of no importance and failed to mention it when the history was first taken. About a year after the accident he began to suffer from fatigue and dyspnea on exertion. A diagnosis of "chronic heart disease" was made by the patient's physician at the time, but the nature of the cardiac abnormality and its relationship to the previous injury of the thigh apparently was not recognized. He was told however, that his blood pressure was 148/58, and his pulse rate 122. During the next 6 years he continued his activity as a student and then as a clerk, the symptoms of weakness, dyspnea on exertion, and cardiac palpitation becoming increasingly severe.

About 2 years prior to admission to the consultation service, a decayed molar tooth was extracted and the root canal of an adjoining devitalized tooth was filled. Soon thereafter he became acutely ill, with fever and malaise. Loss of weight, strength, and appetite, followed shortly. All of these symptoms, in addition to the pre-existing dyspnea and palpitation, continued with remissions and exacerbations during the next 8 months. About 1½ years prior to admission he suffered an attack of severe left-sided pleuritic pain associated with productive cough, but without hemoptysis. Evening rises of temperature to 103 degrees F and drenching sweats then began. These symptoms at first caused only periodic confinement to bed, but during the 3 months prior to admission the fever, sweats, and weakness, became so severe that he was bedridden most of the time. During the last month he suffered another attack of left-sided pleuritic pain and three shaking chills each lasting about 20 minutes.

During the year preceding admission he had received large doses of sulfanilamide, and during the last 3 months he had been kept continuously on sulfa-pyridine therapy.

Examination. The patient first came under the observation of one of us (H L) in the consultation service, February 15, 1941. At that time examination disclosed a thin, pale, sweating, somewhat dyspneic young man who appeared acutely and chronically ill. The temperature was 102 degrees F, pulse rate 126, and respiratory rate 22.

A summary of the essential findings follows. Arterial pulsations were distinctly visible in the vessels of the optic fundi. Forceful pulsations were present in the suprasternal and subclavicular areas, and harsh murmurs were noted over the carotid and subclavian arteries. Cardiac action was regular, the apical rate being 126 per minute. The heart was moderately enlarged to the left on percussion, diffuse forceful pulsations being noted in the fourth and fifth intercostal spaces outside the midclavicular line. The first sound here was loud and booming. The second pulmonic sound was louder than the

Fig. Preoperative roentgenogram of chest. Note enlargement of heart to the left and pulmonary vascular congestion.

secondortic sound. Over the apex and pulmonic areas, short, soft high pitched, blowing systolic murmurs were present. All pulses were of the collapsing (Corrigan) type. The arteries of both lower extremities pulsated freely, the pulsations of the vessels on the left being more forceful than those on the right.

Small, almost invisible, scars were present over the lateral and medial aspects of the midportion of the left thigh. At the same level, a plum sized expansile mass, embedded within the muscles close to the inner aspect was palpable. Over this mass, coarse thrill and harsh to-and-fro machinery murmur were readily audible. The left common femoral artery was obviously enlarged on palpation and could be seen to pulsate very vigorously. The to-and-fro murmur in the thigh could be heard down to the knee and over the great vessels of both legs. The left thigh, leg, and foot were warmer than the right. The diameter of the left thigh was greater than that of the right. The superficial veins of the left leg and foot were prominent.

The liver was palpable for a distance of three fingerbreadths, and the spleen for a distance of four fingerbreadths, below the costal margin. No petechiae, Osler nodes, or Janeway lesions were noted. The fingers were clubbed. Lightly and capillary pulsation of the nail beds was increased.

The blood pressure in the right arm was 3/70, in the left arm 24/60 in the right thigh 60/70, and in the left thigh 180/0. On firm compression of the pulsating mass in the left thigh, the pulse rate decreased from 110 and the blood pressure in the right and left arms rose to 35/80, and 3/74 respectively. Oscillometric readings at the right

thigh, calf and ankle were 33/5, 16, and 3/6 respectively. At the same levels on the left they were 20, 43/6 and 3/6.

Laboratory data. A teleroentgenogram revealed enlargement of the heart to the left and the presence of pulmonary vascular congestion (Fig. 1). On fluoroscopy the left ventricle appeared dilated. The left auricle, as not enlarged, and the general configuration of the heart was not that usually noted with valvular disease. The electrocardiogram revealed sinus tachycardia, the rate being 105 per minute. Right axis deviation was present. *RT* and *RT* were depressed slightly and *T* inverted the tracing suggesting either right ventricular hypertrophy or vertically placed heart. Upon compression of the left femoral artery the rate slowed from 5 to 90 per minute, *RT* became isoelectric and *T* upright. Upon release of compression the rate returned to 5 and *RT* and *T* assumed their original abnormality. The phonocardiogram revealed systolic murmur and a short, early diastolic murmur in the pulmonic area. The cardiac output was 7.2 liters per minute and fell to 5.5 liters upon compression of the left common femoral artery.

X-ray examination of the abdomen revealed marked enlargement of the liver and spleen. X-ray examination of the lower extremities revealed a small irregular area of calcification in the midportion of the left thigh, medial to the shaft of the femur. The specific gravity of the urine ranged from 1.020. Albumin and dextrose were absent. The microscopic examinations were essentially normal. The blood contained 4,850,000 red cells per cubic millimeter. The hemoglobin content was 6 per cent. There were 9,000 white cells, of which 70 per cent were segmented polymorphonuclear leukocytes, 1 per cent unsegmented polymorphonuclear leukocytes, 6 per cent lymphocytes, and 2 per cent monocytes. The color index was 7. The smear revealed chromia polychromasia, and anisocytosis. The erythrocyte sedimentation rate was 20 minutes (markedly accelerated). The Wassermann and Kahn tests gave negative results. The blood agglutination reactions for *Bacillus abortus* and *Bacillus melitensis* were negative. Blood cultures on two occasions yielded *Streptococcus viridans* (alpha) 5 colonies and 1 colony per cubic centimeter respectively.

For the sake of clarity the history and laboratory data have been presented in sequential order. Actually the complete history was elicited with difficulty and it was not until all the details finally were learned that appropriate clinical and laboratory investigations were carried out. For example when first questioned the patient omitted entirely the history of gunshot wound of the thigh. In view of the negative past history of rheumatic fever and cardiac symptoms during

Fig. 3 Interior of excised specimen. Probe passed through proximal artery enters aneurysm from above. Proximal vein is completely obliterated by scar tissue. Lower probe enters aneurysmal sac through the distal artery. Note that the distal vein is widely dilated and, extending downward from the point of hemorrhagic constriction, forms the lower half of the aneurysm. Diverticula (false aneurysms) are present in upper half of sac. Note particularly the scattered vegetations within the interior of the upper half of the sac and the large triangular vegetation within the lower half of the sac. Specimens taken from these vegetations revealed large numbers of streptococci, which on culture were reported as *Streptococcus viridans*.

femoral artery and vein were markedly dilated. Below the aneurysm, the deep femoral vein was found to be the site of enormous fusiform dilatation; the deep femoral artery was of very small caliber. Numerous collateral vessels, both arteries and veins, entered the main sac. The accessory sac was quite free of collaterals and apparently represented a false aneurysm—the result of a hematoma formed at the time of the original injury.

The profunda femoris artery and vein, below the aneurysm, were doubly ligated with heavy silk thread, and divided. All collateral vessels, entering and leaving the sac, also were ligated and divided. Finally the two main vessels below were ligated and divided, and the entire lesion was removed en masse.

Oozing from the dead space within the adductor muscles was controlled by temporary packing, and the wound closed by loose appositioning the deep fascias of the thigh. The skin was closed with clips. No drainage was employed. A transfusion of 500 cubic centimeters of citrated blood was administered at the conclusion of the operation.

Description of specimen. The specimen consisted of a shrunken arteriovenous aneurysm received in situ, which in the opened state measures 7.5 by

6 cm. in its largest diameters. The artery proximal to the aneurysm measures 4 cm. in length. It appears thin and elastic. The proximal vein is 5 cm. long and is entirely obliterated by dense fibrous tissue. The proximal vessels open into a multilocular cavity lined by endothelium. The distal artery measures 3 cm. in length and is patent. The distal vein, which is approximately 3 cm. long, is the site of fusiform dilatation measuring 4 cm. across when opened. At the ostium of the distal vein there is a constriction below which the enlargement of the distal vein takes place. Between the ostia of the arterial and venous channels, a flat but definite ridge is present. Thus, the opened specimen assumes an hour glass appearance. Connected with the true aneurysmal sac there are diverticula (false aneurysms) each 1 cm. in length. A third diverticulum, the size of a large hazel nut, appears to be obliterated by thrombus; the surface of which is covered by endothelium. Red and gray irregular vegetations, varying in size from the head of a pin to peas, stud the sacculus portion of the aneurysm. The more fusiform portion, formed by the dilated proximal portion of the distal vein, is the site of large, flat, triangular organizing grayish red vegetation. The interior of the fusiform portion of the aneurysm presents many sclerotic plaques. The outside of this portion of the aneurysm also presents a calcific plaque. Flat, sclerotic plaques also are present within the wall of the specimen (Fig. 3). (It is of interest to note that these calcific masses are discernible on preoperative roentgen examination of the left thigh.)

Microscopic report. "Arteriovenous aneurysm showing subacute bacterial endovascularitis (numerous gram-positive cocci) found within the cystic spaces."

Bacteriological report. Culture of vegetations which were obtained from within the arteriovenous aneurysm yields heavy growth of the *Streptococcus viridans*.

Postoperative course. The patient, immediately after operation, was extremely satisfactory. By the third postoperative day striking improvement in the general appearance and condition was noted. At that time the cardiac murmurs were almost inaudible, the pulse rate considerably slower and had lost its collapsing character. The highest postoperative temperature was 36.6 degrees F. on the second day. Thereafter it receded progressively and was normal by the 8th postoperative day. The wound was healed by primary union in 6 days and 4 days later the patient permitted out of bed. By the 10th postoperative day the systolic murmur at the apex had disappeared. A short, harsh diastolic murmur was heard over the polmonic area, only on complete inspiration. The bruit and thrill over the thigh had disappeared. The heart no longer was palpable. The spleen greatly reduced in size but still could be palpated one finger breadth below the costal margin. Four days later the spleen no longer was palpable.

Fig. 4. Graphic chart indicating temperature and blood cultures in relationship to operations.

The first blood culture, taken 4 hours after operation, was reported sterile after 14 days of incubation. Four additional blood cultures were taken on the 1st, 5th, 10th, and 16th postoperative days respectively (Fig. 4). These likewise were reported sterile after 14 days of incubation. No chemotherapy was administered during the postoperative course and accordingly the prompt disappearance of organisms from the blood stream could be ascribed only to the operative procedure. The patient was kept in the hospital for 21 days following operation in order to observe him closely and to repeat various investigative studies (Tables I, II, III). At the time of discharge, the temperature had been essentially normal for 2 weeks, and he was gaining weight and appeared to be in excellent general physical condition.

Subsequent course. Three days after returning home, the patient experienced a sensation of fullness and pressure in the abdomen. The following day severe diarrhoea developed and the temperature rose to 100.4 degrees F. During the next 5 days irregular fever, ranging as high as 103.6 degrees F, and nightly sweats were present. Accordingly, he was advised to re-enter the hospital for investigation.

On admission March 20, 1941, to the medical service of Dr. George Bachr, temperature was 101.4 degrees F, pulse 92, and respirations 20. He did not appear acutely ill and his general condition seemed even better than when last observed. The cardiac findings were unchanged except for the presence of a short faint high pitched apical systolic murmur which presumably was of functional origin. The blood pressure in the extremities was essentially the

same as at the time of discharge 9 days previously. The liver was not palpable. The spleen however again was palpable 3 fingerbreadths below the costal margin. The operative wound was well healed and all clinical evidence of the previously existing arteriovenous aneurysm was absent.

X-ray examination of the chest disclosed further diminution in the size of the heart and previously prominent pulmonary vessels. The electrocardiogram revealed no change as compared with the tracing made shortly before discharge from the hospital. The phonocardiogram revealed a faint systolic murmur over the precordium, a tracing made over the region of the femoral vessels on the left side failed to reveal the presence of abnormal sounds. The specific gravity of the urine was 1026. Albumin and dextrose were absent. The microscopic examination was negative. The hemoglobin content of the blood was 70 per cent. There were 4,600 leucocytes per cubic millimeter of which 44 per cent were segmented polymorphonuclear leucocytes, 20 per cent nonsegmented polymorphonuclear leucocytes, 19 per cent lymphocytes, 5 per cent monocytes, and 3 per cent eosinophiles. A blood smear did not reveal macrophages. The erythrocyte sedimentation rate was normal. Culture of the stool revealed only enterococci and *Bacillus coli*.

Three blood cultures, performed during an 8 day period of observation, were negative after 14 days of incubation. Blood agglutination tests for heterophilic antibody, dysentery, typhoid, paratyphoid, *Bacillus abortus*, and *Bacillus melitensis* also were negative. During this period, the temperature ranged between

99 and 103.8 degrees F and the pulse rate between 8 and 20. In spite of the irregular fever the patient continued to look quite ill, and various circulatory studies confirmed the absence of the previously existing arteriovenous communication.

In view of the pre-existing infection, it appeared essential to exclude recurrence of sepsis as the cause of the symptoms. It was postulated that if sepsis were present, it most likely was derived either from previously unrecognized endocarditis or from a thrombophlebitis involving vascular channels immediately adjacent to the former site of the arteriovenous aneurysm. However the diagnosis of recurrent subacute *Streptococcus viridans* septicemia appeared to be excluded by the negative blood cultures. (In an effort to exclude the diagnosis of thrombophlebitis in living vascular channels in the thigh, one of the blood cultures was taken directly from the left common femoral vein.) Furthermore, the erythrocyte sedimentation rate now was normal and leukopenia as present. Finally the re-enlargement of the spleen seemed too marked and too rapid to be consistent with the diagnosis of subacute bacterial septicemia. The history of abdominal pain and diarrhoea at onset, together with the acute en-

largement of the spleen and leukopenia, suggested the possibility of an intercurrent typhoid or paratyphoid infection. However these diagnoses are excluded by appropriate examinations of the stool and blood. Finally in view of the fact that the patient had received a number of transfusions during the first admission, the diagnosis of accidental malarial infection was entertained. The rapid splenic enlargement and leukopenia appeared to be consistent with such a diagnosis but several blood smears proved negative for plasmodia. After consultation with Dr Harold Verboet it was decided as a precautionary measure to re-explore the original operative site for evidence of local thrombophlebitis. In spite of the fact that the blood cultures were sterile it was considered possible that such a focus might be found. Furthermore, it was the consensus that even if exploration proved negative no harm could result.

On March 28, 1941 an operation was performed (b. A. S. W. T.) under ethyl ether anesthesia. The incision was begun at point A above Poupart ligament and carried downward and medial to the old operative scar to the junction of the upper and middle third of the thigh. The common femoral artery and vein were exposed and found to be of approximately normal caliber (The artery measured approximately 1/2 inch and the vein 1/2 inch in diameter). The common femoral and superficial femoral arteries were freed and retracted laterally in order to expose the point of confluence of the superficial femoral vein and the short, proximal stump of the previously excised deep femoral vein. Above the point of confluence the vein was divided between ligatures, the level of Poupart ligament. The vein then was freed in downward direction and the stump of the deep femoral vein, together with a 1 inch section of the superficial femoral vein, was excised. Oozing from the surrounding tissues was

controlled by a small gauze packing which was left *in situ* and brought out through the lower angle of the wound. The fascia was sutured loosely and the skin was closed with clips.

The pathological report upon the excised specimen was as follows: "Vein showing focal phlebosclerosis, otherwise no significant change is present."

The immediate postoperative reaction was satisfactory. During the first 3½ days, the temperature ranged between 100 and 102.4 degrees F. A blood culture, taken on the third postoperative day, was reported sterile. Four grams of sulfapyridine was administered on the day of operation and 6 grams on the first postoperative day. The temperature became normal on the 5th day after operation.

The wound healed kindly, the drain and the skin clips being removed on the 5th postoperative day. By the 7th postoperative day, the spleen had diminished appreciably in size. The patient was discharged on the 11th postoperative day in good physical condition. At the time of discharge there was moderate edema of the left lower extremity.

When last observed in the follow-up clinic on March 17, 1942, the patient had gained 42 pounds in weight and was entirely free of symptoms. The operative incisions were well healed, and edema of the left lower extremity, noted after the second operation, no longer was present. The spleen was not palpable. The heart was essentially normal in size. The blood pressure was 122/74. The electrocardiogram was normal. The cardiac output was normal (4.6 liters). The phonocardiogram revealed a very faint systolic murmur over the precordium which was interpreted as being of functional origin. A sound tracing taken from the thigh failed to disclose any abnormality. On the basis of the complete absence of symptoms and with the findings herein noted, recovery from both the arteriovenous aneurysm and subacute *Streptococcus viridans* bacteremia was considered to have taken place.

SUMMARY

The patient, a male aged 26, suffered a through-and-through gunshot wound of the left thigh 9 years previously. Within a year of the injury, evidence of an arteriovenous aneurysm associated with manifestations of cardiac insufficiency developed. Although the diagnosis of a "heart condition" was made, the existence of an arteriovenous aneurysm was not recognized. Following the extraction of a tooth and some dental reparative work, 7 years after the original injury, symptoms of sepsis began. The manifestations continued for almost 2 years before the diagnosis of arteriovenous aneurysm and subacute *Streptococcus viridans* septicemia was made. Clinical and laboratory investigations failed

Fig 5 Roentgenogram of chest 6 months after excision of arteriovenous aneurysm. Note reduction in size of heart.

to reveal conclusive evidence of an infective endocardial lesion as the source of the sepsis. It therefore was postulated that the focus of infection was situated within the arteriovenous aneurysm. Under the circumstances, surgical excision of the aneurysm appeared to offer a hope of cure. At operation, a large arteriovenous aneurysm involving the profunda femoris artery and vein, and filled with vegetations containing *Streptococcus viridans*, was found and excised widely. The course following operation was one of rapid improvement, the local and constitutional manifestations of arteriovenous aneurysm disappearing rapidly and the blood cultures becoming sterile promptly. In view of the fact that chemotherapy had been administered prior to operation for one year without effect and was not administered at all after operation, the sharp termination of the sepsis appeared attributable solely to the operative removal of the infected aneurysm. The patient was discharged from the hospital 3 weeks after operation in excellent physical condition, all postoperative blood cultures having been reported sterile.

He was readmitted 9 days later because of abdominal pain, diarrhoea, recrudescence of septic temperature, and enlargement of the

spleen. During an 8 day period of observation 3 blood cultures including one taken directly from the left common femoral vein were reported to be sterile. After a number of infectious diseases including typhoid fever and malaria has been excluded it was decided to re-explore the old operative site for evidence of thrombophlebitis despite the negative blood cultures.

At operation no abnormality was found locally but the common femoral vein the upper portion of the superficial femoral vein and the stump of the deep femoral vein were excised as a precautionary measure. Microscopic examination of the specimen failed to reveal the presence of any significant changes. Following operation recovery ensued rapidly.

One year has elapsed since the last operation and the patient remains entirely well. This is the second case of acquired arterio-

venous aneurysm complicated by subacute Streptococcus viridans septicemia in which recovery has followed surgical treatment.

CONTRAST MEDIA IN CYSTS AND ABSCESES OF THE CEREBRAL HEMISPHERE

EDGAR A. KAHN, M.D., Ann Arbor, Michigan

THE effectiveness and ease of performance of any technical procedure is enhanced by its simplification. Thus in surgery, that approach to a large, deep seated lesion which is most direct is the one of choice, provided vital structures are not traversed.

It has been the experience of all neurosurgeons in attempting ventricular air injection or biopsy of a cerebral tumor, to enter unexpectedly a cystic cavity with the exploring needle, xanthochromic fluid or pus being obtained. To approach such a lesion in the most direct manner and thus simplify operative procedure, the use of a contrast medium is desirable.

Air and iodized poppy seed oil have been used for this purpose but do not mix with fluid contents. Sodium iodide is miscible and Rocky instilled a 20 per cent aqueous solution into a brain abscess to show "the post-operative course after the original drainage had been instituted." The visualization in this case was excellent. It showed, moreover, how a portion of the collapsed abscess capsule had wrapped itself around the drainage tube and caused loculation of the abscess cavity rather than the desired evacuation. Colloidal thorium dioxide (thorotrast) is less irritating than sodium iodide, mixes readily, and has the added advantage of being phagocytized by the cellular elements of an abscess wall, making the capsule radio-opaque. This has been previously demonstrated by me. Jensen first reported the use of colloidal thorium dioxide for ventriculography. In a discussion on this same subject, Freeman and Schoenfield suggested that this contrast medium be used in cysts or encapsulated abscesses of the brain.

The following histories are selected from a small group of cases in an effort to show the value of colloidal thorium dioxide cystography.

From the Department of Surgery, The University of Michigan Clinic of Dr. Max M. Peet

CASE I. A L., a 14 year old girl, entered the University Hospital with a 6 months' history of gradually increasing intracranial pressure. There was found on examination marked papilledema and a quadrantic type of homonymous hemianopsia but little else in the way of localization.

A ventriculogram was performed which gave evidence of a large expanding lesion of the left cerebral hemisphere. A trephine opening was then made on the left, a half inch above and behind the ear. A cyst was entered with the exploring needle close to the surface of the brain. Twenty cubic centimeters of somewhat viscous xanthochromic fluid was removed and 5 cubic centimeters of colloidal thorium dioxide (thorotrast) was injected.

Roentgen ray studies revealed a large cyst. A lateral film, taken with the forehead up allowing gravity to aid in filling out the posterior wall of the cavity, revealed a perfectly smooth contour. A lateral film with the forehead down, however, outlined a mural nodule attached to the anterior wall (Fig. 1).

Under avertin anesthesia, the trephine incision of the left side was carried forward and superiorly in the shape of a hockey stick. The temporal muscle was stripped downward, thus exposing the squama of the temporal bone. Trephine openings were made to center a small bone flap directly over the mural nodule. These were connected with the Gigli saw, and the bone was removed to be replaced as a free graft. The dura was opened. The underlying brain substance was extremely thin and an opening was made into the cyst. The mural nodule which was about the size of an English walnut was seen anteriorly exactly as pictured in the x-ray film. It was widely excised with the electrosurgical unit.

Convalescence was uneventful and the patient was discharged on the tenth postoperative day. She has remained well for the past 2 years. There has been no change in the hemianopic defect except for some concentric contraction which was attributed to secondary optic atrophy. The tumor was shown microscopically to be a fibrillary astrocytoma.

This lesion, as the ventriculogram suggested, was of considerable size. Judging from the air studies alone, to have exposed it completely would have meant turning down a large bone flap. Cushing long ago showed that if the mural nodule of an astrocytoma were removed the cyst wall need not be dealt with. By accurately visualizing the mural

spleen. During an 8 day period of observation 3 blood cultures, including one taken directly from the left common femoral vein were reported to be sterile. After a number of infectious diseases including typhoid fever and malaria has been excluded, it was decided to re-explore the old operative site for evidence of thrombophlebitis despite the negative blood cultures.

At operation no abnormality was found locally but the common femoral vein the upper portion of the superficial femoral vein and the stump of the deep femoral vein were excised as a precautionary measure. Microscopic examination of the specimen failed to reveal the presence of any significant changes. Following operation recovery ensued rapidly.

One year has elapsed since the last operation and the patient remains entirely well. This is the second case of acquired arterio-

venous aneurysm complicated by subcut Streptococcus viridans septicemia in which recovery has followed surgical treatment.

Fig 2 Case 2 Ragged irregular outline of the cyst of a glioblastoma multiforme

Consequently, the cyst is always surrounded by solid or semisolid necrotic tumor and the wall is poorly defined. On surgical incision into such a cavity it tends to obliterate due to the rapid expansion on all sides of the broken down, edematous, discolored tumor tissue. One might draw a comparison between this lesion and the unencapsulated abscess of the brain secondary to pulmonary suppuration (Fig 3). Both form their cavities by a process of liquefaction necrosis without any tendency toward walling off. There is consequently a certain resemblance as shown by contrast media.

From the above discussion I have reached the following conclusion. If on attempting biopsy or ventriculogram, a cyst is entered it should be outlined by the injection of colloidal thorium dioxide. If a ragged, irregular cavity is demonstrated one may be fairly certain of the diagnosis of glioblastoma multiforme or at least, of a malignant glioma. The tumor must, of course, be subjected to biopsy examination for confirmation and in this procedure, again, the contrast medium is of value in showing where best to take the specimen. Microscopic diagnosis from biopsy material

is admittedly not infallible, but the presence of a malignant type of growth can usually be determined. Every case is a law unto itself but if the Rolandic area or the various speech centers are involved, operation is inadvisable.

CASE 3 H O, a 57 year old male, was admitted to the Hospital in a stuporous condition. He could be roused enough to demonstrate a left sided hemiplegia which seemed complete. There was a previous 6 months' history which was undoubtedly related to a cerebral lesion.

On attempting ventricular oxygen injection through a trephine opening, a half inch above and behind the right ear as is the usual procedure in this clinic, a cyst was entered and dark xanthochromic fluid was obtained. Between 6 and 8 cubic centimeters of colloidal thorium dioxide were introduced. X-ray studies gave evidence of a temporoparietal cyst with a large mural nodule (Fig 4).

The patient was returned to the operating room and under local anesthesia, a moderate sized bone flap was turned down directly over the lesion. The cyst was entered after traversing a little less than a centimeter of brain substance. At the posterior medial aspect of the cyst wall an irregular brownish mural nodule about the size of a large plum was found. This was completely excised together with the cyst wall until normal white substance was everywhere encountered, the tumor having been thought to be a cystic oligodendroglioma. (Cushing and Eisenhardt have shown that this type of tumor

Fig. Case 2, left, Lateral roentgenogram with forehead up showing smooth posterior wall outlined by 5 cubic centimeters of colloidal thorium dioxide. Right, head thor-

oughly tilted with the fluid contents of the cyst. Right, Lateral projection with forehead down outlining the neural nodule anteriorly.

nodule in this case an effective operation was carried out by means of a comparatively simple procedure. It is doubtful if 50 cubic centimeters of air could have demonstrated this lesion as well as 5 cubic centimeters of colloidal thorium dioxide.

CASE 3 J. G., a 6 year old man, was admitted to the hospital because of difficulty in speaking and headache both of which had been present for 3 months.

On examination the usual fields revealed suggestive right homonymous hemianopsia but no papilledema. There was slight right sided hemiparesis. The patient had mixed expressive receptive type of aphasia. No definite right sided sensory changes could be elicited but the patient was unable to co-operate fully. A diagnosis was made of lesion of the left temporoparietal region, probably tumor.

A trephine opening was made on the left, an inch above and half an inch behind the top of the ear (this is somewhat higher than the usual opening made in this clinic for ventricular air injection). When the dura was opened, the cortex appeared normal. At a depth of about 3 centimeters a cyst entered with the exploring needle though there was no buccal sense of resistance. About 5 cubic centimeters of viscid yellow fluid was obtained and 5 cubic centimeters of colloidal thorium dioxide

instilled. X-ray studies were completed after closure of the wound and demonstrated a deep seated cavity with an irregular ragged wall (Fig. 3).

The patient was returned to the operating room here a biopsy specimen was taken with the hollow needle. The microscopic diagnosis glioblastoma multiforme. The patient was discharged as hopeless on the fifth postoperative day.

The glioblastoma multiforme because of its microscopic infiltrative growth defies surgical removal. Though biological or physicochemical methods of treatment may be developed in the future the fact remains that this lesion does not respond to gross surgical excision, roentgen ray therapy or both. The first real contribution to the palliation of this lesion was the "internal decompression" of McKenzie. Spurling on the other hand, when a glioblastoma multiforme is strongly suspected takes a biopsy specimen and does not ordinarily operate if the microscopic examination brings confirmation.

Cyst formation is common in the glioblastoma multiforme and is undoubtedly due to central necrosis within the tumor itself.

Fig 4 Case 3 Cystogram of tumor diagnosed as primary sarcoma of brain

ness of the left leg Babinski's sign was negative bilaterally. There was a leucocytosis of 20,000. A pansinusitis on clinical examination was confirmed by x-ray studies.

A diagnosis of subdural abscess was made. Inasmuch as the infection was thought to have extended through the right frontal sinus, epidural pus was also suspected. It was decided first to perform a right sided Killian operation.

At operation by Dr. James Maxwell of the department of otology, an empyema of the right frontal sinus was found. The entire wall of the frontal sinus was removed but there was no evidence of erosion of the inner table. The ethmoidal cells were found to be grossly infected and were exenterated. The anterior face of the sphenoid was removed and the sphenoid found to contain thick pus. The inner table of the frontal sinus was removed but there was, in this case, no evidence of epidural pus or even granulation tissue over the tense dura. It was thought best to expose the dura through a clean field above the operative site. It was believed that the patient's condition warranted waiting until the following day before this procedure was carried out.

The patient was carefully watched for the next 24 hours since any further evidence of acute increase in intracranial pressure would have necessitated immediate operation.

At the end of this period the patient's condition was unchanged. Under local anesthesia, a trephine opening was made over approximately the center of the frontal bone. The dura appeared tense and bluer than normal. When the dura was opened there was an escape of a large amount of thick green

ish white, odorless pus which was extra-arachnoid. The incision was now enlarged and an area of bone about the size of a silver dollar was removed with the rongeur. The dura was further opened in a stellate manner, the pus extending in all directions. There now developed a herniation of the brain through the defect, making retraction of the brain impossible. In order to gain relaxation so that all pus could be removed and adequate drainage be established without making a tremendous bone defect, it was decided to perform a lumbar puncture.

The patient was turned and the lumbar puncture needle was introduced. The pressure was between 600 and 700 millimeters of water. The fluid was cloudy and contained 5,600 cells per cubic millimeter. After approximately 50 cubic centimeters had been obtained, the brain commenced to pulsate and to drop away from the dura. With the lumbar puncture needle left in place, the surface of the brain was now easily depressed with a lighted retractor, the entire surface of the brain being explored back to at least the midparietal region. All pus was removed by suction even as far forward as the tip of the frontal pole. The wound was washed out with Ringer's solution and hydrogen peroxide, inasmuch as it was thought that the pus could not be extended any farther than it had already gone. Rubber tissue drains were inserted as far as possible in four directions, to the postparietal region, the midline, the tip of the frontal pole, and down onto the temporal lobe near its tip. This procedure was carried out without difficulty and with almost no trauma to the arachnoid since the hemisphere following lumbar puncture retracted from the dura for

Fig. 3 Outline typical of unencapsulated abscess metastatic from pulmonary suppuration

tends to recur rapidly.) During this process it was found that tumor substance extended posteriorly almost to the occipital pole, basally to the inferior surface of the temporal lobe and anteriorly to the midparietal area. The compressed right lateral ventricle was entered and the choroid plexus clipped. The upper surface of the tentorium was widely exposed and to some extent the right side of the falx.

The patient made excellent convalescence except for complete left homonymous hemianopsia (with splitting of the macula). The tumor, as histologically thought to be primary sarcoma of the brain.

The patient returned 8 months later in semicomatous condition. Operation was again performed and enormous recurrence was found. Again the tumor seemed to be completely excised. Immediate convalescence from the second procedure was surprisingly good but he returned 3 months later and died. The autopsy which was limited to the head, revealed massive recurrence.

This tumor from the point of view of cystography with colloidal thorium dioxide might be considered as midway between a benign lesion and a malignant one. The fact that the cyst was extremely large suggested the former while the size of the mural nodule and the slight irregularity of the cyst wall was in favor of the latter. Where there is real doubt as to operability direct attack

upon the lesion itself rather than biopsy is indicated.

The following case is reported in detail, first as a method of handling an acute subdural abscess and second because a contrast medium was of such help in dealing with a complicating cerebral abscess.

CASE 4. A 7-year-old boy entered the University Hospital with the following history. Two weeks previous to admission the patient had suffered an ordinary head cold. This began to subside within few days but bilateral frontal headache persisted. One week before admission the headache became more severe on the right and swelling of the right upper eyelid developed rapidly. Ten days later, the swelling had reached peak and rapidly subsided. There as now noted, besides increasing headache stiffness of the neck and increasing irritability. Ten days before admission, nausea and projectile vomiting developed and numbness of the left hand was complained of. This was rapidly followed by weakness of the entire left side.

Examination revealed an extremely ill and apathetic patient. The temperature was 38 degrees, the pulse 78 and respiration 20. There was stiffness of the neck and positive Kernig sign. Fundoscopic examination revealed early papilledema. There was a left central type of facial paralysis and the tongue deviated to the left on protrusion. There was marked weakness of the left arm and slight ext

Fig 6 a, left, Decompression was placed too high because the abscess was not visualized previously b Three

days later the capsule is shown to have risen toward the decompression

Fig 7 Case 5 Colloidal thorium dioxide thoroughly mixed with pus in infected subdural hematoma

formed at that time without difficulty. The most recent x-ray films which were taken 3 months after operation show stereoscopically a fine circular line less than 1 centimeter in diameter in the substance of the brain just above the tegmen tympanum. This is undoubtedly due to colloidal thorium dioxide in what remains of the capsule. It is probably of no significance as the patient is back at full time work, but it will be followed with interest.

CASE 5 R. F., a 7 months old male infant, was admitted to the hospital with the appearance of being *in extremis*. The child according to the parents' story, had been well up to the age of 4 months at which time he had developed bilateral otitis media and a pneumonia which was confirmed by x-ray. This had gradually cleared but a spastic tetraplegia with enlargement of the head had developed.

On examination the infant was found to weigh but 10 pounds. Though the head was generally enlarged this was most marked on the left side. There was no papilledema. The leucocyte count was

Fig. 5. Case 4. a, left, Encapsulated abscess of brain secondary to subdural abscess. The large anterior skull defect as made for drainage of the subdural abscess, the trephine opening just posterior as used for the injection

at least 15 centimeters in all directions. The drains were gradually removed within the course of the next 4 days. Convalescence was comparatively eventful, the mild hemiparesis noted 4 times was controlled by lumbar puncture till granulation was complete.

Three weeks after discharge the patient returned to the hospital with increasing left hemiparesis having had on generalized convulsion. There was moderate bulging of the decompression.

A trephine opening was made just posterior to the frontal defect in order to reinspect the subdural space. When the dura was opened normal convolution was seen showing that the subdural abscess had been apparently cured. The wound was closed.

A needle was now inserted through the scalp over the large frontal defect and was passed deeply in several directions. The abscess was evacuated.

An encephalogram was made a few days later by the lumbar route which showed displacement of the left lateral ventricle to the left but did not accurately localize the abscess. A few days later ventriculogram was made through left sided trephine opening. This gave definite evidence of large lesion of the right parietal region.

The trephine opening which had been made posterior to the frontal defect previously in order to inspect the subdural space was reopened. A needle was passed downward through the brain substance and to a depth of about 3 centimeters, met with an elastic resistance through which the needle was plunged. About 60 cubic centimeters of pus was obtained (Fig. 5) and 8 cubic centimeters of colloidal thorium dioxide instilled. A roentgenogram (Fig. 5) revealed large abscess cavity. Six days later the abscess cavity was seen to have increased six by roentgen ray. The heavily encapsulated abscess was uncapped and drained. Recovery was uneventful

of the colloidal thorium dioxide. Postoperatively trephine is that used for intracranial oxygen injection. b, Four days later showing increase in size of the abscess which has taken place.

A year later an encephalogram was performed because of few Jacksonian seizures. This showed slight dilatation of the entire ventricular system but no evidence of recurrence.

At the present time this patient feels perfectly well and goes to nursing daily.

Here we have the problem of a patient with a large bulging frontal decompression and a suspected subcortical cerebral abscess which might have been anywhere in that cerebral hemisphere. The abscess was finally entered with the exploring needle and outlined with colloidal thorium dioxide. Its exact position and the point at which it lay closest to the surface was determined.

Another case might be briefly mentioned in this connection. A 45 year old doctor entered the hospital in coma with a 3 weeks previous history of otitis media. An encapsulated abscess was tapped through an incision just above and in front of the right ear (Fig. 6). Colloidal thorium was instilled and a small decompression made over where the abscess was thought to be most superficial. Roentgenograms were not taken at this time because of the patient's precarious condition. Subsequent x-ray films showed that this opening had been placed higher than it would have been had films been obtained before decompressing. In spite of this the abscess migrated toward the surface sufficiently within 3 days so that uncapping and drainage were per-

SO CALLED LATERAL ABERRANT THYROID TUMORS

WILLIAM I. M. KING, M.D., and J. deJ. PEMBLERTON, M.D., F.A.C.S.,
Rochester, Minnesota

THE existence in the lateral regions of the neck of cellular masses derived from thyroid tissue has been recognized for more than a hundred years (15), but no serious attempt was made to describe these masses as a separate clinical entity until late in the nineteenth century when isolated reports of cases began to appear in the English and the German literature (1-6).

By 1900, enough cases of these tumors had been reported to give rise to speculation concerning the origin and the pathological characteristics of the growths. There was evidence to indicate that the thyroid gland originated from two separate anlagen, an unpaired median component and paired lateral components, which fused early in fetal life. The earliest school of thought, and by far the largest one today, attempted to explain the origin of "lateral aberrant thyroids" by some abnormality in the development of the lateral anlagen. Schrager, in 1906, expressed the belief that these masses were essentially benign tumors arising as a hyperplasia of normal thyroid elements detached from the lateral anlagen before fusion, in response to an increased demand for thyroid created by subefficient function of the thyroid proper.

The predominantly papillary nature of these tumors and their frequent association with similar tumors in the corresponding thyroid lobe were first pointed out by Low in 1903. He emphasized that their rate of growth was slow and that metastasis to distant regions was rare, spread tending to occur rather by local invasion of the lymph channels. Many years later Billings and Paul reiterated these observations. The peculiar structure of these tumors led to the belief that "lateral aberrant thyroids" were derived not from normal thyroid elements but from tissue which was constitutionally inferior to that of the thyroid proper.

Kingsbury demonstrated that the lateral anlagen degenerated after fusion with the median anlage and probably disappeared completely. Leech, Smith, and Clute and, later, Cattell expressed the belief that "lateral aberrant thyroids" originated from fetal rests derived from the degenerated lateral anlagen and were intrinsically malignant. They concluded that the frequently

coexistent papillary tumor in the corresponding thyroid lobe arose from a fetal rest derived from the same source. Crile (7, 8) concurred in their explanation of the origin of thyroid and "aberrant" tumors, but expressed the opinion that these tumors were remarkably benign in their behavior.

In 1931 Dunhill revived Schrager's conception of the physiological stimulus concerned in the genesis of "lateral aberrant thyroids." He expressed the belief that the lateral anlagen were constitutionally inferior to the median anlage and that tissue derived from them, whether situated within or without the thyroid lobe, was prone to undergo papillary change in response to stimulation by ordinary physiological demands. Thus arose the theory of "activated rests." Van den Wildenberg expressed the belief that the papillary cystadenomas so formed were precancerous and that further stimulation by relative thyroid insufficiency caused them to become malignant.

Gretelman and Russum extended this idea to account for recurrences, stating that continuation of the stimulus caused other tiny and previously unaffected rests, missed at the first operation, to develop into palpable tumors. They suggested that the thyroid itself be explored because it frequently is involved by a similar tumor.

In 1940 Ward further elaborated the theory of "activated rests." He, like Dunhill, expressed the belief that stimulation of any tissue derived from the lateral anlagen resulted in papillary change, however, he was of the opinion that this change, occurring among children, was in a reversible stage and would regress if the stimulus were removed by treatment of the patients with iodine, whereas, among adults, owing to the loss of some cancer-resisting factor, the process became irreversible and went on to malignancy. Thus he advocated radical surgical procedure and radiation in the treatment of adults. Cohn and Stewart, in the same year, stated the belief that the location of a papillary tumor within or without the lateral thyroid lobe depended on whether embryonic tumor cells were split off the lateral component before or after fusion took place. If this splitting off occurred both before and after fusion, coexistent primary tumors appeared in the thyroid and side of neck. They stressed importance of complete excision of tumor to prevent recurrence.

15.800 and the temperature was 99 degrees. A diagnosis was made of abscess of the left cerebral hemisphere, metastatic from the lung rather than secondary to the otitis media which in my expert mind so rarely causes abscess in infants.

A needle was passed through the left side of the anterior fontanelle to a depth of about 3 centimeters. On withdrawing the stylet 45 cubic centimeters of pus was obtained, following which 15 cubic centimeters of colloidal thorium dioxide as injected (Fig 7).

X ray studies, to our great surprise, revealed the contrast medium to be in the left subdural space. By means of two large trephine openings, one in the frontal and one in the parietal region, the subdural space was entered. There was a purulent membrane attached to the inner surface of the dura. There was a heavy inner membrane apparently holding the brain down. Several incisions were made into the latter but it was soon obvious that removal of much of this membrane was out of the question. Specimens of both membranes were taken for pathological examination. Multiple rubber tissue drains were placed in the subdural space.

The infant now made an amazing improvement. The drains were removed on the sixth postoperative day. He was discharged with the incisions completely healed, 7 weeks later.

Pathological examination of the membranes revealed that infection had developed in what had undoubtedly been a chronic subdural hematoma. Culture of the pus obtained at operation showed *Staphylococcus aureus*.

On examination five months later the child could still not sit up alone but noticed things and was making an effort to use both upper extremities. It has been impossible to contact the family since that time.

The advantage of using a contrast medium which mixed freely with the contents of a purulent cavity is obvious in this case. The operator had thought that he was dealing with an intracerebral abscess until the x ray studies were obtained.

CONCLUSIONS

1. Colloidal thorium dioxide can be used to advantage in outlining cystic tumors of the cerebral hemispheres. This not only gives a

due to the pathological nature of the neoplasm but simplifies the surgical approach should operation be deemed advisable.

2. This contrast medium is of value in the treatment of the encapsulated abscess of the brain whether it be dealt with by repeated tapping after the method of Dandy open drainage or complete excision as performed by Vincent.

3. Colloidal thorium dioxide has the advantage over iodized poppy seed oil or air in that it mixes readily with fluid contents and may be phagocytized by the surrounding wall of an abscess so that the capsule itself will be visible in the roentgen-ray within 3 days or less.

4. There can be little danger in the use of colloidal thorium dioxide from the effect of long standing radioactivity since the main mass of this substance is removed in the evacuation of the cavity.

5. It is suggested that there might be wider application in the field of general surgery as in visualization of an empyema cavity. In the drainage of a thoracic empyema, the difficulty increases as the cavity becomes smaller. It is at this later stage that the colloidal thorium dioxide which has been phagocytized by the empyema wall might show when obliteration is complete.

Figs 1, 2, and 3 Lateral aberrant thyroid tumors in the 3 cases in our series in which the growths were benign. Sections from all three are indistinguishable from sections of colloid adenoma.

died of carcinoma of the thyroid gland subsequent to removal or biopsy of a malignant "aberrant thyroid", in 4 cases the survival period varied from 11 to 19 years. One patient lived for 9½ years subsequent to the appearance of pulmonary metastatic lesions a year after removal of the "aberrant thyroid". It is apparent, therefore, that malignant "aberrant thyroids" are very slow-growing on the average, but that they eventually may cause death.

Of the 54 patients 3 had "lateral aberrant thyroid tumors" which, on microscopic examination, proved to be benign (Figs 1, 2, and 3). In 2 of these cases a large, nodular goiter was associated with the "aberrant" thyroid tumor, which in each instance was situated immediately above one or the other superior thyroid pole. In the third case, the "aberrant" tumor was situated at the angle of the jaw on the right side and had been present for 30 years without change in its size. There was no direct connection between the thyroid tumor and the "aberrant" tumor in any of the 3 cases, in each case, microscopic examination revealed that tumors were composed of colloid and fetal adenomatous thyroid tissue without evidence of cellular undifferentiation, mitosis, vascular invasion, or lymphoid tissue.

The 51 other "aberrant" thyroid tumors on microscopic examination proved to be malignant. In 31 cases, 60 per cent, there was an associated tumor of the thyroid, the malignant nature of which was confirmed by microscopic examination, by obvious inoperability, or by subsequent death of the patient from carcinoma of the thyroid. In each of these 31 cases the thyroid tumor and the "aberrant" tumor were on the same side of the

neck, and in each of 19 of these cases in which specimens from both tumors were obtained, the structure of the tumors was histologically identical (Figs 4 to 9). All of the 10 deaths in the series of 54 cases occurred in this group, and of 24 patients who experienced recurrence of tumor, 19 had both thyroid and "aberrant" tumors.

Of the 20 patients remaining, 3 had associated thyroid tumors, the pathological nature of which was doubtful clinically and was not determined by operation. In the 17 other cases clinical evidence of thyroid tumor was not observed, in 13 of these cases, attempt was not made to examine the thyroid at operation, but in 4 the gland was exposed and, since it seemed normal on palpation, was left undisturbed by the surgeon. In the whole group of 20 cases, recurrence took place in 4, of which 1 was in the group of 4 in which the thyroid gland was left undisturbed at operation. The thyroid gland was not involved later in any case, nor was death related to the disease in any case. At the time this paper was written 10 patients were living and free from recurrence of tumor, 4 had had one recurrence, 1 died of natural causes, reports were not received from the 5 others after dismissal.

In 38 of the 51 cases of malignant tumor, 75 per cent, the pathologist on examination of the "aberrant" tumor made a diagnosis of papillary adenocarcinoma. Of these tumors, 20 were classified as of grade 1, 18 as of grade 2, the grading was on a basis of 1 to 4, in which grade 1 is the least malignant and grade 4 the most malignant. In 12 of the tumors of grade 2 the papillary tissue was mixed with nonpapillary, solid carcinomatous tissue. The tumors of grade 1 were distinguished by the long, arborizing processes which projected from

A second school of thought, much in the minor it held that lateral aberrant thyroids were metastatic carcinomas in the cervical lymph nodes secondary to primary carcinoma of the corresponding thyroid lobe. Wohl, in 1917, advised thinking of this possibility when a so called lateral aberrant thyroid was found and Eberts, in 1933, advocated removal of the corresponding thyroid lobe even though it appeared normal. It was pointed out by one of us (J. def P.) in 1934 (25) and again in 1939 (26) that these lateral masses, incorrectly termed "lateral aberrant thyroids," were in reality true metastatic carcinomas.

A few other investigators explained the origin of these tumors as nests of normal thyroid cells which either occupied their aberrant position because of natural distribution (31, 35) or were dragged away from the thyroid proper by muscles, vessels and nerves which were developing (9, 23, 37).

George Crile, Jr. in two recent papers, swung back to the opinion held by Schragger that these were benign tumors. Crile stated that papillary tumors of the thyroid gland, in his experience, did not metastasize to lymph nodes and that lateral aberrant thyroids were not metastatic carcinomas and were not as a rule malignant. He expressed the opinion that the finding of a hard, palpable tumor in the thyroid gland, together with multiple nodules in the neck, was confirmatory evidence of the presence of lateral aberrant thyroid tumor. He expressed the belief that because these tumors were benign and did not spread, because they did not recur after operation for their removal, and because they never caused the death of the patient, complete cure would result provided they were removed completely.

Since 1920 the microscopic diagnosis of malignant disease in thyroid tissue has received much attention. Graham (13) stated the belief that capsular invasion was the main criterion in the diagnosis of the nonpapillary type of cancer that capsular invasion and lymphatic invasion were the criteria in the purely papillary types. Ward and others (22) stated that capsular invasion and lymphatic and vascular invasion were the only reliable signs of malignant change. Neither Ward nor Crile believed that the presence of lymphoid tissue in an aberrant thyroid was a sign that the tumor was a metastatic lesion in a lymph node. However, Broders (3, 4) expressed the opinion that the most reliable signs of malignancy were cellular undifferentiation and mitoses.

A LIAISON OF FIFTY FOUR CASES

In the selection of cases at the clinic to correspond with those described by other writers, all

those were chosen first in which a benign or a malignant tumor of thyroid tissue was discovered in the lateral region of the neck, without any gross connection with the thyroid gland itself. This group included cases in which the lateral cervical tumor had been removed elsewhere prior to the patient's visit to the clinic and other cases in which it had been removed or in which biopsy had been made at some time after operation on the thyroid gland. In many cases there had been also a tumor in the thyroid itself before or at the time of or after operation on the cervical tumor. The whole group was divided into two series: the first series, 54 cases, included only cases in which the lateral cervical tumor was the patient's main complaint or as the main reason for performing the operation. In these cases the cervical tumors were considered "lateral aberrant thyroids" irrespective of the presence of a thyroid tumor. In all the other cases there were malignant tumors of the thyroid gland which were themselves the reason for operating and the associated lateral cervical tumors were unquestionably, in our opinion, regional metastatic lesions. In 5 cases of the second series the cancers were papillary; microscopic analysis of these cancers was made for comparison with the tumors in the first series of cases.

Of the 54 patients in the first series, 29 were females and 25 were males. The highest age incidence occurred in the fourth decade among the former. In the third decade among the latter. The clinical diagnosis most commonly made was of tuberculous adenitis in those cases in which the thyroid tumor was not present, carcinoma of the thyroid with metastatic extension in those in which thyroid tumor was present. In many of the latter cases, a double diagnosis was made of adenomatous goiter together with cervical adenopathy, lymphoblastoma, adenitis, and so forth. In 16 cases there were symptoms of pressure on surrounding tissue but they were not of help in arriving at correct diagnosis.

The "aberrant thyroid" tumor consisted of multiple nodules in 36 of the 54 cases, and of a single mass in 18. The growth was situated deep to one or the other sternocleidomastoid muscle in 50 per cent, in the posterior triangle of the neck in 27 per cent, in the submaxillary triangle in 19 per cent, and in the carotid triangle in the remainder of the cases. Before operation, the average duration of the tumor had been 5 years; the duration exceeded 10 years in 7 of the cases in which the lesion was malignant. Recurrence of the tumor usually took place from 6 months to 1 year after operation, but in 5 cases there was a delay of more than 5 years. Ten patients, 18.5 per cent,

Figs 10 to 13 Histological evidence of malignancy in lateral aberrant thyroid tumors, tumor thrombus in a capsular vein (Fig 10), capsular lymphatic distended by tumor tissue (Fig 11), typical lymph node structure with carcinomatous metastasis (Fig 12), tumor cells lying in a peripheral sinus of a lymph node (Fig 13)

marked The tumors of grade 4 invaded all the tissues surrounding them, as would be expected

Twenty-eight, 55 per cent, of the malignant "aberrant" tumors contained lymphoid tissue, usually in the form of a shell around the cancerous tissue with finger-like processes extending into it (Fig 12) Often peripheral sinuses were seen between lymphoid tissue and capsule, at times these contained cancer cells (Fig 13) Only one of the thyroid tumors contained lymphoid tissue

The operative procedures used in the treatment of these 54 patients are given in Table I

An analysis of the results was made, from the standpoint of recurrence of tumor, according to the completeness of the operative procedure, and as to whether or not postoperative treatment by radiation was given Removal of all grossly involved structures, including the corresponding thyroid lobe if it, too, was involved, constituted a complete procedure Of 21 cases in which complete removal of the tumor was followed by radiation, recurrence took place in 8, or 38 per cent In 16, in which removal was incomplete but was followed by radiation, recurrence took place in 10, or 62.5 per cent In 12 cases of complete removal,

without radiation, recurrence took place in 5, or 42 per cent, an incidence equal to that in the first group Therefore, among those patients who received postoperative treatment by radiation, complete removal of the grossly involved structures,

Figs. 4 to 9. The pathological characteristics of papillary lateral aberrant thyroid tumors (Figs. 4, 5, and 6) and of the tumors in the corresponding thyroid lobe compared (Figs. 7, 8, and 9). Papillary adenocarcinoma, grade (Figs. 4 and 7) pure papillary adenocarcinoma, grade (Figs. 5 and 8) mixed papillary and nonpapillary adenocarcinoma, grade (Figs. 6 and 9).

thin cystic walls into large spaces, the lining epithelium being one layer thick. In the most part in the tumors of grade 2 the processes were thick and stubby, were covered by two or more layers of epithelial cells, and usually projected into small cystic spaces which often were surrounded by sheets of less well-differentiated cancer cells. Evidence of mitosis was present in all specimens of the papillary group and was observed more frequently in the tumors of grade 2. Prolonged search was required to discover mitotic figures in the majority of tumors of grade 1. Vascular invasion could not be demonstrated in any tumor of grade 1 and in only a few of the tumors of pure grade 2, but in the majority of the tumors in association of the capsule or the capsular lymphatics was evident. The majority of the tumors of mixed grade 2 revealed vas-

cular capsular and lymphatic invasion (Figs. 9, 11).

The 3 other malignant aberrant tumors are nonpapillary adenocarcinomas and all are associated with thyroid tumors. They were graded from 1 to 4 according to the degree of cellular undifferentiation, the tumors of grade 4, or diffuse carcinoma, being totally undifferentiated. Evidence of mitosis was extremely difficult to find in the tumors of the first three grades but was abundant in those of grade 4. Invasion of the capsule was discovered in all the tumors of higher grade and in most of those of grade 2 but was lacking in some of the tumors of grade 2 and of grade 1. Capsular and lymphatic invasion was less prominent in the lesions of this group than in those of the papillary group, but nevertheless as well

Figs 20 to 29 Lateral aberrant thyroid tumor (Figs 20, 22, 24, 26, and 28) and the tumor of the corresponding thyroid lobe (Figs 25, 26, 27, 28, and 29) compared in 3 cases (Figs 20 and 21, 22 and 23, 24 and 25) in which the thyroid tumor was discovered by the pathologist after its removal, and in 2 other cases (Figs 26 and 27, 28 and 29) in which it was discovered by the surgeon at operation

nosis, we found that the metastatic nodes, if not bilateral, were always on the same side as the involved thyroid lobe and that their histological structure invariably was identical with that of the thyroid carcinoma. There was definitely lymphoid tissue surrounding the malignant regions in 9 of the 15 representative metastatic nodules, 60 per cent, an incidence which compares almost exactly with that in the series of so called lateral aberrant thyroid tumors. Lymphoid tissue was present in the thyroid tumors in 2 cases. Vascular invasion was evident in 1 of the 7 tumors of grade 1 and in 7 of the 8 tumors of grade 2. The frequency of mitosis and of capsular and lymphatic invasion closely approximated that of "aberrant thyroid" tumors.

It is obvious, therefore, that the cases of the 2 series are indistinguishable from one another pathologically and that the separation out of some of the tumors as examples of "lateral aberrant thyroid tumor" was purely empirical according to the relative degree of prominence of the clinical his-

tory and findings of the "aberrant" or the thyroid tumor. The frequent insignificance of the associated thyroid tumor is illustrated by the fact that in 4 cases the thyroid tumor was not discovered until the gland was exposed at operation, in 3 others, the surgeon removed the homolateral thyroid lobe, even though it looked and felt normal, because the pathologist's report of the excised cervical tumor was papillary adenocarcinoma of the thyroid type, and in each a tiny and identical tumor was found buried inside the lobe. In no case in which the homolateral lobe was removed did the pathologist fail to find in that lobe a tumor identical in structure with that of the "aberrant thyroid." The following report of cases serves to illustrate the points mentioned in this paragraph.

CASE 1 (Figs 20 and 21) A man, aged 32 years, who came to the clinic complaining of dysphagia, had had two tumors, one under the right sternocleidomastoid muscle and one at the angle of the jaw, for 10 years. In the 5 months previous to admission he had noticed rapid increase in size of the masses. A clinical diagnosis of Hodgkin's disease

Figs. 4-9. Evidence confirming the lethal power of papillary tumors of thyroid tissue. All 6 patients represented in Figures 4-9 died of carcinoma of the thyroid. Figures 4, 5, and 6 were taken from the "lateral aberrant" thyroids in cases in the first series. Figures 7, 8, and 9 were taken from the thyroid tumors of patients in the second series. Papillary adenocarcinoma, grade (Fig. 4) pure papillary adenocarcinoma, grade (Fig. 5) mixed papillary and nonpapillary adenocarcinoma, grade (Fig. 6) pure papillary adenocarcinoma, grade (Fig. 7, 8, and 9) of the type commonly called benign papillary cystadenoma.

both thyroid and aberrant thyroid afforded a better prognosis for cure. All of the deaths occurred in the group in which the surgical procedure was incomplete in spite of the fact that recurrence developed in 4 per cent of the cases in which removal was complete. Recurrence took place in 5 of the 38 cases of papillary tumor (40 per cent) and in 9 of the 3 of papillary tumor (70 per cent) of the 30 occurred in the latter group. Of the 3 deaths in the papillary group, 2 were caused by those unmixt with nonpapillary elements (Figs. 4, 5, and 6). Thus it becomes clear that although the papillary tumors are clinically much less potent than the nonpapillary, their power

to cause death cannot be questioned even when nonpapillary carcinomatous elements are lacking. Confirmatory evidence is furnished by the photomicrographs in Figures 17, 18, and 19. Treatment by radiation would seem to be of questionable value unless the surgical procedure was "complete" and even then it is not strikingly effective.

ANALYSIS OF 15 CASES OF PAPILLARY CARCINOMA OF THYROID WITH REGIONAL METASTASES AND COMPARISON WITH CASES OF ABERRANT TUMOR

Comparing with the cases in the series described previously, those 15 cases in which papillary carcinoma of the thyroid with regional metastatic extension was conceded to be the correct diag-

frequent mitotic figures and showed capsular invasion, lymphoid tissue was not found. The thyroid tumor was composed of mixed solid and cystic tissue, contained many mitotic figures, and gave evidence of vascular, capsular, and lymphatic invasion.

Six months later the patient was subjected elsewhere to right radical block dissection of tumors of the neck and afterward was treated by radiation. Seven years after her first operation she reported that she was in good health, free from recurrence.

CASE 3 (Figs 24 and 25) A woman, aged 37 years, came to the clinic because of gradually increasing tumor of 4 years' duration situated under the right sternocleidomastoid muscle. Clinical diagnosis was made of cervical adenopathy, and the tumors were excised. The pathologist reported that the growths were papillary carcinoma. Although the thyroid on surgical exploration apparently was normal, the surgeon was doubtful and resected the right lobe, in the upper pole of which were found two small nodules that proved to be carcinomatous. Microscopic study revealed mixed papillary and nonpapillary adenocarcinoma, grade 2, of the thyroid with regional metastatic extension. Patient received radiation treatment.

Five months later the patient returned with recurrence of tumors under the right sternocleidomastoid muscle. Radical block dissection was made and was followed by radiation. The pathologist's report was identical with that made 5 months previously. The "aberrant" tumor was solid, contained abundant mitotic figures and evidence of vascular invasion, lymphoid tissue was not present. The thyroid tumor was of the same type but in addition showed evidence of capsular and lymphatic invasion. The recurrent tumor which was removed at the second operation possessed all the features of both the "aberrant" tumor and the thyroid tumor and contained lymphoid tissue.

Nine years after first operation the patient living and well.

CASE 4 (Figs 26 and 27) A man, aged 24 years, had had multiple tumors of the right side of the neck, under the sternocleidomastoid muscle and at the angle of the jaw, for 10 years. They gradually had increased in size. When operation was performed for excision of the tumors, surgical exploration of the thyroid revealed a tumor in the right lobe, and right hemithyroidectomy was done. The pathologist reported papillary adenocarcinoma, grade 1, of the thyroid with regional metastatic extension. Both the thyroid tumor and the metastatic tumors were cystic and contained occasional mitotic figures, lymphoid tissue was present, and there was evidence of capsular and lymphatic invasion. The papillary carcinoma arose from an adenoma. The lymphoid tissue in the thyroid was a nodule extrinsic to the encapsulated tumorous tissue and was not invaded by it. Patient later received treatment by radiation.

Eight years afterward the patient returned to the clinic because of recurrence of tumors under the left sternocleidomastoid muscle, he again received treatment by radiation. Two years later it was reported tumors were still present. The patient did not return for further treatment.

CASE 5 (Figs 28 and 29) A woman, aged 22 years, came to the clinic because of multiple tumors of the neck and at the angle of the jaw on the right side. The growths had been present for 2 years and gradually were increasing in size. Physical examination revealed that the tumors in the neck were under the sternocleidomastoid muscle. Diagnosis was made of tuberculous adenitis. Biopsy at the time of surgical intervention revealed the presence of papillary carcinoma, a right radical block dissection of the tumors was made and after exploration of the thyroid, the right lobe which was enlarged slightly, was removed.

The pathologist reported papillary and nonpapillary carcinoma, grade 2, of the thyroid with regional metastatic

extension. The specimen of tissue removed for biopsy was solid and, on microscopic examination, was found to contain occasional mitotic figures. The thyroid tumor and metastatic tumors were solid and mitotic figures were present with evidence of capsular, vascular, and lymphatic invasion. None of specimens contained lymphoid tissue.

Subsequent to operation the patient received treatment by radiation. Two months afterward recurrence of tumors had not taken place.

CASE 6 (Figs 4 and 7) A girl, aged 18 years, registered because of the presence for 9 months of multiple tumors on the left side of the neck. On physical examination the growths proved to be under the left sternocleidomastoid muscle and in the left posterior triangle. Three weeks before the patient came to the clinic, biopsy had been performed elsewhere of one of the tumors in posterior triangle and pathologist's report papillary carcinoma.

A clinical diagnosis was made of cervical carcinoma and at operation all the cervical nodules were removed. The thyroid was examined and apparently was normal. The pathologist reported the nodules as papillary adenocarcinoma, grade 1, probably metastatic from the thyroid. Treatment by radiation was not given.

The patient returned 1 month later with a recurrence under the left sternocleidomastoid muscle and a palpable tumor in the left lobe of the thyroid. Left radical block dissection and left hemithyroidectomy were done. Both tumors proved to be papillary adenocarcinoma, grade 1, identical with the nodules removed earlier. Microscopic examination of the "aberrant" tumor revealed solid tissue that contained occasional mitotic figures, lymphoid tissue was present and capsular invasion had taken place. The findings in thyroid tumor and metastatic nodes were the same except thyroid tumor contained no lymphoid tissue.

The patient received treatment by radiation, 9 months later she had remained free from signs of recurrence.

In 9 cases, the thyroid tumor did not become clinically detectable until some time after removal of the "aberrant" tumor, in 3, the thyroid tumor was the first to appear. In 17 cases, as has been stated, a tumor in the thyroid gland never developed, even though there was recurrence of the "aberrant" tumor in the neck. As but 4 of the 17 patients received radiation and by this treatment a primary growth in the thyroid may have been destroyed. Believing, as we do, that all "lateral aberrant thyroids" are metastatic tumors from primary growths in the thyroid, the failure of appearance of a thyroid tumor in the last 4 cases must be attributed to the slow rate of growth which has been shown to characterize this type of carcinoma.

EVALUATION OF STUDY

It has been pointed out previously herein that some of the authors who believe in the "activated rest" theory of origin of "lateral aberrant thyroids" have expressed the opinion that physiological overstimulation of the constitutionally inferior tissue derived from the lateral anlage causes to develop in that tissue papillary change which proceeds to malignancy. These men accept the view that the lateral components do form part

from mixed papillary and nonpapillary adenocarcinoma, grade 1. Figure 34, metastases to the bregma from nonpapillary adenocarcinoma, grade 1. 35b papillary elements. Figure 35, histological section of scalp nodule secondary to pure papillary adenocarcinoma, grade 1. Figures 33, 34, 35 all represent so called lateral aberrant thyroid tumors.

as made and operation as performed for excision of the tumors, the thyroid was not examined surgically. The pathologist at first reported that the tumors were bronchial cystadenomas but later changed diagnosis to papillary adenocarcinoma, grade 1. Treatment by radiation not given.

The patient returned 9 months later with recurrence under the right sternocleidomastoid muscle and at the angle of the jaw on the right and on the left side. Right partial block dissection as done. The pathologist reported that the tumors were adenocarcinoma, grade 1, probably metastatic from the thyroid. Although the thyroid felt and looked normal, because of the pathologist's diagnosis of adenocarcinoma, the right lobe was resected. Macroscopic examination revealed in the lower pole a tiny nodule of meaty looking tumor which proved to be papillary carcinoma, grade 1. The nodule at the angle of the jaw on the left side was not removed. The "aberrant tumor" as cystic contained lymphoid tissue and mitotic figures were evident. The thyroid tissue was solid and there were occasional mitotic figures. The metastatic lesions were cystic gave evidence of capsular and lymphatic invasion, and con-

tained lymphoid tissue. All the growths were simple papillary carcinomas arising in adenomas, except in the metastatic nodes, for occasional regions which were suggest of nonpapillary adenocarcinoma.

The patient received treatment by radiation. Two months later recurrence had not taken place.

CASE (Figs. 36 and 37). A woman aged 37 years, on examination at the clinic had had a single tumor under the right sternocleidomastoid muscle for 10 months. The patient stated that the tumor fluctuated in size and that when it was large it caused dyspnea by pressure on the trachea. A diagnosis of bronchial cyst was made clinically and operation as performed for removal of the growth. The thyroid appeared normal on surgical exploration, but because of the pathologist's report that the cyst was papillary carcinoma, right hemithyroidectomy was done and in the extreme tip of the superior pole of the lobe there was found a tiny nodule of carcinoma tissue. Microscopic examination of the specimen revealed mixed papillary and nonpapillary carcinoma, grade 1 of the thyroid, with repeated metastatic lesions. The cervical cystic tumor contained

frequent mitotic figures and showed capsular invasion, lymphoid tissue was not found. The thyroid tumor was composed of mixed solid and cystic tissue, contained many mitotic figures, and gave evidence of vascular, capsular, and lymphatic invasion.

Six months later the patient was subjected elsewhere to right radical block dissection of tumors of the neck and afterward was treated by radiation. Seven years after her first operation she reported that she was in good health, free from recurrence.

CASE 3 (Figs 24 and 25) A woman, aged 37 years, came to the clinic because of gradually increasing tumor of 4 years' duration situated under the right sternocleidomastoid muscle. Clinical diagnosis was made of cervical adenopathy, and the tumors were excised. The pathologist reported that the growths were papillary carcinoma. Although the thyroid on surgical exploration apparently was normal, the surgeon was doubtful and resected the right lobe, in the upper pole of which were found two small nodules that proved to be carcinomatous. Microscopic study revealed mixed papillary and nonpapillary adenocarcinoma, grade 2, of the thyroid with regional metastatic extension. Patient received radiation treatment.

Five months later the patient returned with recurrence of tumors under the right sternocleidomastoid muscle. Radical block dissection was made and was followed by radiation. The pathologist's report was identical with that made 5 months previously. The "aberrant" tumor was solid, contained abundant mitotic figures and evidence of vascular invasion, lymphoid tissue was not present. The thyroid tumor was of the same type but in addition showed evidence of capsular and lymphatic invasion. The recurrent tumor which was removed at the second operation possessed all the features of both the "aberrant" tumor and the thyroid tumor and contained lymphoid tissue.

Nine years after first operation the patient living and well.

CASE 4 (Figs 26 and 27) A man, aged 24 years, had had multiple tumors of the right side of the neck, under the sternocleidomastoid muscle and at the angle of the jaw, for 10 years. They gradually had increased in size. When operation was performed for excision of the tumors, surgical exploration of the thyroid revealed a tumor in the right lobe and right hemithyroidectomy was done. The pathologist reported papillary adenocarcinoma, grade 1, of the thyroid with regional metastatic extension. Both the thyroid tumor and the metastatic tumors were cystic and contained occasional mitotic figures. Lymphoid tissue was present, and there was evidence of capsular and lymphatic invasion. The papillary carcinoma arose from an adenoma. The lymphoid tissue in the thyroid was a nodule extrinsic to the encapsulated tumorous tissue and was not invaded by it. Patient later received treatment by radiation.

Eight years afterward the patient returned to the clinic because of recurrence of tumors under the left sternocleidomastoid muscle, he again received treatment by radiation. Two years later it was reported tumors were still present. The patient did not return for further treatment.

CASE 5 (Figs 28 and 29) A woman, aged 22 years, came to the clinic because of multiple tumors of the neck and at the angle of the jaw on the right side. The growths had been present for 2 years and gradually were increasing in size. Physical examination revealed that the tumors in the neck were under the sternocleidomastoid muscle. Diagnosis was made of tuberculous adenitis. Biopsy at the time of surgical intervention revealed the presence of papillary carcinoma, a right radical block dissection of the tumors was made and after exploration of the thyroid, the right lobe which was enlarged slightly, was removed.

The pathologist reported papillary and nonpapillary carcinoma, grade 2, of the thyroid with regional metastatic

extension. The specimen of tissue removed for biopsy was solid and, on microscopic examination, was found to contain occasional mitotic figures. The thyroid tumor and metastatic tumors were solid and mitotic figures were present with evidence of capsular, vascular, and lymphatic invasion. None of specimens contained lymphoid tissue.

Subsequent to operation the patient received treatment by radiation. Two months afterward recurrence of the tumors had not taken place.

CASE 6 (Figs 4 and 7) A girl, aged 18 years, registered because of the presence for 9 months of multiple tumors of the left side of the neck. On physical examination the growths proved to be under the left sternocleidomastoid muscle and in the left posterior triangle. Three weeks before the patient came to the clinic, biopsy had been performed elsewhere of one of tumors in posterior triangle, and pathologist's report papillary carcinoma.

A clinical diagnosis was made of cervical carcinoma and at operation all the cervical nodules were removed. The thyroid was examined and apparently was normal. The pathologist reported the nodules as papillary adenocarcinoma, grade 1, probably metastatic from the thyroid. Treatment by radiation was not given.

The patient returned 1 month later with a recurrence under the left sternocleidomastoid muscle and a palpable tumor in the left lobe of the thyroid. Left radical block dissection and left hemithyroidectomy were done. Both tumors proved to be papillary adenocarcinoma, grade 1, identical with the nodules removed earlier. Microscopic examination of the "aberrant" tumor revealed solid tissue that contained occasional mitotic figures, lymphoid tissue was present and capsular invasion had taken place. The findings in thyroid tumor and metastatic nodes were the same except thyroid tumor contained no lymphoid tissue.

The patient received treatment by radiation, 9 months later she had remained free from signs of recurrence.

In 9 cases, the thyroid tumor did not become clinically detectable until some time after removal or biopsy of the "aberrant" tumor, in 3, the thyroid tumor was the first to appear. In 17 cases, as has been stated, a tumor in the thyroid gland never developed, even though there was recurrence of the "aberrant" tumor in the neck. All but 4 of the 17 patients received radiation and by this treatment a primary growth in the thyroid may have been destroyed. Believing, as we do, that all "lateral aberrant thyroids" are metastatic tumors from primary growths in the thyroid, the failure of appearance of a thyroid tumor in the last 4 cases must be attributed to the slow rate of growth which has been shown to characterize this type of carcinoma.

EVALUATION OF STUDY

It has been pointed out previously herein that some of the authors who believe in the "activated rest" theory of origin of "lateral aberrant thyroids" have expressed the opinion that physiological overstimulation of the constitutionally inferior tissue derived from the lateral anlagen causes to develop in that tissue papillary change which proceeds to malignancy. These men accept the view that the lateral components do form part

of the lateral thyroid lobes. In support of their opinion, they state further that carcinoma seldom, if ever, occurs along tract of median anlage.

It is well recognized that among adolescents physiological overstimulation of the thyroid in the presence of iodine deficiency results in diffuse colloid goiter. Goiter of this type is devoid of any of the papillary elements which one would expect to find, according to these writers, if the lateral anlagen were constitutionally inferior. Furthermore papillary carcinoma of the thyroid gland often involves a whole lobe uniformly commonly stopping abruptly at the midline. Thus both median and lateral components are in a way similarly the line of demarcation appearing to be based on direction of lymph flow. Probst and Agnew reported a case of papillary change in a nodule of thyroid tissue situated in the right side of the base of the tongue; the position of this nodule would indicate that it was derived from the median component. Such a case offers proof that papillary change is not limited to tissues derived from the lateral anlagen.

We have shown that the majority of the so called lateral aberrant thyroids occupy positions in the neck anatomically identical with the deep cervical lymph nodes and that 55 per cent of them present definite microscopic evidence of lymph nodal tissue that is, in capsule lymph follicles and peripheral sinuses (Figs. 2 and 13) which have not been entirely destroyed by the malignant cells. It has been pointed out that some observers have expressed the opinion that such tissue is not indicative of metastatic infection of a lymph node but is characteristic of lateral aberrant thyroid tissue. Yet in our series of cases we were unable to find any evidence of lymph nodal tissue in the thyroid tumors which, according to the same men are derived from the same source as the aberrant thyroids. Furthermore photomicrographs of the developing median and lateral anlagen at the stage of budding out from the pharynx, reveal no lymphocytes associated with the thyroid epithelial primordium (34). In our opinion, it is impossible to distinguish microscopically metastatic lymph nodes from aberrant thyroids in the same or in different cases.

Tumors derived from the median anlage are found at its site of origin or along the path of its descent. If lateral aberrant thyroid tumors were really derived from the lateral anlagen, one would expect to find them situated also somewhere along the tract of the lateral anlagen from the pharyngeal wall to the thyroid. Weller showed that this tract lies between the carotid sheath and the thyroid lobe laterally and the trachea and esophagus

medially. We have found that the majority of these "lateral aberrant" tumors lie superficial to or external to the carotid sheath. There is no record at the clinic of the finding of normal thyroid tissue elements lateral to the thyroid gland during the course of the routine microscopic examination of material removed in several thousand radical dissections of the neck performed for conditions other than cancer of the thyroid gland.

Lahey and others expressed the belief that the papillary thyroid tumors coexistent with many "aberrant thyroids" are metastatic from the latter into the thyroid. Mahorner and others showed that the direction of the flow of lymph in the thyroid gland is outward from the gland to the deep cervical nodes, the lymphatics of each lobe going to the nodes of their own side and not crossing over to the opposite side. In our experience metastatic tumors discovered in the thyroid gland invariably have been blood borne, most commonly from a hypernephroma (37). Carcinomas of the tongue, lips, pharynx, and so forth characteristically invade the cervical nodes but have rarely ever been found to metastasize to the thyroid.

Because of the unusually slow growth in many instances, the contention has been made that these "lateral aberrant papillary tumors" are not malignant; that recurrence does not take place subsequent to their surgical removal; that they do not give rise to distant metastatic growths, and that they do not cause death. We believe that we have presented data that are convincing evidence that these low grade "lateral aberrant thyroid tumors" spread more commonly by way of lymphatic extension and invasion of the capsule than by vascular invasion and that harmless looking papillary cystadenomas of the thyroid tissue as well as the more complex mixed papillary tumors, may cause death (Figs. 4 to 19). Figures 30 to 35 illustrate the fact that not only tumors of mixed papillary and nonpapillary elements but also simple papillary tumors of thyroid tissue may give rise to distant metastatic lesions.

The following report of 3 cases will serve to emphasize that a patient with lateral aberrant thyroid tumor together with gross metastatic extension such as to the lungs may live a long time and that a low grade tumor that has been present for years may bring about a fatal termination.

CASE 7 (Fig. 34). A girl, aged 9 years, was brought to be clinic because of rapidly growing multiple tumors of months' duration under the left sternocleidomastoid muscle. Enlargement of the left lobe of the thyroid gland had been noted for months. The child, as before and examined, revealed that the left vocal cord was fixed. Diagnosis as made of cervical malignant disease. Biopsy of left cervical node disclosed carcinoma, grade 2, in an adenoma.

metastatic from the thyroid. The tumor was solid, composed chiefly of nonpapillary elements with a few papillary elements. Mitotic figures were rare, vascular invasion had not occurred and lymphoid tissue was not present. The condition of the thyroid was inoperable. Treatment by heavy radiation was given.

A year and a half later pulmonary metastatic lesions developed, for which roentgen therapy was applied at repeated intervals. Eleven years after her first examination at the clinic the patient died of carcinoma of the thyroid with metastatic extension to the lungs.

CASE 8. A man, aged 28 years, had had multiple tumors in the right and the left posterior triangles for 14 years. The growths had increased in size in the 3 months previous to his admission to the clinic. For two years the left lobe of the thyroid had been greatly enlarged, the right lobe less so. Examination revealed that the left vocal cord was fixed. The clinical diagnosis was of lymphoblastoma. Biopsy of a left cervical tumor revealed papillary adenocarcinoma, which was diagnosed as metastatic from carcinoma primary in the thyroid. The tumor was cystic, contained occasional mitotic figures, capsular invasion had occurred, lymphoid tissue was not present. The condition of the thyroid was inoperable. The patient was treated by intensive radiation.

As the result of repeated application of radiation, the cervical tumors remained stationary for 14 years, when the patient died from carcinoma of the thyroid.

In our opinion, the most likely explanation of the presence of benign thyroid tumors (Figs 1, 2, and 3) in the side of the neck, separate from the thyroid, is the pinching off of adenomatous masses from a large nodular goiter by surrounding structures, especially muscles, these masses then drift laterally or upward (24, 28). Analogous cases have been reported in which large adenomas were found in the thorax completely separated from the mother tumor.

CONCLUSIONS

1. So called lateral aberrant thyroid tumors are nearly always metastatic extensions to the deep cervical lymph nodes from a primary carcinoma in the homolateral lobe of the thyroid gland.

2. Seventy-four per cent of these tumors are papillary adenocarcinomas and spread by lymphatic extension.

3. Sixty per cent of "lateral aberrant thyroid tumors" are associated with thyroid tumors of identical structure which always are situated on the same side.

4. The "aberrant" tumors should be treated by radical block dissection of the neck and removal of the corresponding thyroid lobe, whether or not a tumor can be felt or seen in that lobe at the operating table.

5. Complete removal of all nodes and thyroid tissue known to be involved is essential if recurrence is to be prevented. Treatment by radiation is of questionable benefit unless surgical removal of the diseased tissue has been complete.

6. Following complete surgical removal the prognosis is good in cases of papillary and low grade nonpapillary carcinomas because the rate of growth of these lesions is very slow and these tumors do not commonly invade surrounding structures, in the inoperable or neglected cases, they may have little effect on the patient's general health for years but they eventually may cause death.

The Removal of the Right and Left uterine Vessels i. C. over f the Broad of the l. h. as—II II J. J. J.

THE REMOVAL OF THE REGIONAL LYMPH NODES IN CANCER OF THE BODY OF THE UTERUS

H W JOHNSTON, M D , Toronto, Canada

IT is a recognized surgical fact that any operation for cancer is incomplete unless the regional lymph nodes are removed. The lymph vessels that drain the body of the uterus are found in the suspensory ligament of the ovary, along the uterine vessels, and the round

ligament. The nodes lie along the uterine, external, and common iliac vessels. An inconstant node is found at the internal inguinal ring. An operative procedure embodying these principles is presented.

The technique of the operation The patient is placed in the lithotomy position, and the vagina is thoroughly cleansed and disinfected. A catheter is passed. The external os is oversewn. This pre-

From the Department of Obstetrics and Gynecology, University of Toronto, and the Gynaecological Service of the Toronto General Hospital.

Fig 3

vents soiling of the field with malignant cells when the uterus is being removed.

The patient is now changed to the Trendelenburg position and the abdomen is opened. The round ligament is identified at the internal inguinal ring, clamped, and divided. The ovario-pelvic ligament containing the ovarian vessels is clamped and divided. The ureter is very superficial at this point, and should be identified before the forcep is applied. The uterus is firmly drawn to the opposite side by traction on the two forceps (Fig. 1). The other forceps are separated and the broad ligament is opened up widely. This

is carried out by inserting two fingers between the leaves of the broad ligament and incising the anterior fold of peritoneum, outside and parallel to the ovarian vessels (Fig. 2). The cellular tissue is brushed aside by blunt and sharp dissection. The regional nodes lying along the uterine, external, and common iliac vessels are removed (Fig. 3). A similar procedure is done on the opposite side.

Pan hysterectomy is now performed. Since the ureter is discernible at all times it is never injured. This preliminary anatomical dissection also makes the hysterectomy easier, safer, and is much more radical.

THE DIAGNOSIS AND MANAGEMENT OF INCARCERATED AND STRANGULATED FEMORAL HERNIA

RAYMOND W McNEALY, M D, F A C S, MANUEL E LICHTENSTEIN, M D, F A C S, and
M A TODD, M D, Chicago, Illinois

THERE has been a recent revival of interest in the treatment of incarcerated and strangulated femoral hernia. The hope of lowering the prevailing very high mortality rate seems to have furnished the incentive. The more favorable outlook, which has resulted from advances in the management of most forms of intestinal obstruction, has not been shared by those patients in whom the obstruction has been due to incarceration or strangulation of a femoral hernia. In a recent article, Dunphy calls attention to the seriousness of this condition and lists three factors which he believes have contributed to the high mortality rate: (1) delay in treatment, (2) the advanced age of the patients, (3) improper surgical management.

DIAGNOSIS

Delay in treatment is often due to error in diagnosis, and this is frequently the result of failure to examine for a mass in the femoral region in the presence of preobstructive gastrointestinal symptoms, or failure to appreciate the significance of a femoral mass when it is noted.

Dunphy points out that the diagnosis of a strangulated femoral hernia usually can be established clinically if it is given due consideration. Whenever a patient, especially a woman past middle life, complains of unexplained gastrointestinal symptoms, obstipation, and particularly abdominal pain and vomiting, the possibility of a strangulated femoral hernia should be considered. A proper appreciation of these remarks will prove to be the first step toward a reduction of the prevailing high mortality rate.

One of the most common causes of intestinal obstruction is incarceration of abdominal contents in a hernial sac. Examination, therefore, of the site of the hernial rings is necessary to make a diagnosis, because local pain may be so mild that it does not direct attention to the seat of the trouble. The mass is commonly small in size and for this reason, in some instances, the patient or the surgeon may fail to appreciate the relation between the abdominal symptoms and the unobtrusive mass present in the groin.

The anatomical relations of the sac in a femoral hernia are such that once the sac has appeared in the groin it is seldom replaceable into the abdomen, even by manipulation. The narrow neck of the sac and the small size of the femoral canal provide circumstances which occasionally result in strangulation of the sac alone (Figure 1, a and b). It may be difficult at times to differentiate this condition from strangulation of the contents of the sac. The relation of the sac to its contained structures is such that incarceration of the contents of the hernial sac can occur with relative ease (Fig. 1).

Acutely inflamed lymph nodes in the groin in an elderly individual may be confused with a strangulated femoral hernia (Fig. 2). This is due to the similarity of the constitutional and local disturbances in both conditions.

The differential diagnosis of a femoral hernia from an inguinal hernia can be made by noting the relation of the swelling in the groin to the pubic spine. In femoral hernia the neck of the sac is always lateral to the pubic spine, while in the inguinal hernia the sac makes its exit from the abdominal wall above or medial to the pubic spine. This difference in the site of exit from the abdomen usually can be seen on inspection while the patient is standing and bearing down to increase the intra-abdominal pressure. In the recumbent position many inguinal hernias are spontaneously reduced and thus lose their physical manifestation. The sac of a femoral hernia, however, will persist in place, even though it is freed of its contents, and it can be palpated lateral to the pubic spine. When incarceration of contents occurs, the differentiation between an inguinal and femoral hernia usually can be made by noting the relation of the mass to the pubic spine (Fig. 3). In each instance the mass may lie in the femoral or inguinal regions, but in the femoral hernia all of the mass is lateral to the pubic spine.

We have felt that the study of a series of consecutive cases of strangulated femoral hernia, with the emphasis placed on certain important findings, should yield a better insight into the problems of diagnosis and management of such conditions.

*T April, 1940.

STUDY OF 225 CASES OF STRANGULATED OR INCARCERATED FEMORAL HERNIA

In a series of 404 patients with femoral hernia admitted to the Cook County Hospital during the past 9 years, it was found that in 225 (55.7 per cent) there was incarceration or strangulation of hernial contents at the time of admission (Table I). In 46 of these 225 patients nonoperative reduction of the contents of the hernial sac into the abdomen was possible. These patients were relieved of their symptoms. In 6 instances the hernia could not be reduced manually and the patients died before operative reduction could be attempted. Some of these deaths could be attributed directly to complications incident to the strangulation of the hernial contents, while in other patients there was no direct relationship between the cause of death and the pathological condition of the hernia. One hundred and seventy-three of the 225 cases required and received urgent surgical care. Of these 121 were females and 52 were males, distributed in age groups as listed in Table II.

NONOPERATIVE REDUCTION OF HERNIAL CONTENTS

In the 46 patients who had nonoperative manipulative reductions of their hernias, there were no failures to relieve the symptoms immediately. Many of these patients, however, returned at a later date for elective surgery.

The technique of nonoperative reduction is based on the anatomical configuration of the sac

TABLE II.—DISTRIBUTION OF OPERATIVE CASES OF INCARCERATED AND STRANGULATED FEMORAL HERNIA BY AGE GROUPS

Age	Number operated upon	Age	Number operated upon
5 years		51 to 60 yrs	33
1 to 20 yrs		61 to 70 yrs	42
21 to 30 yrs	3	71 to 80 yrs	35
31 to 40 yrs	14	81 to 90 yrs	5
41 to 50 yrs	15	91 yrs	
Under 40 years of age—9 cases			
Over 40 years of age—34 cases			

and its relation to the surrounding structures. Pressure directly against the fundus of the hernial mass is inclined to increase the difficulty of reduction, because this maneuver tends to increase the angulation of the sac which is usually present where it turns abruptly to pass under the inguinal ligament. Gentle stroking of the mass downward and slightly inward with the hand will decrease the angulation just mentioned, and if the patient is supported in a moderate Trendelenburg position, it will facilitate the reduction of the contents of the hernial sac (Fig. 4). It is inadvisable to persist too long or to be too vigorous in one's attempts to reduce a femoral hernia. The communication between the peritoneal cavity and the sac may be too narrow to allow replacement of distended bowel, edematous omentum, or viscera. There have been many reports of the rupture of strangulated, necrotic bowel by too vigorous manipulation.

OPERATIVE MORTALITY

In the patients operated on (173) there were 40 deaths, or 23.1 per cent (Table III). There is a striking correlation between the mortality rate and the duration of symptoms. Fifteen patients were operated on within 48 hours of the onset of symptoms and only 6 died, 6.6 per cent. In 4 patients on whom the operation was performed 1 week after the onset of symptoms there were 9 deaths, 30 per cent (Table IV).

TABLE IV.—MORTALITY RATE IN RELATION TO DURATION OF SYMPTOM

Duration acute symptoms	No. cases	Deaths	Mortality
less than 48 hrs	5	6	
48 hrs to 3 days	7	5

Fig 4 Direct pressure against the sac makes the angle at the neck more acute and reduction is then rendered less likely With the patient in the Trendelenburg position, stroking of the sac toward the knee may aid in the reduction of the contents

SURGICAL PATHOLOGY

Contents of the sac The contents of the sac in our reported cases varied as shown in Table V In 10 instances there were no contents in the sac In these the sac itself was either incarcerated in the femoral canal or strangulated, and the condition of the sac alone was responsible for the pa-

tient's complaint These cases are the basis of a separate report which has recently been published (2)

When intestines were incarcerated in the hernial sac, an elevation of temperature was usually present (Table VI) A rapid pulse rate was an almost constant accompaniment

resulting changes in the blood chemistry and body tissues which ensue following the creation of an intestinal fistula. The avoidance of the fistula if possible, is most desirable, and one should make every effort to restore the continuity of the intestinal tract.

SUMMARY

In a consecutive series of 404 patients with femoral hernia admitted to the Cook County Hospital from June 1931 to April, 1940 225 were incarcerated or strangulated on admission. Attempts at nonoperative reduction of the contents of the hernial sacs were successful in only 46 instances. Six patients died before operative reduction could be done. One hundred and seventy three patients received surgical treatment. Sixty per cent of the patients with gangrenous bowel died (20 of 33 cases). In the absence of gangrene of the intestines the mortality rate was only 14 per cent (20 of 140 cases).

CONCLUSIONS

1. The diagnosis of incarcerated and strangulated femoral hernia must be made early if treatment is to afford a reduction in the prevailing high mortality rate.

2. Intestinal obstruction, partial or complete due to a femoral hernia in elderly individuals, must be suspected, sought for and treated early because gangrene of bowel jeopardizes recovery from this serious condition.

3. Restoration of intestinal continuity following bowel resection is more desirable than the establishment of an enterostomy.

4. In the operative treatment the sac should be opened and the contents inspected before the femoral canal is enlarged. This will avoid accidental reduction of the hernial contents before examination of questionably viable viscera is possible.

5. Enlargement of the femoral canal is accomplished by severing the lacunar and, if necessary the inguinal ligament adjacent to the pubic spine.

6. A minimum of suture material should be used to approximate the inguinal ligament to the pectineus fascia, and the closure of the incision should be made with interrupted sutures not too closely spaced.

ANESTHESIA IN CASES OF POOR SURGICAL RISK

Some Suggestions for Decreasing the Risk

R CHARLES ADAMS, M D, M S (Anes), and JOHN S LUNDY, M D,
Rochester, Minnesota

WHEN a patient who is classified as presenting a poor surgical risk comes to operation today, he stands a better chance of withstanding the effects of both the anesthesia and the operation than he did a few decades ago. Advances in many fields of medicine have helped to decrease the risk of operation and anesthesia in these cases. For instance, the use of insulin for diabetes, together with other methods of treatment, has reduced greatly the incidence of complications which accompanied surgical procedures on such patients. The preoperative management of patients who have thyrotoxicosis has reduced the morbidity and mortality rate accompanying thyroidectomy. Improved operative procedures have decreased the risk in certain fields, such as the present method of transurethral prostatic resection for prostatic hypertrophy.

Advances in the field of anesthesia and its related specialties have been of prime importance in the successful preoperative, operative, and postoperative management in cases of poor surgical risk. These advances are classified broadly as follows: (1) the evolution of less toxic anesthetic agents, (2) improved methods of administration of anesthetic agents, (3) the use of a combination of agents and methods, thereby decreasing the toxicity resulting from the use of a single agent, for instance, the so called balanced anesthesia as previously described by one of us (Lundy, 25), (4) improved methods of administration of oxygen and other inhalants, (5) supportive measures during the operative and postoperative period and (6) special measures, such as the use of tracheo-bronchial aspiration after operation. Finally, the skill and versatility of the anesthetist must be considered as important contributing factors to the welfare of the patient for whom the risk of operation is great. The patient's life often depends more on the way a certain anesthetic agent is administered than on the effects of the anesthetic agent itself.

Various methods have been employed in grading the degree of risk which each patient presents.

Saklad (36), as a member of a committee of the American Society of Anesthetists, Inc. studied problems of classification of anesthetic data and suggested that the term "operative risk" be supplanted by the term "physical state." The reason for this suggested change was for the purpose of limiting many variable factors, such as the type of operative procedure, ability of the surgeon and anesthetist, and the type of anesthetic agent the patient will receive. On the basis of "physical state," 4 classes were made, with two additional classes for emergencies. In brief, the first 4 classes are as follows:

In class 1 are included cases in which organic pathological change is absent or the pathological process is localized and does not cause any systemic disturbance or abnormality, for example, any type of operation for fractures without shock or loss of blood or uncomplicated hernias.

In class 2 are included those cases in which a moderate but definite systemic disturbance, caused either by the condition that is to be treated by surgical intervention or which is caused by other existing pathological processes is present, for example, mild diabetes, mild acidosis, moderate anemia, or mild thyrotoxicosis.

In class 3 are included those cases in which severe systemic disturbance from any cause or causes is present. It is not possible to state an absolute measure of severity, as this is a matter of clinical judgment. For example, these conditions include complicated or severe diabetes, combinations of cardiac disease and respiratory disease, pulmonary tuberculosis associated with tachycardia or dyspnea, and severe accidental trauma associated with shock.

In class 4 are included those cases in which extreme systemic disorders already have become a threat to life regardless of type of treatment. For example, these disorders include cardiac decompensation, a combination of cardiovascular-renal disease with marked renal impairment and of an operation on a patient already in poor condition to arrest hemorrhage after much loss of blood.

One of us (Lundy) suggested a brief classification of operative risk as follows: grade 1 patients in such good physical condition that they will probably tolerate any anesthetic agent well; grade 2 cases of so-called average risk, in which the risk of the operation is greater than the risk of the anesthetic; grade 3, patients for whom the anesthetic agent must be selected with care since owing to pathological conditions, the risk of the anesthetic is as great or greater than the risk of the operation; and grade 4, patients who are in such serious physical condition that the use of any anesthetic agent is dangerous. For such patients, local infiltration may be used to control the pain but only half the concentration and half the usual amount of solution should be employed.

The risk of operation in a certain case can be evaluated intelligently only after all findings from physical and laboratory examinations are available. In certain cases, the effects of pathological lesions are so well marked that the risk is obviously poor. In others, there may be a number of obscure and less marked pathological changes which do not become apparent until the results of a complete examination have been obtained.

All anesthetic agents may be toxic to human tissue, but certain organs and tissues may suffer more acutely than others. The liver and kidneys are usually affected owing to their functions of detoxication and excretion (32). Certain anesthetic agents produce specific damage to certain organs, such as damage to the tissue of the liver by chloroform. When pre-existing damage is present, the toxic effect of the anesthetic agent becomes more marked and results in greater inhibition of function. Therefore, in choosing the anesthetic agent for a patient who presents a poor surgical risk, the main factor to consider is to what extent the agent or agents will affect physiological processes already impaired. It is difficult and impractical to attempt to lay down general rules as to the choice of anesthetic agent for these patients, as each presents an individual anesthetic problem. (3) The method of choice is one which will produce the least deleterious effects in the light of the existing pathological processes and which, at the same time, will be adequate for the anticipated operation. By the choice of the proper anesthetic agent, skillfully administered and preceded by careful preoperative preparation of the patient and accompanied by suitable supportive measures, it is possible to improve the status of his risk from one of doubtful outcome to one which offers him more than a reasonable chance of satisfactory convalescence and recovery (1, 37).

GENERAL FACTORS CONTRIBUTING TO THE PATIENT'S RISK

A few basic facts which can be ascertained from the physical and laboratory examinations usually will be all that are required in order to form a fair approximation of the risk of anesthesia and operation in a particular case. Important among these are the estimation of hemoglobin, the level of blood pressure, findings on urinalysis, degree of cardiac and renal sufficiency and the general appearance of the patient in regard to nutrition, debility and loss of weight. Although a more detailed examination may uncover further evidence of physiological abnormalities, such information may not be essential to the choice of the safest anesthetic agent. If these salient features are weighed and estimated carefully, it is not essential that facilities for a thorough laboratory examination be available. Some of the more ordinary factors to consider follow:

Age. Anesthesia and operation are not tolerated as well by patients at the extremes of life. The respiratory system of infants and young children is depressed easily by anesthetic agents. Debility and cardiovascular-renal disease may be complicating factors in the cases of aged persons. Miller observed that the mortality rate of surgical patients more than 50 years of age was eight times as great as that for patients less than 50. The need for supportive treatment should be anticipated for aged patients (15). Elderly patients fare better after operation if they are gotten up out of bed at the earliest possible time.

Habits. The mode of life of a patient has a bearing on the risk. Those who use tobacco excessively and have accompanying bronchitis are prone to respiratory complications after anesthesia and operation. Chronic alcoholics usually fare poorly under anesthesia and seem more susceptible to complications during the postoperative period. The same applies to drug addicts, since there are often accompanying nutritional and nervous disturbances.

Nervous system. Patients who are "high strung" usually are more difficult to anesthetize than those of more stolid type. Those who come to the operating room worried, frightened, and with the mental attitude that death is imminent or that they cannot survive the operation do not present a good risk and often have a stormy convalescence. Adequate preliminary medication and assurance are important therapeutic measures in these cases.

Taric states. Toxemia, whether attributable to systemic or malignant disease, infections, or other causes, increases the gravity of the risk in direct proportion to the degree of toxemia present.

Debility Patients who are frail, debilitated, underweight, and poorly nourished lack the reserve of robust patients to withstand the toxicity of anesthesia and the shock associated with the operation. The risk of operation on markedly debilitated patients is always high. The vital functions of these patients are depressed by even small doses of anesthetic agents and great caution must be observed to prevent overdosage. Prolonged vomiting is serious, since it leads to nutritional disturbances, decrease of glycogen in the liver, and to the more serious conditions of acidosis and ketosis. The other extreme, also serious, is alkalosis, which can be produced, among other conditions, by intestinal obstruction.

Obesity Obese patients need not necessarily present a poor surgical risk, but by and large a patient who is grossly overweight does not have as good a chance of withstanding anesthesia and operation as one whose weight is nearer a normal figure. In the cases of obese patients, the operative manipulations often are more difficult and fatty infiltration of the cardiac muscle may be present, thereby lowering cardiac reserve and more or less inhibiting respiratory exchange.

HEPATIC FUNCTION

The liver and the state of its function have an important bearing on the anesthesia and its effect on the patient (31). One of the principal functions of the liver is its power of detoxification, including detoxification of certain anesthetic agents (3). In addition, the functions of the liver are inhibited and liver tissue is damaged by the action of certain anesthetic agents in the body. Bourne stated that with the exception of cyclopropane, all anesthetic agents may cause some impairment of hepatic function. The normally functioning liver, however, handles the strain imposed on it by anesthesia and operation well, provided its store of glycogen is adequate and anoxia is prevented. If its function has been impaired by toxemia and if nutritional disturbances have depleted its supply of glycogen, it then not only performs its normal functions poorly, but its vulnerability to further damage from the anesthetic agent is increased. The malfunctioning liver invariably has a low content of glycogen which always increases the risk from the anesthesia and operation. The most toxic anesthetic agent to hepatic tissue is chloroform, manifested by toxic changes in the lobules of the liver, degeneration and necrosis, leading to inhibition of function of varying degrees. For this reason, chloroform anesthesia has been largely abandoned. Divinyl ether anesthesia also may damage the liver, particularly if the

state of anesthesia is prolonged, but not to the extent or with the frequency of that produced by chloroform. Ether anesthesia impairs the function of a normal liver slightly, causing diminution of its content of glycogen, hyperglycemia, and decrease in hepatic secretion, but normal function is soon resumed during the postoperative period. Cyclopropane has little, if any, deleterious effect on hepatic function, and the same is thought to be true in the case of the very short acting barbiturates.

The best means of protecting an impaired liver are diet high in carbohydrates in order to increase the content of glycogen of the liver before operation and the maintenance of adequate oxygenation during the anesthesia and after operation. In cases of obstructive jaundice, in which the prothrombin time is increased and postoperative hemorrhage is feared, treatment with vitamin K before operation is indicated (38). Allen and Livingstone stated that the early postoperative fall in prothrombin in cases of jaundice and biliary fistula seems to be caused primarily by the inadequate administration of vitamin K before the operation, rather than from anesthesia, operative trauma, or hemorrhage. Blood transfusions are also of value. Adequate oxygenation during anesthesia is of the utmost importance in protecting the liver against the toxic effects of anesthetic agents.

RENAL FUNCTION

Although the kidneys are affected directly by certain anesthetic agents, their function also is impaired indirectly as a result of the effect of the anesthesia and operation. Chloroform may produce direct damage to the renal epithelium. Ether anesthesia causes a marked decrease in urinary output, ending in almost complete suppression after an hour or more of anesthesia. Normal function is resumed in the first 24 hours after operation. Cyclopropane anesthesia also suppresses urinary output during anesthesia; this is followed by a compensatory increase in excretion after operation. Tribromethanol anesthesia also causes urinary suppression and Veal, Phillips, and Brooks have shown in rabbits that when even mild degrees of nephritis are present, the margin of safety with this type of anesthesia is small (41). If, at the time of operation renal damage has occurred, anesthetic agents which are toxic to renal tissue and tend to inhibit renal function will produce more drastic disturbances in these organs than if they were normal. Thus, renal insufficiency markedly increases the gravity of the patient's risk.

Indirect effects of the anesthesia and operation also have an important bearing on renal function. These effects, according to Beecher, depend on several things. A marked fall in blood pressure during operation can diminish and arrest urinary secretion. Asphyxia may cause constriction of the renal vessels, leading to diminished blood flow through the kidneys and decreased formation of the urine. Owing to the resultant local anoxia the glomerular epithelium is damaged and permits the passage of albumin, proteins, and blood. Loss of fluids and blood during the course of the operation also contributes to postoperative anuria. In cases of advanced nephritis the risk of operation is not good and nephritis often is accompanied by arteriosclerosis, hypertension and cardiac insufficiency which further increase the gravity of the risk (33). In such cases, careful tests for renal function should be performed and the level of blood urea and nonprotein nitrogen should be evaluated. In the preparation of such patients for operation, the values for blood urea, creatinine and nonprotein nitrogen should be reduced as far as possible by forcing fluids and intravenous therapy before operation. If these values stabilize readily to values not grossly abnormal, the patient may stand operation and anesthesia satisfactorily.

CARDIOVASCULAR SYSTEM

Cardiac insufficiency if advanced and uncompensated, forms one of the gravest complications the anesthetist has to face. However, it is agreed among cardiologists that patients who have many types of cardiovascular conditions, provided that compensation is adequate and cardiac reserve is satisfactory stand anesthesia and operation remarkably well (17). Patients who give the most concern are those who have advanced myocardial degeneration accompanied by circulatory insufficiency and marked dyspnea. Although a careful cardiovascular examination should be routine before any operation, a fair estimate of the patient's cardiac reserve may be obtained from information the patient can supply. If he does not have dyspnea or precordial pain, either with or without moderate exertion, and if he is able to carry on the usual activities of daily life it is probable that his heart will stand the strain of anesthesia and operation. The risk increases in proportion to the extent with which his activities are limited by the cardiac condition. If perturbation itself does not increase the risk markedly, provided cardiac reserve is satisfactory. From a review of the literature Woodbridge stated, "it is generally agreed that coronary occlusion, angina pectoris, congestive failure and syphilitic

aortitis carry high operative mortality and that valvular heart disease and auricular fibrillation if uncomplicated by failure, and paroxysmal auricular flutter fibrillation, or tachycardia do not add appreciably to the anesthetic or surgical risk.

RESPIRATORY SYSTEM

Disease of the lungs and of the respiratory passages obviously has an intimate bearing on the course of anesthesia, the complications that may arise and the degree of risk for the patient during and after operation. The effect is dependent on the site, nature, and extent of the lesion to what extent the lesion will interfere with the supply of oxygen and its transportation to the body tissues and the elimination of carbon dioxide. There is also the added risk of the production of other pulmonary complications after operation as a result of the anesthesia and operation or the extension of those which existed before operation. Any pathological condition which lowers vital capacity to a marked degree increases the patient's risk. Moersch stated that the closer the vital capacity approximated tidal air the graver was the risk. Examples of lesions which affect vital capacity are emphysema, abscess of the lung, tuberculosis, pneumonic pleurisy with effusion, asthma defects of the thorax, and also certain cardiac conditions, particularly mitral stenosis.

A reduction in vital capacity always calls for particular care in the maintenance of adequate ventilation during anesthesia. The most important factor for accomplishing this is a free airway. When there is any question of difficulty in maintaining an adequate supply of oxygen, an intratracheal tube should be inserted after induction of anesthesia. Klotz pointed out that obstruction of the upper or lower portions of the respiratory tract which prevents the free passage of air to the blood and tissues is always serious. He also emphasized the great importance of terminal blockage of large numbers of air sacs, which reduces vital capacity and interferes with adequate exchange of oxygen and carbon dioxide, as well as that of anesthetic gases. One of the greatest hazards of deficiency of oxygen as demonstrated by Courville (6, 12) is its damaging effect on the central nervous system, particularly on the cerebral cortex. A few minutes of severe anoxemia may produce permanent damage. Waters (41) stressed the necessity of maintaining the integrity of the patient's mechanism for transportation of oxygen, of maintaining a free airway and maintaining adequate tidal exchange, by mechanical means if necessary. For the relief of pain, he further stressed caution in the use of drugs which may

aggravate respiratory depression and predispose to postoperative pulmonary complications (43). Asthma usually does not produce an untoward surgical risk. After both ether and intravenous pentothal sodium anesthesia, periods of relief from the asthmatic attacks have been observed.

Anemia frequently accompanies pathological lesions of the respiratory system and is present often when the patient is debilitated and when the risk of operation and anesthesia is great. This condition, owing to the lowered oxygen carrying capacity of the blood, interferes with adequate transportation of oxygen to the tissues. When concentration of hemoglobin is less than 8 to 10 grams per 100 cubic centimeters of whole blood, it is wise to give a blood transfusion before operation.

When indicated, the value of suction aspiration of the tracheobronchial tree during the immediate postoperative period is assuming major importance in relation to the control and prevention of postoperative pulmonary complications, such as atelectasis, massive collapse of the lung and bronchopneumonia (18, 30). According to Hinshaw, defective pulmonary drainage appears to be the primary cause of many cases of pneumonia after operation. If permitted to exist for long, depression of respiration during anesthesia and the formation of viscid mucus may plug a bronchus and lead to lobular, lobar, or massive collapse of the lung. The use of suction bronchoscopy is one of the greatest advances in helping to lower the incidence of postoperative pulmonary complications after anesthesia.

The administration of oxygen, whether by tent, nasal catheter, or special masks, such as the B. L. B. (Boothby, Lovelace and Bulbulian) oxygen mask, has become of routine importance in the postoperative management of surgical patients (8, 42). The administration of 100 per cent oxygen after operation has been useful in the relief of gaseous distention. Helium with mixtures of oxygen may be respired with less effort than oxygen or oxygen and air. Treatment with oxygen and helium has been beneficial after operation for patients who have asthma and mechanical obstruction to respiration as a result of infections, tumors, foreign bodies, or laryngeal edema.

DIABETES

Generally speaking, modern methods of diabetic therapy and anesthesia have lifted the diabetic patient out of the group of patients who present a poor risk. Unless these patients have other pathological conditions which in themselves would lead to abnormal hazards from surgical procedures and anesthesia, their outlook is

generally favorable. Other conditions frequently do exist in cases of diabetes, among which are tendencies to coronary thrombosis and cerebrovascular accidents. Many clinicians are of the opinion that the diabetic patient under satisfactory control can even withstand the disturbance of such agents as ether without untoward reactions. This seems to be true, but with the anesthetic agents available we are of the opinion that we are justified in using those which interfere least with carbohydrate metabolism. Ether not only elevates the level of blood sugar but tends to produce acidosis as a result of postoperative vomiting and restriction of food. Nitrous oxide, ethylene, and cyclopropane are suitable since they only slightly affect carbohydrate metabolism. Anoxemia may result in acidosis and thus, cyclopropane is preferable to nitrous oxide or ethylene, unless these agents will produce adequate anesthesia without deficiency of oxygen. Neff and Stiles found that Bourne's buffer phosphate solution reduced the incidence of postanesthetic nausea and vomiting with cyclopropane anesthesia. Spinal and regional anesthesia also are satisfactory for diabetic patients. Pentothal sodium intravenously administered and used alone or in combination with local or regional anesthesia also is advocated. If it is necessary to operate on a patient who has uncontrolled diabetes, every effort should be made to control the diabetes before the operation is performed unless the operation is urgent. When stabilization has occurred, any of the suggested methods of anesthesia which are adequate for the operation may be employed and if ether is necessary, it may be used in minimal amounts.

AGENTS AND METHODS

It would be impractical to attempt to establish criteria for the types of patients who present poor surgical risks, but brief mention may be made of the potentialities of certain anesthetic agents. A discussion of chloroform and ethyl chloride is purposely omitted because of their toxicity. Divinyl ether and tribromethanol have a place in anesthesia, but the former is somewhat toxic to the liver, particularly for prolonged administration, and the latter produces toxic effect on both the liver and kidneys and is considered safe only when used as a basal anesthetic agent.

Nitrous oxide. On the basis of its low toxicity, nitrous oxide and oxygen is safe, but the toxic effect of the anoxemia which may accompany the anesthesia definitely is deleterious. If the nature of the operation will permit adequate oxygenation, the method is commendable in cases in which

risk is poor. Local or regional anesthesia used with nitrous oxide and oxygen permits larger interventions and is relatively safe for these patients.

Ethylene. Like nitrous oxide the toxicity of ethylene is low and better oxygenation may be obtained than with nitrous oxide. Its uses parallel those of nitrous oxide.

Ether. Valuable as ether is in anesthetic practice its use should be avoided as much as possible in cases of poor surgical risk, owing to its irritating action on the respiratory tract which predisposes to postoperative pulmonary complications, and the vomiting, acidosis, and hepatic dysfunction it causes.

Cyclopropane. The value of cyclopropane in many types of cases of poor surgical risk is inconceivable on the basis of its low toxic effect on the liver and kidneys, its anesthetic potency with high concentrations of oxygen and absence of irritation to the respiratory system (43). Its use is particularly indicated in thoracic surgery (35).

Cyclopropane has certain disadvantages, however. It is a very potent gas and in high concentrations is thought to be toxic to cardiac muscle. Cardiac arrhythmias have been observed during the course of cyclopropane anesthesia, but ventricular fibrillation and complete heart block are among the few that are of great significance. If local or regional anesthesia is withheld used with cyclopropane epinephrine is withheld from the local anesthetic solution since it increases the tendency to ventricular fibrillation (4, 10). Goedel suggested the combination of cyclopropane anesthesia with subarachnoid, peridural or local block to increase abdominal relaxation in certain cases. Another hazard of cyclopropane is its explosiveness in anesthetic concentrations. It should never be used in the presence of cautery or other electrical apparatus. Steps are now being taken to decrease the hazard of electrostatic sparks, among which is intercoupling of the anesthetic gas machine, patient and operating theater gas machine, patient and operating table (20). When cyclopropane is used with all proper precautions, its advantages in certain cases of unfavorable risk far outweigh its hazards.

Intratracheal anesthesia. Respiratory obstruction and resultant anoxemia should never be allowed to persist when such difficulties may be promptly controlled by passage of an intratracheal tube. In cases of great risk or in those in which complications are anticipated, its routine use may be advisable. The effortless breathing that results, the ease and control of anesthetic administration and oxygenation and the facility

of aspirating mucus through the tube, all favor better control. The intratracheal tube has another important use in addition to its use in anesthesia, that is, its value in resuscitation. Prompt resuscitative measures during operations in the presence of poor risk are required frequently. The effectiveness of treatment with oxygen and artificial respiration depends on the patency of the airway. The intratracheal tube assures a patent airway. Reid and Bruce drew attention to the danger of altered cardiac and respiratory function and circulatory derangement as a result of irritation of the respiratory tract, particularly when anesthesia is light. This occurs as a result of reflex action in the autonomic nervous system by introduction of intratracheal tubes or other mechanical airways.

Local and regional anesthesia. Since procaine is the least toxic of local anesthetic agents, its use is preferred in the cases in which the risk of operation is great. Infiltration and block anesthesia, either alone or supplemented, continues to be one of the safest methods for such patients (26). In cases in which cardiac disease or hypertension is present, epinephrine is contraindicated in the anesthetic solution. Hypersensitivity to local anesthetic agents in certain cases must be borne in mind, as well as the inadvertent injection of the solution into a blood vessel.

A few regional methods may be mentioned. Cervical block, skillfully performed, produces adequate and safe anesthesia for most operations about the neck. For operative procedures on the upper portion of the abdomen, abdominal wall block, bilateral intercostal nerve block of the seventh to eleventh intercostal nerves, inclusive, and splanchnic block are valuable procedures. Splanchnic block, supplemented by one of the gases, in addition to either abdominal or intercostal block often is used for operations on the upper portion of the abdomen in cases in which the condition of the patient is unfavorable. Peridural block also may be used with relative safety. For operations on the nose, lower portion of the rectum, penneum and prostate gland, sacral block carries a relatively wide margin of safety. Individual nerve block and simple infiltration frequently are adequate procedures for small interventions.

Spinal anesthesia. Spinal anesthesia, although preferred in certain cases of poor operative risk, often is contraindicated in others. Here again, procaine is the agent of choice, but if the risk of operation for the patient is fair the use of metylocaine may be considered because of the longer duration of effect.

Regardless of other factors, spinal anesthesia is contraindicated when the value for hemoglobin is less than 50 per cent (Dare), or persistent hypotension, disease of the central nervous system, or marked debility exists. Spinal anesthesia is the preferred method for many acute abdominal conditions and for operations in the presence of intestinal obstruction. Spinal anesthesia is safer for operations on the lower portion of the abdomen than on the upper. In considering spinal anesthesia for a patient of doubtful risk, it must be remembered that varying degrees of circulatory and respiratory deficiency are produced through paralysis of the sympathetic and intercostal nerves. These conditions increase in severity with the height of the spinal anesthesia, and this circulatory and respiratory deficiency leads to deficiency of oxygen and varying degrees of anoxemia, the dangers of which have been pointed out.

The method of continuous spinal anesthesia as advocated by Lemmon (22, 23) has certain advantages for prolonged operations in which spinal anesthesia appears to be the method of choice. Its use may be advantageous for spinal anesthesia for certain patients whose condition is unfavorable and for whom it is not desirable to give a dose of the spinal anesthetic agent sufficient for the whole operation. By using the continuous method, a minimal dose is administered and if the patient is reacting favorably to the effects of the spinal anesthetic, subsequent doses may be added as required. In this way it may be possible to prevent circulatory and respiratory insufficiency, which often occurs after a single large dose of a spinal anesthetic agent has been given.

Intravenous anesthesia. Pentothal sodium is the anesthetic agent of choice in intravenous anesthesia. Evipal soluble (sodium salt of n-methyl-C-C-cyclo hexamyl-methyl barbituric acid) although less potent, also is short acting and satisfactory. In cases in which intensive treatment with sulfanilamide has been given up to the time of operation, evipal soluble is preferred since it does not contain sulfur. Adriani (2) demonstrated that evidences of increased toxicity occur when pentothal sodium is administered to animals that have been receiving sulfanilamide. Lorhan and his associates concluded from their experiments that no cumulative toxic action on the liver or kidneys occurred from the administration of sulfanilamide and evipal soluble. It is generally felt that the concurrent use of these agents should be with caution, if at all.

Ordinary anesthetic doses of pentothal sodium have relatively little effect on the liver and kidneys, but when the drug is administered too rap-

idly or in too large doses respiratory function is depressed acutely. A 2.5 per cent concentration is preferred. The normal heart and the heart in which reserve is within normal limits tolerate the effects of pentothal sodium well. Advanced myocardial degeneration associated with dyspnea is a definite contraindication to its use. Most patients, even when debilitated and intoxicated, tolerate the effects of intravenous anesthesia satisfactorily, provided anoxemia is prevented. The risk to the patient is increased when, in order to produce satisfactory relaxation for certain operations, marked respiratory depression and anoxemia are allowed to persist.

The recent trend of opinion is pointing more and more to the increased usefulness and safety of intravenous anesthesia combined with various other methods.

Comment. If it is possible to generalize concerning anesthesia in cases of grave surgical risk, it may be said that combinations of regional anesthesia and cyclopropane and oxygen anesthesia, or regional anesthesia, intravenous anesthesia and nitrous oxide and oxygen anesthesia possess the widest margin of safety. The latter combination obviates the hazard of explosion or fire. Abdominal wall and intercostal block, when supplemented by intravenous anesthesia and the continuous administration of oxygen or 50 per cent nitrous oxide and 50 per cent oxygen by inhalation, is one of the safest methods for anesthetizing patients of doubtful risk. Light pentothal sodium anesthesia forms a satisfactory supplement to spinal anesthesia when indicated and aids in the control of nausea and mental trauma. Small doses, slowly administered, are indicated, since the circulatory and respiratory functions already are depressed by the spinal anesthesia.

RISK AND THE OPERATIVE PROCEDURE

Certain operations carry with them more than the usual degree of risk. Anticipation of the added risk of such procedures to that already existing is necessary from the standpoint of intelligent supportive therapy during the operation. Intracranial interventions usually are serious. It is important that the method of anesthesia does not elevate intracranial pressure. Open drop ether administered by means of an intratracheal tube is satisfactory for many intracranial operations, since an obstructed airway tends to elevate intracranial pressure.

Operations on the thyroid gland do not carry the risk they did in the past, owing to the preoperative management of the patient. Crile (14) stated that the only two absolute contraindica-

tions to operation on the thyroid gland are persistent delirium and persistent vomiting. Local infiltration in addition to gas and oxygen anesthesia usually is satisfactory. In cases in which the gland is exceptionally large or is substernal, the gland is exceptionally large or is substernal, the tracheal collapse because of prolonged pressure on the trachea is a serious potential complication. In such cases, intratracheal anesthesia is the safest method, or at least facilities for prompt intratracheal intubation should be available. Patients who do not respond favorably to preoperative medical treatment present more serious risks than those whose basal metabolic rate and pulse rate do drop satisfactorily after medical treatment. When the basal metabolic rate and pulse rate continue to remain above normal levels despite treatment, many surgeons prefer to perform thyroidectomy in two stages.

Most intrathoracic operations, such as lobectomy pneumonectomy and open drainage of emphysema, carry unusual risk. All open operations on the thorax require delicate anesthetic control, owing to disturbances of respiratory function. Cyclopropane administered by means of an intratracheal tube permits better anesthetic control than any other method. This method often is chosen for operations on the diaphragm, such as in repair of diaphragmatic hernia. Slight amounts of ether sometimes may be added to increase the degree of relaxation and exposure.

Operations on the stomach, duodenum, gall bladder, liver and spleen may present serious anesthetic problems.

Either low spinal anesthesia or intravenous anesthesia with pentothal sodium as the anesthetic agent has been the preferred method for transurethral prostatic resection or for other manipulations on the urethra or bladder (39). Many of these patients are in poor condition because of their advanced age, debility and the prolonged retention of urine which has resulted in retention of nitrogenous waste products and uremia.

SUPPORTIVE MEASURES

Modern methods of preoperative and postoperative treatment and advances in the field of surgical shock and supportive therapy have changed the condition of many patients from that which constituted a poor surgical risk to one for which the risk was fair or even good. Modern methods of intravenous therapy such as administration of sodium chloride, dextrose and so forth have been important. Collier and Maddock mentioned the importance of the kidneys in maintaining water balance. They stated that for seriously ill patients, particularly those who have

a septic condition, severe disease of the biliary tract or some renal impairment from any cause an intake of water that provides at least 1,500 cubic centimeters of urine daily is often desirable. Intravenous therapy is important in maintaining water and electrolyte balance when, because of vomiting, fluids cannot be taken by mouth. Drew and associates stated that in the presence of shock treatment, to be rational, must overcome the severe arteriolar and venular spasm, the capillary paralysis and dilatation and the great capillary circulating blood volume. Hypertonic solution of sodium chloride is used successfully in relieving these effects. The use and value of chemotherapy particularly with the sulfonamide compounds, for infective conditions, is well known.

High in the scale of importance is the treatment of shock during and after surgical operations (40). Shock occurs during operation as a result of several factors, for instance, the anesthesia, operative manipulation and trauma, dehydration, hemorrhage, fear, exhaustion, and anoxemia. Shock, as Moon has pointed out, may become a vicious cycle, associated with low blood pressure, low volume of circulating blood, and hemoconcentration. This circulatory deficiency is associated intimately with oxygen want in the tissues and with atony of the capillaries. Shock, if allowed to persist without treatment tends to become irreversible. Varying degrees of shock occur during any operative procedure, depending on the preoperative condition of the patient, the anesthetic, and the type and duration of the operation. It is obvious that debilitated, anemic, toxic, and functionally abnormal patients will succumb to shock both more easily and to a more profound degree than will more normal patients. Therefore, the anticipation of the need of treatment for shock is particularly important in a case in which the risk of operation is poor.

If shock is to be treated effectively it must be treated promptly. Better still, if it is known that the patient is in poor condition, the shock should be treated before it actually occurs. This is accomplished by various measures, depending on the urgency. A fall in blood pressure during the operation need not be serious if it is not persistent and if it is not associated with marked loss of fluid or blood. Vasopressor agents, such as ephedrine or neosynephrin hydrochloride, may be injected intramuscularly or intravenously in order to elevate the blood pressure. If the fall in blood pressure occurs in the presence of marked loss of fluid (profuse sweating) or is obviously attributable to hemorrhage, vasopressor agents give only transient relief and a false sense of security.

manent respiratory arrest was established for each animal by repeated experiments. For this purpose the initial dose employed was below the average of the series. It was then increased or decreased as required until we had determined the amount of the drug which produced an apparently permanent respiratory arrest in not less than 2 of 3 consecutive experiments and which, when reduced by 10 per cent produced arrest in not more than 1 of 3 consecutive experiments. When the respiratory paralysis had lasted 10 to 15 seconds the mask was removed and the animal was resuscitated by artificial respiration and the administration of oxygen. An essential feature of this technique is that the dose required for each animal is repeatedly confirmed—a procedure which helps to eliminate technical errors. After the minimal dose for respiratory arrest, as here defined, had been determined for each individual dog, a second series of 3 anesthetics was administered, each consisting of this predetermined dose. As soon as the animal had passed into deep surgical anesthesia but before the appearance of respiratory arrest, 0.05 cubic centimeters per kilogram of a 10 per cent solution of metrazol was injected intravenously—a dose of metrazol equivalent for the average adult human to 3.5 cubic centimeters of the commercial 10 per cent solution. In the event of respiratory arrest the animal was resuscitated by the same method used for the controls. There was no indication that tolerance to the anesthetics developed in the course of these experiments (5).

EVALUATION OF AN ANALEPTIC

The first step in the evaluation of an analeptic should be an accurate assay of the quantitative toxicity of the depressant. With this information as a basis it is possible to balance the antidotal action of the analeptic against a standardized depth of depression. Unless the experiments are carried out in this orderly manner the resulting data become so haphazard that the relative efficiency of the various analeptics cannot be ascertained. This is the confused situation now obtaining with respect to the relative value of the numerous drugs recommended for use in emergencies developing under inhalation anesthesia. Consequently, in this attempt to study the analeptics, our first concern has been with the development of an accurate method for the determination of the quantitative toxicity of ether, divinyl ether, and chloroform.

The best evidence for the reliability of a method of bio assay is the ability of the user to obtain consistent median doses for the production of a

TABLE I—CORRESPONDENCE OF MEDIAN MINIMAL DOSES FOR RESPIRATORY ARREST

Series*	Ether	Divinyl ether	Chloroform
A	1 65	0 70	0 175

C	1 60	0 66	0 180

*The number of dogs in each of the series was as follows: Series A—ether 35, divinyl ether 35, chloroform 35. Series B—ether 10, chloroform 19. Series C—ether 16, divinyl ether 19, chloroform 17.

standardized pharmacological effect. The data presented in Table I show that the technique we have devised has yielded consistent median doses for respiratory arrest in three successive series of animals. The doses given refer to cubic centimeters of the anesthetic per kilogram of dog.

EXPERIMENTAL RESULTS

1 *Influence of metrazol upon the minimal dose required to produce respiratory arrest.* The influence of an injection of metrazol upon the development of respiratory arrest following the administration of the individually determined minimal dose for respiratory arrest of the three anesthetics is shown in Table II. Data from a previous paper dealing with coramine (27) were incorporated in the table in order to facilitate a comparison of the antidotal efficiency of these two drugs.

It is apparent that metrazol, under the experimental conditions employed, is capable of significantly reducing the percentage of respiratory arrests from the minimal dose for respiratory arrest of ether and divinyl ether. Its antidotal value, however, should not be exaggerated because a much greater reduction in the incidence of respiratory arrest can be obtained if the dose of the anesthetic is reduced by only 10 per cent. The important implication of this fact for resuscitation is discussed in the next paragraphs. The percentage of respiratory arrests from the minimal doses for respiratory arrest of chloroform was not significantly reduced by metrazol. Evidently the respiratory effects of chloroform are more difficult to combat than those of ether and divinyl ether. In the case of all three anesthetics visible stimulation of respiration only occasionally followed injection of the drug. It is noteworthy that coramine completely failed to reduce the incidence of respiratory arrest from both ether and chloroform.

2 *The influence of metrazol upon the probability of resuscitation.* Resuscitation from respiratory arrest produced by an inhalation anesthetic is a race between the elimination of the toxic agent

STUDIES OF THE ANALEPTICS II METRAZOL

R. W. WHITEHEAD M.A. M.D. and W. R. DRAPER M.S. M.D.
Denver, Colorado

In a previous paper (27) we have reported experiments dealing with the antagonistic action of coramine (nikethamide) against ether and chloroform. In this paper we present an analogous series of experiments designed to make a similar determination of the antidotal value of metrazol or pentamethylenetetrazol against overdoses of ether divinyl ether and chloroform.

Metrazol has the distinction of acceptance by the Council on Pharmacy and Chemistry of the American Medical Association. Although closely related to camphor in its pharmacological and therapeutic applications, metrazol has a more rapid and intense action due probably to its greater solubility in the body fluids. The voluminous literature dealing with metrazol up to 1937 is reviewed by Hildebrandt (2).

A definite antagonism has been shown to exist between metrazol and certain members of the hypnotic group, particularly the barbiturates. Thus, Tarter and later Maloney found metrazol an efficient antagonist to sodium barbital in rats. Werner and Tatum and also Barlow have reported that metrazol is an efficient antagonist to pento-barbital in rabbits.

Several investigators including Hildebrandt (11), Helander, and later Lendle found that metrazol increased the respiratory rate and volume in morphine depressed rabbits. An awakening action has been observed against small doses of avertin by Barlow but he found that metrazol was not lifesaving in the presence of fatal doses of avertin. Schoen has reported that the depression produced by ethyl alcohol in rabbits is considerably reduced by metrazol but, according to McCrea and Taylor this antagonism is demonstrable in dogs only when the dose of alcohol is sublethal. In their experience lethal doses of alcohol are not successfully combated even by very large doses of metrazol.

Apparently the antidotal efficiency of metrazol, as is the case with coramine (27) varies with the depressant. Thus, Aymacher as well as Maloney and Tatum, found that there was little antagonism between urethane and metrazol in rabbits. Similarly Whitehead and Draper (26) obtained

no evidence of a diminution of chloralose or urethane depression in dogs and cats.

Although metrazol is widely employed by clinicians to treat emergencies developing under the inhalation anesthetics, there are few controlled experimental studies which support this use. Some experimenters have found it of no value. Thus Camp (4) found that metrazol exerted little or no action on the respiratory center of rabbits and dogs deeply depressed by ether and chloroform. Similar results are reported by Jackson. In deeply etherized dogs, Jackson found that metrazol produced tremors or convulsions with little or no stimulation of the respiration. Evipal depressed dogs, on the contrary responded to metrazol with marked specific respiratory stimulation and no tremors or convulsions.

It appears, therefore, that the use of metrazol against the barbiturates and certain of the other depressants is supported by a considerable body of experimental evidence. The experimental basis for the use of metrazol in emergencies occurring under inhalation anesthesia is less convincing.

TECHNIQUE

Measured per kilogram doses of ether divinyl ether, and chloroform were administered to healthy mongrel dogs by the same method which we employed in our coramine experiments. This method is more fully described in a previous paper (5). In brief the apparatus is a closed soda lime absorption system having a capacity of approximately 55 liters, within which the anesthetic is volatilized in a atmosphere of pure oxygen. The mask contains a rubber diaphragm through which by means of a syringe and needle the dose of the anesthetic is injected on to a wire screen for volatilization. The mask is fitted tightly to the dog's muzzle by means of a rubber face piece. Every effort was made to prevent gas leakage at this point and the entire system was checked frequently for leaks. Volatilization of the anesthetic within such an apparatus is rapidly completed, and the drug develops its maximum effects within an average period of 2 minutes. The experiments were performed at intervals of 4 days.

The minimal dose of each of the three anesthetics required to produce an apparently per-

which metrazol was injected. The conclusion seems warranted that metrazol increased the probability of resuscitation from a standardized dose of chloroform.

EVALUATION OF STUDY

The varied and complicated circumstances surrounding death under anesthesia always provide a plausible explanation for the tragedy but, in the final analysis, the same ultimate cause must be assigned—there has been a failure to resuscitate. Resuscitation, therefore, is the master key to safety in anesthesia.

It is something of a paradox that much of the greater safety of ether is due to the fact that it causes respiratory paralysis earlier in the course of the poisoning than is the case with chloroform. Ordinarily in ether anesthesia the respiration ceases—that is to say, a further amount of the poison is rejected—while the circulation is still in comparatively good condition. Under these circumstances there is a greater probability of resuscitation than would be the case if, through postponement of respiratory failure, the subject inhaled a concentration of ether more injurious to the circulation. Thus early respiratory arrest may be regarded as an automatic safety mechanism which operates to limit the intake of an inhalation anesthetic to the minimal respiratory arresting dose. No such mechanism, of course, exists to protect the circulation from a fatal overdose of a nonvolatile anesthetic.

The period of time separating respiratory arrest from circulatory failure might be termed appropriately "the resuscitation interval" because it is only during this interval that attempts at resuscitation are likely to be successful. One of the most important factors operating to determine the probability of resuscitation, therefore, is the length of the resuscitation interval. It is possible, under certain circumstances, for the administration of a respiratory stimulant to shorten this interval by postponing respiratory arrest and in this way actually to diminish the probability of resuscitation unless the drug simultaneously increases the resistance of the circulation to the anesthetic. Some so-called analeptics are, at least potentially, injurious to the circulation. There is reason to believe that this may be the situation with respect to alpha lobeline (Camp, 3, Whitehead and Elliott) and coramine (Peters and Visscher).

Our own unpublished experience with lactic acid is a further illustration of this point. Lactic acid powerfully stimulates the respiration and is capable of delaying respiratory arrest from chloro-

form but it is also injurious to the circulation. Consequently, it acts to shorten the resuscitation interval at both ends: first by delaying respiratory arrest and second, by hastening circulatory failure. Although its administration results in some reduction in the incidence of respiratory arrest from a standardized dose of chloroform, any such advantage is more than overcome by the reduced probability of resuscitation, should respiratory arrest develop. Our experience with lactic acid and other respiratory stimulants has impressed us with the view that it is the behavior of the circulation which determines the final outcome of an attempt to resuscitate and that respiratory arrest, at least when produced by the inhalation anesthetics, should be treated with analeptics chosen for their circulatory rather than their respiratory effects.

The reasons for our position can be made clearer by a brief consideration of the physiology of resuscitation. In the great majority of instances respiratory arrest occurs before the concentration of the anesthetic becomes sufficient to cause failure of the circulation. Although, absorption of the poison does not continue after respiratory arrest there is, unfortunately, a rapid development of anoxemia. The ultimate failure of the circulation is the result of disastrous synergism between anoxemia and the anesthetic. Forced ventilation of the lungs following respiratory arrest merely replenishes the oxygen supply within the lung alveoli and removes the anesthetic from these passages. This alone will not ensure resuscitation. For success the circulatory minute volume must be large enough to provide effective transport of these gases between the lungs and the body tissues. The most efficient artificial respiration cannot save a patient whose circulation lacks the necessary vigor.

We have shown in Table II that the removal of a small amount of the anesthetic will act more effectively to restore spontaneous respiration than will the injection of a respiratory stimulant. Moreover, the highly developed mechanical methods now available for forcible ventilation of the lungs greatly reduce our dependence upon pharmacological respiratory stimulants. However the position is otherwise if the analeptic acts upon the circulation to speed the rate of transport of gases between the lungs and tissues. Such a drug should be a very useful aid to resuscitation.

In this connection it is of interest that an increased cardiac minute output after metrazol is observed in animals by Mueller, and by Gollwitzer Meier and also in humans by Grosskurth and Bansi and by Henon and Neuhard. Doses of

TABLE II—INFLUENCE OF CORAMINE AND METRAZOL UPON THE AMOUNT OF EITHER, DIVINYL ETHER, AND CHLOROFORM REQUIRED TO PRODUCE RESPIRATORY ARREST

MDRA plus metrazol		51	
MDRA reduced by 50 per cent	26	84	

¹⁰The MDRA is the Metrazol Dose required to produce Respiratory Arrest in at least 10 consecutive administrations

through the lungs and the development of its fatal effects upon the circulation. A drug can be properly termed analeptic only if its use helps to win this race. The definite test for analeptic action therefore should determine the influence of the drug upon the probability of resuscitation. So far as we are aware no other controlled studies of analeptics have been made which subject them to this critical test against otherwise fatal doses of the inhalation anesthetics.

In the course of the experiments here reported we have carried out 542 resuscitations from respiratory arrest produced by overdoses of ether, divinyl ether, and chloroform both with and without the aid of analeptics. This has given us the opportunity to determine the influence of metrazol and of coramine upon the probability of resuscitation. All our resuscitations have been conducted under conditions controlled so as to make them identical with the exception of the anesthetic and the analeptic employed. The data are presented in Table III.

TABLE III—INFLUENCE OF CORAMINE AND METRAZOL UPON THE PROBABILITY OF RESUSCITATION

Ether	No. of dogs used	Respiratory arrests produced	Failures to resuscitate	Percentage failures to resuscitate
Control resuscitations	26	99		
Resuscitations with coramine	20			
Resuscitations with metrazol	26	75		
Divinyl ether				
Control resuscitations	26	81	3	3
Resuscitations with metrazol	20	30		
Chloroform				
Control resuscitations	53	54	5	
Resuscitations with coramine	20		8	
Resuscitations with metrazol	17	17		

Of the 149 control attempts at resuscitation from an overdose of ether only 3 or 1.4 per cent resulted in failure. The relatively low probability of failure to resuscitate when ether is the anesthetic makes it difficult to determine the value of a pharmacological antidote but, as will be noted, there were no failures to resuscitate following the administration of either coramine or metrazol. It is quite possible that the absence of failures to resuscitate in the ether experiments was due to the smallness of the analeptic series.

The probability of failure to resuscitate was somewhat greater in the divinyl ether series. In the 81 control attempts to resuscitate, 3, or 3.7 per cent, were unsuccessful but again there were no failures to resuscitate in the 30 respiratory arrests treated by an injection of metrazol. The probability of failure to resuscitate from an overdose of divinyl ether in the control experiments was not sufficiently high to warrant the conclusion that metrazol was an aid to resuscitation.

The much higher mortality resulting from an overdose of chloroform affords a better opportunity for the evaluation of an aid to resuscitation. In 154 control attempts to resuscitate 15, or 9.7 per cent, ended in failure. Following the administration of coramine there were 5, or 3.1 per cent, failures to resuscitate in 45 attempts. It is apparent that the addition of coramine did not increase the effectiveness of artificial respiration and oxygen. On the other hand, we experienced no failures to resuscitate in the 37 experiments in

EXTENSION OF INDICATIONS FOR RADICAL OPERATION IN CANCER OF THE RECTUM

SIR W. ERNEST MILES made a noteworthy contribution to the surgery of cancer of the rectum when he emphasized the possibility of lateral and high lymphatic involvement in the disease and in 1907 strongly recommended the one stage abdominoperineal operation as the one which insured the greatest guarantee of complete removal of the carcinoma and its local extensions. In the Lettsomian lectures which he delivered in 1923 he traced the development of the surgical treatment of carcinoma of the rectum from the purely local operations to the much more radical one stage abdominoperineal operation and made a report of 116 such operations which he had performed. Radical operations were carried out in only 29.3 per cent of the patients coming under his care. Of his first 63 one stage resections there was a 36.2 per cent mortality rate and no patient over sixty survived. In the next

53 operations his mortality fell to 9.3 per cent, which he modestly attributed to the use of better anesthesia. Patients over sixty-five years of age, fat patients, patients with arteriosclerosis, diabetes, tuberculosis, Bright's disease, were considered unsuitable for operation. Growths attached to surrounding soft parts were not considered amenable to operation.

Since that time Miles' advocacy of the one stage abdominoperineal operation has been accepted as the operation of choice in many clinics and additional knowledge of the frequency of carcinomatous involvement of the lymphatic glands (65 per cent in removed specimens) as well as the height of their involvement has tended to confirm the soundness of that choice. Extension of the indications for operation has also increased in the last five years due to the maintenance of a relatively low operative mortality rate and increased knowledge as to what can be done surgically to carefully prepared patients. The extension of indications for resection of carcinoma of the rectum has been also furthered by the radioresistant character of cancer in this region, which leaves surgery as the outstanding chance for cure of these patients according to our present knowledge.

As Gilchrist and I have recently reviewed our last ten years' experience in the selection of patients with cancer of the rectum for radical operation, I was asked to comment on our findings in this editorial. The material studied concerned 277 patients coming to our service in the Presbyterian Hospital for operation. Five were considered inoperable. Two hundred seventy-two patients were operated upon and 179 had a radical removal

the order we have used in our experiments have been shown by Haury and Gruber to dilate the peripheral vessels. A favorable action upon the circulation depressed by chloroform has been observed by several workers including Elchler and Hildebrandt, Russu and Spärchez and Leffkowitz.

There is thus some experimental support for the view that metrazol may aid resuscitation from chloroform overdose through a stimulant action upon the circulation which tends to lengthen the resuscitation interval and to increase the rate of gas transport between the lungs and tissues.

SUMMARY AND CONCLUSIONS

Metrazol increases slightly the amount of ether and divinyl ether but not of chloroform required to produce respiratory arrest in dogs. Only occasional brief stimulation of the respiration is seen when metrazol is injected in toxic anesthesia produced by these agents.

2. In 543 attempts to resuscitate from respiratory arrest produced by ether divinyl ether and chloroform were carried out by means of artificial respiration and the administration of oxygen with and without an injection of metrazol or coramine.

3. Of 149 attempts to resuscitate from ether overdose without the aid of an analeptic 2 or 1.4 per cent, were unsuccessful. In 81 similar control resuscitations following an overdose of divinyl ether 3, or 3.7 per cent, ended in failure. The mortality from an overdose of chloroform fell in 15 or 9.7 per cent of the 154 control experiments. There were 6 failures to resuscitate when metrazol was administered in addition to artificial respiration and oxygen in the treatment of 25, 30 and 37 respiratory arrests produced by ether divinyl ether and chloroform, respectively.

4. The low probability of failure to resuscitate without the aid of an analeptic from an overdose of divinyl ether and especially from ether makes evaluation of a pharmacological aid to resuscitation difficult. When the very high incidence of failures to resuscitate from chloroform induced respiratory arrest in the control series is contrasted with the complete absence of failures when metrazol was administered, the conclusion

seems justified that metrazol was useful as an aid to resuscitation.

5. As previously reported coramine does not exert a favorable influence upon the probability of resuscitation from an overdose of chloroform.

that the condition is far more common than had been realized. It is curious that during this period of awakened interest in anatomical defects in the diaphragm, there has been no corresponding revival of curiosity about its origin and structure. As a matter of fact, most English textbooks of anatomy and embryology have either made no changes in their discussions of this subject or have curtailed them so much in the latest editions that they leave much to be desired in both clarity and completeness. This state of affairs is remarkable in view of the fact that Ballou has shown, in a recent historical review, that the diaphragm has fascinated anatomists for centuries. Perhaps anatomy has become too completely divorced from surgery.

The diaphragm is something of an afterthought in the evolutionary process, being present as a complete septum only in mammals. The major part of it is assembled from three ill assorted structures, the septum transversum (itself something of an embryological enigma), the pleuroperitoneal membranes, and the dorsal mesogastrium. These structures descend from the cephalic portion of the celomic cavity on different time schedules and finally unite to form a single complete septum between the abdominal and thoracic cavities at about the seventh or eighth week of fetal life. Obviously, any disturbance of the orderly progress of this intricate process may result in the formation of defects in the diaphragm.

The phrenic nerve develops and descends with the segment formed from the septum transversum and invades the remainder of the diaphragm after fusion of the three segments. If this invasion is arrested prematurely, the musculature of that part of the diaphragm that has not received a nerve supply probably undergoes atrophy, leaving only the peritoneum and the pleura to separate the two great body cavities in that particular location.

Soon after the diaphragm becomes a complete septum, the mid-portion of the celomic cavity is rapidly expanded by growth of the liver, and the resulting tension of the diaphragm causes it to pick up from the body wall a supplementary rim of tissue. One would therefore expect the diaphragm to be continuous with the inner layer of the abdominal cavity. Recent anatomical studies by D. D. Baker have shown that this is actually the case and that the conventional descriptions of the attachments of the diaphragm are incomplete and to some extent inaccurate. He finds that the anterior and lateral portions of the diaphragm are continuous with the transversus abdominis muscles and the posterior sheath of the rectus muscles. The attachment of these structures to the costal arch is by means of what is, in effect, a common aponeurosis. Likewise the posterior or lumbar segments of the diaphragm are continuous with the anterior layer of the lumbodorsal fascia, except for the central portion, which is attached to the bodies of the lumbar vertebrae.

While these observations are original with Baker, the idea is not new, for, according to Ballou, in 1676 Caspar Bartholin, son of Thomas, described the diaphragm and transversus abdominis muscles as a trigastric muscle, and in 1905 Sir Arthur Keith noted their developmental association.

A surgeon studying Baker's dissections is immediately struck by the fact that when the common aponeurosis of the transversus abdominis and the diaphragm is detached from the under surface of the costal arch, the diaphragm has been supplemented by a structurally similar fibromuscular membrane which increases its area by at least one-third. If there should be a very large defect in the anterior half of the diaphragm it could be closed without tension if the transversus abdominis were advanced into the thoracic cavity and

of the tumor with a hospital mortality of 7.2 per cent and a resectability rate of 65.5 per cent. Ninety-three patients were found to be unsuited for radical removal of the tumor due to extensive liver metastasis in 40, infiltration of the growth into the base of the bladder in 18 and marked infiltration of the growth into the prostate, vagina, or sacrum in 25.

Of the 179 patients from whom the tumor was removed 105 presented some doubtful factors concerning the possibility of completely removing the tumor or in making the operation more difficult than usual. These factors were in the main: age over sixty-five years, adiposity, one or two small suspicious nodules in the liver, obliterated pelvic peritonitis from previous pelvic operation or diverticulitis, attachment of the tumor to the bladder, abdominal wall, adnexa, prostate, bladder, urethra, vagina or sacrum and constitutional disease as diabetes or heart disease. Of this group of 105 patients the operative mortality rate was 9.5 per cent. In 74 favorable cases where there were no doubtful factors the operative mortality rate was 4.3 per cent. The long term survival rate can not be given at this time but in general it can be said that there are many of these patients who came in the doubtful group who have lived three to five years.

The consideration of a few of the doubtful groups may emphasize the value of extension of the indications for radical operation in cancer of the rectum.

There were 38 patients over 65 years of age given the benefit of removal of the tumor with four deaths (pneumonia or embolism). Nine of these patients were operated upon more than five years ago and five are still alive.

One of the most difficult decisions to make in favor of radical removal of the tumor is in the case where the tumor is adherent to

of the prostate was removed with the tumor in 5 patients, the rectovaginal septum in 6, the uterus and adnexa in 4, the ureter in 2, the dome and posterior half of the bladder in 1 and another loop of bowel in 1 patient with 2 deaths in all groups.

There were 16 patients who had one or two small nodules in the liver in whom it was difficult to be sure that the growths were carcinoma and in whom radical resections were done. Four of these patients died of cancer of the liver on an average of ten months after operation but four others are alive and well three to seven years after operation.

In very fat patients there is no doubt an added risk of hemorrhage, infection, evisceration and cardiovascular accidents, but in view of the extremely poor prognosis in nonoperative treatment we did not consider adiposity a contraindication for operation. Of eleven very fat patients there was one death from embolism and one evisceration which was repaired successfully.

No more details of problem groups will be considered here, and it only remains to suggest that radical operation for cancer of the rectum can be carried out in an increasing number of patients and that it offers the patient the best chance of cure provided the preoperative treatment of decompression of the bowel and restoration of the blood to normal (cells, electrolytes, vitamin content, sugar, chlorides, plasma protein) as well as safe anesthesia and a reasonable surgical technique are considered essential principles.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE title of the informal, chatty little book *Wounds and Fractures*¹ by H. Winnett Orr, may be misleading and prospective readers should be told that little space is devoted to the subject of wounds proper. Actually it is a treatise on fractures, in which stress is placed on the care of those associated with contaminated or infected wounds. As one might suspect from the name and fame of the author, wide open aseptic packing with vaseline gauze, coupled with rigid immobilization by the pin fixation plaster cast technique, is offered as the *sine quo non* of successful treatment in such cases. In this method Dr Orr is, of course, a pioneer, and throughout the book the reader will find photographs, x-ray productions, and case abstracts covering every possible situation in which the method may be used.

Innumerable useful variations in technique are found, most of them simple and appealing to those working with barest essentials. The subject matter, the arrangement in which it is presented, and the distinction of the author combine to make this a valuable work. Let those who oppose the method for various well grounded reasons review the literature emanating from Europe during the past four years, and they will find that the method is becoming less and less controversial, certainly as it has to do with the wounds of war.

Solely as a textbook on fractures it probably is not suitable for students. It seems too advanced and broad enough view of the subject is not given. It should, however, be included in any collection of fracture texts. The principal lesson which the author intends to portray for the general practitioner particularly, is that the compound infected fracture, even with loss of substance, does not necessarily call for amputation.

J. K. STICK

THE volume *Diseases of the Thyroid Gland*² represents forty years of experience, dedicated to the author's grandchildren—fellow students in medicine—merely half a century behind him is not intended as a treatise on disease of the thyroid gland, but as a record of studies. It makes most entertaining reading and stimulating study. Anyone who makes no objective assertion so persistently and denies self evident conclusions so forcefully is bound to stir up thought and this is certainly the main object of this book. The text is written in a conversational style which makes the reading so

easy and rapid that before you know it you are taking something for granted which is certainly not the intention of the author. The thought provoking character of the text may best be illustrated by a quotation: "Myxedema is a clinical term signifying a myxoid edema of the subcutaneous tissues. It is presumably due to lack of thyroid secretion. This opinion is based on the fact that the condition is ameliorated by giving thyroid extract. This represents about the sum total of our knowledge and has in a measure closed our eyes to some very obvious facts. It is first of all to be realized that the term myxedema is not synonymous with deficient thyroid secretion. This belief has been one of the sacred cows in medicine and any one who made merry with the old bossie did so at his peril, but the old critter has gone to the hamburger factory for ignominious extinction. It is important to keep this in mind because we know now that there can be a deficiency or an absence of thyroid secretion without any of the clinical signs of myxedema, as total thyroidectomies have abundantly shown. Nor is myxedema the superlative degree of thyroid dysfunction or the physical expression thereof. In cases in which myxedema is associated with a waning hyperthyroid state we have a combined minus and plus state. Our sacred bossie has become a hermaphrodite. This emphasizes the paucity of our fundamental knowledge." This paragraph reproduces the mixture so characteristic of the author's work, namely, of denial of much that has been scientifically demonstrated by others with violent assertion of personal knowledge certainly not shared by many students of thyroid physiology.

The volume contains 670 pages, is fully illustrated and well indexed and will be enjoyed and valued by all interested in diseases of the thyroid.

PAUL STAMP

A COMPLICATION of the experience and an outline of the routine in the care of premature infants at the Sarah Morris Children's Hospital of the Michael Reese Hospital in Chicago are presented in *The Premature Infant*³ by Hess and Lundeen. The great detail and step by step description of equipment and its use in the care of the premature infant should make this a good manual for any one interested in the birth or premature nursing setup. Although elementary in some respects it should be a

made to become a part of the diaphragm. Cadaveric dissections have shown that this procedure is entirely practical although it has not as yet been employed in the living subject.

Large defects in the posterior half of the diaphragm cannot be closed by this method but the principle of employing a flat fibro-

muscular sheet that, like the diaphragm itself is continuous with the body wall, can be utilized. Using a posterior transthoracic approach we have bridged the hiatus in such a case with a flap developed from the latissimus dorsi and have found that it served the purpose admirably. JAMES D. RIVERA.

surgery of the heart has been pushed too much into the background

The volume contains an admirable summary of the development of the heart, as well as its comparative anatomy. The normal anatomy is given at some length, but all too often the surgical implications of anatomical facts have been slighted or completely overlooked. Cardiac histology and physiology have been summarized. The chapter on radiological examination of the heart does not discuss angiocardiology. The treatise on electrocardiograms gives a good basic presentation of the normal types of graphs but it is deficient in consideration of abnormal forms.

While one might expect to find exhaustive descriptions and illustrations of surgical procedures in a book pertaining to this field, the volume is deficient in this regard. Of a total of 268 figures, only 9 are concerned with actual surgical technique or other therapeutic procedures, and all but one have been borrowed from the previous publications of other authors.

The reader is struck by the great lack of critical analysis of the results of therapeutic procedures, such as pericardiectomy for constrictive pericarditis, of total thyroidectomy for angina pectoris, of sympathectomy for angina pectoris, of surgical closure of the patent ductus arteriosus. Regarding alcohol injections of the sympathetic ganglia for angina pectoris, there is only a single sentence regarding postinjection alcoholic neuralgia. The impression is given that such a complication is rare. Unfortunately, this is not the true state of affairs as anyone who has had any appreciable experience with such treatments has found.

The author has covered the literature exhaustively, perhaps because of too great stress in this direction and because the author has included so little of his own personal experience in cardiac surgery the present volume lacks authority. Unfortunately, too, the book has been compiled at a time when surgical knowledge has been accumulating rapidly, hence the lag incurred by the process of publication has excluded from the volume several of the more recent advances in cardiac surgery which might be appropriately included in it.

ROBERT E. GROSS

THE form of *The 1941 Year Book of Radiology*¹ follows that established by its predecessors, offering to the medical profession a review of the important articles which have appeared in the literature during the past year. As would be expected because of the war, there has been a relative scarcity of foreign material. Approximately 28 per cent of the articles reviewed in this volume come from outside of the United States. As one scans through the pages of this volume he is impressed by the immense amount of work which is required to assemble the material. As in previous years the authors present

the material in a concise but easily readable manner. Merely paging through the book will review one's reading for the past year and will no doubt reveal a number of articles which have escaped attention, making the book invaluable for reference work.

In the field of radiological diagnosis the authors have been reluctant to choose any particular work as outstanding but mention a number of interesting and refreshing subjects. Articles of interest on the osseous system include changes in the epiphyses found in observing hyperthyroid children, "pseudo-fractures" as related to faulty nutrition and military service, injuries following metrazol therapy, solitary eosinophilic granuloma, and porotic conditions. The use of organic salts of iodine in bronchography, the results of mass surveys for tuberculosis and "virus" or "type X" pneumonia, are important contributions. In the field of gastroenterology considerable attention is being given to the small bowel. The use of the Miller-Abbott tube in intestinal obstruction, and a new dye, phenyl propionate acid, for the study of the gall bladder, are subjects of more than ordinary interest.

In the introduction to the section on radiotherapeutics, Dr. Kaplan has given a very excellent, concise, and interesting review of the progress in this field during the past year. Because of the war there has been a transition from old to new world dominance in the field of medical radiology. In some countries research centers have been entirely destroyed, while in others the chief emphasis has been placed on scientific achievements associated with military needs. Because of the destruction of hospitals and medical centers in England it has been necessary to rely more and more upon radium, particularly radon, rather than x-ray therapy. There has been continued interest in the treatment of non-malignant lesions. A number of articles have appeared on the use of supervoltage therapy as compared to the conventional 200 kilovolt type. The question of whether tuberculosis can be treated by x-ray again is receiving some attention but the answers have been either cursory or negative. The question of preoperative x-ray therapy for carcinoma of the breast is still unsettled, possibly because of the great variations in methods and technique. The value of ovarian irradiation, in breast carcinoma and metastases, has received considerable attention during the past year. Paging through this section one is impressed by the great amount of work which is being carried out, particularly in the United States.

It is hoped that in spite of the interruption of the work in foreign medical centers and the currently disordered world, it will be possible for the authors and publishers to see their way clear to continue the publication of this excellent yearly review of international literature. As the reviewer has stated in previous years, he finds this volume indispensable in his work and ventures to say that this is the feeling of the great majority of radiologists throughout the country.

FARL C. BARTH

¹THE 1941 YEAR BOOK OF RADIOLOGY. DIAGNOSIS edited by Charles A. Waters, M.D., and Whitmer B. Frior, M.D. THERAPEUTICS edited by Ira I. Kaplan, B.Sc., M.D. Chicago: The Year Book Publishers, Inc., 1941.

therapy admittedly is of the most important subjects; prematuration care are very brief. The subject of vitamins is given considerable discussion as are the care and management of wet-nose. A helpful description is given of the various diagnoses and treatment procedures, such as a spinal puncture and the administration of intravenous fluids. Some of the major and minor disorders that occur in the premature infant are briefly described. This book is concluded with a rather interesting and enlightening chapter on the late mental and physical development of premature infants. L. MARTIN HARDY

In the Oxford War Manual the author has briefly summarized the treatment of burns. Most of the English authors in the current literature are not in agreement with the tannic acid method as advocated in the volume, and there has been much added to the local treatment of burns since this volume was published.

The early chapters on classification and clinical course of burns are excellent. The method outlined for recognizing and combating burn shock and toxemia are practical and up to date.

In the complications of burns, chapter IV the author ignores the subject of infection but later implies that infection is a normal sequel to all serious burns. This, in the reviewer's experience, is unjustified.

The greatest part of this volume is devoted to outlining in detail each step taken in the tannic acid method of treatment. It has only briefly mentioned the method of cleansing of the raw surface. This is in marked contrast to memorandum published later E.M.S./Gen/343 circulated by the Ministry of Health for the guidance of medical officers which lays great stress on the proper method of cleansing the burned area with soap and water before the wound is treated by either open or closed methods.

The final chapter on the hospital care of burns simply outlines the various equipment needed but no mention is made of the scrupulous aseptic care which must be attained to prevent infection from occurring in these large open wounds.

With the exception of burn shock, too little of recent advances on this common war injury has been mentioned. HARVEY S. ALLEN

To correlate the clinical and pathological statistics relative to cancer of the face and mouth as found in a large clinic over a period of years is a tremendous task. In a clinic where cancer work has been carried on with an open mind as to the value of the various methods of treatment the summation of these findings should prove of immense value. Drs. Blai Moore and Byars together with other mem-

bers of their staff have presented their findings in view of the collective impression gained from the radiologist, the surgeon, and pathologist. Their broadening the scope of the book by cementing the impressions of these combined groups rather than letting one method of treatment dominate.

The authors stress again and again that the doctor first seeing the patient is responsible for his ultimate. The convenience of certain methods of treatment used as a substitute for surgery does not remove the responsibilities from the shoulders of those first consulted by the patient.

The book must be read carefully to appreciate fully the authors' viewpoint, but the impressions gained are unmistakable and invaluable. Force is added to their contentions by numerous excellent photographs. A unique feature of the book is a large collection of fine drawings under the heading of "Operative Technique" which show graphically various steps in operative procedures, and these are in turn directly related to some particular case in the text.

A general impression of the scope of the book may be gained from a statement by Dr. Moore in which he says that the proper management of cancer means the proper co-ordination of surgery, x-ray and radium as means of therapy. The use of any one method in all cases of cancer must be to the detriment of the patient.

This book should be of immense value to surgeons, radiologists, and dentists as well as the general practitioner not only to tell them what to do but also to tell them what not to do. CLAUDE L. STARR

An attempt is made to summarize the knowledge of diseases of the heart and great vessels of the thorax in King's *Surgery of the Heart*. Unfortunately it has been given a title which does not accurately indicate its contents. While Dr. King has been primarily interested in surgical problems, the finished book has included almost all types of pathology which might affect the heart and the immediately adjacent to it. A large number of conditions have been included which do not fall within the realm of surgical diseases, nor could they conceivably be brought into this field at any future time. Indeed, the medical diseases are given more space in the book than are those which are being currently treated by the thoracic surgeon. Inasmuch as such a wide range of material has been collected here in book form, the volume would probably attain a wider range of usefulness for students and practitioners if it had been published under a more general title indicating its true scope. The author has probably intended that the cardiac surgeon should be familiar with all of the major lesions which might exist in the organ upon which he is operating, but in this attempt to set forth a broad view he has produced an imbalance so that the

PRIMARY TUMORS OF THE SUBMAXILLARY GLAND WITH SPECIAL REFERENCE TO MIXED TUMORS

MALCOLM B DOCKERTY, M D , and CHARLES W MAYO, M D , F A C S ,
Rochester, Minnesota

IN an analysis of the array of conflicting evidence extant on the subject of "mixed salivary gland tumors," one is almost led to the conclusion that the word "complicated" should have been used as a designation for these neoplasms. That their histogenesis is still not understood is evidenced by the fact that the "mesenchymal," the "endothelial," the "branchial," the "enclavement" and the "epithelial" theories of origin still have their protagonists. The strange clinical behavior of these tumors was well expressed by Kennon who wrote, "Salivary-gland tumours, though not of frequent occurrence, share with sebaceous cysts and ganglion a peculiar power to elicit in their possessors a morbid delight in their presence, with its attendant self-pity. This, with the luxury of an ever-sympathetic group of friends, makes them blind to the hideousness of their deformity and deaf to the warnings of the profession as to the ultimate outcome of this silent death. The knowledge of surgical failures in patient and doctor alike, has weakened the demand for treatment." Nor have pathological researches on these lesions clarified the difficulty of their interpretation. Stein and Geschickter, in a report on tumors of the parotid gland, wrote as follows:

"The benign neoplasms of this organ often show malignant tendencies in that they recur frequently after simple excision, whereas the malignant tumors often show benign features in that distant metastases rarely develop. Whether recurrence in a given case is a clinical feature of a benign process or a malignant feature of a type of carcinoma in which a tendency to widespread metastases is practically absent is not always easily decided. The composition of the majority of these new-growths as seen through the microscope is likewise difficult of interpretation."

The lack of unanimity of opinion regarding the nature of these neoplasms is adversely reflected in the results of surgical treatment. Because these mixed tumors have been regarded by many as being essentially benign, surgeons all too often have yielded to the temptation to "shell them out," so to speak, especially when the tumors appeared to be encapsulated. In the case of tumors of the parotid gland this tendency toward conservatism was further influenced by the proximity of the important facial nerve. As a consequence the carrying out of radical procedures usually was avoided until the tumors recurred—a tragedy which happened all too frequently.

In recent years, however, experience has accumulated to show the necessity for revision

the tumor, in the hilus of the salivary glands—where the latter were available—and among the nodules of tumor tissue in recurrent lesions. Multiple blocks of tissue were then cut from the tumors, the salivary glands, and the lymph nodes. These were placed in a 10 per cent solution of formaldehyde, sectioned at 10 microns on a freezing microtome, and stained routinely with hematoxylin and eosin. In selected cases van Gieson's stain and Galantha's stain for mucus were employed, and paraffin blocks were used. In all, some 400 sections were thus made available for study.

PATHOLOGICAL DATA

Because, as will be shown later, the incidence of recurrence depended more on the microscopic character of the lesion than on the type or the duration of symptoms, we propose first to consider the pathological features of salivary glands tumors so that a better understanding of the clinical picture may be obtained.

From the standpoint of gross examination these neoplasms were all unilateral. Size varied from extremes of 0.5 to 10 centimeters, with an average of about 3 centimeters in mean diameter. Among the primary lesions all were unicentric except 4 which appeared as multiple nodules. Among the 28 recurrent lesions, practically all by contrast appeared as multicentric masses. Encapsulation was the rule in the majority of primary lesions examined, but the thickness of the capsule did not appear to bear much relationship to the size of the lesion or to the duration of clinical symptoms. Bosselations of the capsule were observed in 62 cases, the tumor in the remaining cases being more or less globular in shape. In 5 instances, in which the tumor was small, it appeared situated deep in the substance of the submaxillary gland. In all other instances in which the tumor was primary and in which the gland was present, the gland appeared to be spread out over the surface of the neoplastic nodule. Although it was loosely attached in most areas, nevertheless in almost every instance the gland at one or more points could be separated from the tumor only with difficulty. This observation was made so often that sections were always made, very carefully, through such adherent portions, for microscopic study.

Surfaces made by cutting revealed a somewhat variable picture. Color ranged from white to dark brown, with occasional zones of cyst formation and hemorrhage. Actual necrosis was rarely observed. Consistency varied also, but in general the whitish tumors were firm and the darker ones were soft in texture. The presence of cartilaginous tissue was noted grossly in 10 instances, and in 2 of these cases the entire tumors resembled lumpy masses of homogeneous cartilage.

In the recurrent tumors, in addition to the presence of multicentric nodularity as previously noted, it was also observed that infiltration was the rule instead of the encapsulation that had been noted in connection with the primary lesions. Probably of equal significance was the fact that in most of the recurrent lesions all or part of the submaxillary gland was present and frequently was adherent to the recurrent mass of tumor tissue. The significance of this observation will be brought out subsequently. Regional lymphatic nodes were usually present when the operation had included resection of the salivary gland. These nodes, although they were occasionally adherent to the tumor, were not obviously involved, except in some cases in which the condition was atypical, to be discussed under the miscellaneous group later in this paper.

In addition to this general gross description, certain individual cases presented features of interest. Among the group listed as "primary tumors" were 6 melanoeplitheliomas. Four of these were so deeply pigmented that diagnosis could be hazarded merely on the basis of gross inspection. The tumors involved the regional lymphatic nodes, whereas the gland itself remained free. Although interesting from the standpoint of gross pathology, these melanotic lesions were excluded from the present study because in no instance could we rule out their metastatic nature. (In 2 the eye very probably was the site of the primary lesion.) Tumors of an obvious papillary nature were found in 3 instances and in 2 of these the regional nodes were grossly involved. An unusual appearance was noted in 1 recurrent tumor which presented a gross picture resembling that of a group of uterine fibroid tumors. This tumor proved to be a rhabdo-

of some of the older conceptions regarding the nature of mixed tumors. The occurrence of such tumors elsewhere than in the salivary and lacrimal glands has simplified the problems of histogenesis. Reports of regional and distant metastasis have forced many investigators to question the benignancy of these tumors. This gradual change in the pathological concept is perhaps best illustrated by the observations of McFarland (9) an outstanding authority on the subject of mixed tumors. Reporting on a large series in 1926 this author concluded, among other things, that mixed tumors are inherently benign but commonly recur after excision and if frequently disturbed become locally destructive and invasive without giving metastasis. The same author (10) writing in 1933 stated on the basis of an augmented series in which prolonged postoperative observation was carried out "Recurrence makes it certain that the [mixed] tumors are malignant in themselves, and not by virtue of carcinomatous or sarcomatous degeneration."

It is thus, in a general way, that we wish to introduce our subject of tumors of the submaxillary gland. No attempt will be made herein to review in detail the volume of information written on these tumors. For this the reader is referred to the excellent articles written by Wilson and Willis, Wood, Fry, MacFee, Harvey, Dawson and Innes, Fraser, Albhorn, New and others in addition to those mentioned previously.

PURPOSE OF STUDY

The difficulties encountered during operation on the submaxillary gland are slight in comparison to those that must be met in operation in the parotid region. Mixed tumors of the parotid gland have a tendency to recur and most investigators are ready to admit that such recurrence obtains on the basis of incomplete removal of the original tumor rather than the result of independent neoplasia. Difficult and often inadequate exposure through the tense parotid fascia often results in rupture of the capsule of the tumor and una voidable soiling of the operative field with tumor cells. The intimate proximity of branches of the facial nerve and of other structures makes the surgeon wary of excision instead of enucleation of

the tumor—a tumor considered by many to be slowly growing and benign.

In the submaxillary region where the same types of tumors occur the diagnosis can be made early, the surgical approach is usually simple, and complete removal of the tumor should be a matter of small difficulty. Consequently recurrence of submaxillary mixed tumors should be rare. Observation of a patient who did have such a recurrence prompted us to undertake investigation of the problem we have mentioned briefly with the following questions in mind:

1. Are all submaxillary tumors of "mixed type?"
2. Are mixed tumors benign or malignant?
3. Why do certain submaxillary mixed tumors recur?
4. What surgical procedures for eradication of these tumors are attended with the best results?

An examination of the literature revealed that submaxillary tumors, because of their extreme rarity, had been reported either singly or in small groups. It was therefore conceived that something of value might be learned from the study of a large series.

MATERIALS AND METHODS

Records of some 500 patients suffering from "submaxillary malignancy" were reviewed and carefully analyzed from clinical, surgical and pathological standpoints. More than 80 per cent of these tumors were found to represent metastatic lesions metastasizing usually having taken place from epidermoid carcinoma of the lip, nasopharynx or face. Such tumors were excluded from the present study. Records of the rest of the cases (about 90) were carefully abstracted with special reference to necessary clinical and surgical data and end results. The pathological material available in practically every case was then obtained and was studied in gross detail. In each instance the tumor was drawn to scale and its size, contour and color were noted. The relationship of the tumor to the salivary gland was checked, especially in the matter of the ease or difficulty with which the tumor could be separated from the glandular substance. Regional lymphatic nodes were sought in the tissue surrounding

Fig 3 a, Grade 1 adenocarcinoma mixed tumor type in which an area of squamous cell metaplasia appears (hematoxylin and eosin $\times 170$), b grade 1 adenocarcinoma mixed tumor type in which invasion of fat is evident (hematoxylin and eosin $\times 45$)

study under low magnification that the epithelial cells were giving rise to the stromal cells, or vice versa.

Although the epithelial cells usually were disposed in the form of solid strands and masses (Fig 1b), very frequently they were arranged in alveoli, acini or tubules with the production of a picture approaching that of the normal submaxillary gland. These glandular spaces were frequently filled with a material which stained intensely red with eosin, and this same material gave a slightly positive reaction to the Galantha stain for mucin (Fig 2a).

The lining of these ducts and alveoli, strangely enough was composed of two layers of epithelial cells—a superficial layer and a basal layer. In both layers the cells were small cuboid with large hyperchromatic nuclei and relatively large nucleoli (Fig 2a). This reduplicated lining was comparable to that found in the submaxillary duct (Fig 2b) and its radicles and would seem to favor the theory of the epithelial (and glandular) origin of these tumors. The cellularity and activity of the epithelial elements varied although not considerably. The malignancy of the tumors was such that 41 were classified as being of grade 1 and only 10 as being of grade 2 on the basis of cellular dedifferentiation (Broders' method). Mitotic figures never abundant were found in 8 of the tumors in each grade. Additional noteworthy features as applying to the epithelial elements were the finding of squamous cell metaplasia in 14 instances (Fig 3a) and inva-

sion of islands of capsular fat in 3 instances (Fig 3b). In no case could an actual point of origin from salivary glandular epithelium be proved, but the gross observation of regional tumor attachment was confirmed microscopically. (It may be readily seen from the appearance of the section in Figure 4 why separation of these tumors by "simple enucleation" cannot be effective in all cases, and why "recurrence" is more to be expected than non-recurrence in cases in which the submaxillary gland is allowed to remain. When only simple enucleation is carried out a few tumor cells remain at the points of attachment between tumor and gland. Such regional invasion of the capsule was observed in 18 instances and it explains we believe the multicentric origin of recurrent lesions.)

The stroma varied even more than did the epithelium both in quality and amount. Hyal-

Fig 4 Grade 1 adenocarcinoma mixed tumor type showing close attachment of tumor to submaxillary gland. Shelling out would have resulted in recurrence. In later months changes in histopathological studies are noted.

Fig. 1. a, Typical grade adenocarcinoma, mixed tumor type, in which irregular anastomosing strands of closely packed dark-staining cells can be seen between the strands are masses of hyaline and myxofibrous stroma (hematoxylin and eosin $\times 45$). b, grade adenocarcinoma, mixed tumor type in which epithelial cells are scanty and seem to fuse with the myxomatous and cartilaginous stromal elements (hematoxylin and eosin $\times 70$).

myosarcoma. Five lipomas were found in the collection, and had typical gross appearances as did also an epidermoid carcinoma arising deep in a sebaceous cyst. These 6 last tumors were excluded from the study, but were of interest from the standpoint of differential diagnosis. Through a process of exclusion, therefore, 81 cases finally formed the basis for the analysis herein submitted.

In the microscopic study of these lesions it was soon discovered that the tumors labeled "mixed" could be very conveniently divided into four groups: (1) adenocarcinoma—mixed tumor type, 51 cases; (2) adenocarcinoma—cylindroma type, 15 cases; (3) adenocarcinoma—intermediate form, (1) and (2) 7 cases; (4) miscellaneous, 8 cases.

Group 1. The picture in group 1 was that of irregular masses and strands of closely packed small epithelial cells with practically no intercellular stroma (Fig. 1a). Between these masses, however, were zones of fibromyxomatous tissue which varied from hyaline on the one hand (Fig. 1a) to a substance identical with cartilage on the other (Fig. 1b). In addition, the relationship of the epithelial to the stromal elements varied considerably even in the same microscopic section. In some areas there appeared to be definite lines of demarcation between epithelial and supporting cells; in others, the 2 elements seemed to fuse imperceptibly, one with another. The latter occurrence was especially true in the central parts of tumor nodules, where it would seem from

Fig. 2. a, Grade adenocarcinoma, mixed tumor type, in which formation of acini and tubules lined by double layer of epithelium can be observed and in which the resemblance of these differentiated ducts to the normal subcutaneous duct depicted in Figure 2b is evident. One of the acini is filled with necrus (hematoxylin and eosin $\times 275$). b, normal subcutaneous duct, in which superficial and basal layers of epithelium being are evident (hematoxylin and eosin $\times 35$).

Fig 7 a, Grade 2 adenocarcinoma, cylindroma type, showing invasion of perineural lymphatic structures and actual invasion of the nerve bundles (hematoxylin and eosin $\times 70$), b, grade 2 adenocarcinoma, cylindroma type veritable "carcinomatous neuritis" (hematoxylin and eosin $\times 70$)

changes observed were the presence of inflammatory (lymphocytic) infiltration in 10 cases (Fig 4) and metaplasia of ducts observed on 1 occasion. Regional lymphatic nodes were identified microscopically in 14 of the specimens. Only 2 instances of involvement were found, once in a primary lesion and once in a recurrent lesion. This observation is in keeping with the known facts concerning mixed tumors.

Group 2 In group 2, the purely cylindromatous type of tumor, the microscopic picture was that of honeycombed cylinders or plugs of small, dark-staining epithelial elements in a hyaline stroma (Fig 5a). As in the true mixed tumor, the cells were cuboid, with large, hyperchromatic nuclei and scanty cytoplasm (Fig 5b). Mitotic figures in general were more

abundant, and the average grade of malignancy appeared to be higher than in the mixed tumor group. Using the method of Broders, we found that 2 of the tumors were grade 1 and 12 were grade 2 carcinomas, and 1 was grade 3 carcinoma.

The characteristic honeycombing seen on microscopic section appeared to result from a grouping of epithelial elements around true and pseudoacini. In the former the acinar spaces appeared to be filled with a substance which stained positively for mucus, in the latter the spaces were usually empty and the lining cells had irregular luminal margins. In this group there was in general considerable evidence of origin from duct epithelium, particularly from the basal layers. In several instances foci of neoplastic growth were found in

Fig 8 a Grade 2 adenocarcinoma, cylindroma type, showing infiltration of muscle (hematoxylin and eosin $\times 45$), b grade 2 adenocarcinoma, cylindroma type, metastasis to regional lymphatic node is shown (hematoxylin and eosin $\times 70$)

Fig 5 a, Adenocarcinoma, grade 1, in which the honeycomb arrangement of epithelial cells grouped in lobular pattern of architecture and large amount of hyaline stroma are evident (hematoxylin and eosin $\times 34$). b, Adenocarcinoma, grade 2, in which true and pseudocystic arrangement of closely packed and dark-staining tumor cells are observed the cytoplasm is scanty and nuclei thus stand out very prominently (hematoxylin and eosin $\times 3$)

line connective tissue was found in 45 cases and was sometimes present in broad sheets. It was especially prominent in the tumors which were grossly described as being "hard" (34 cases). Cartilage was present 37 times and in 10 instances constituted the bulk of the tissue microscopically. Myxomatous degeneration was observed in 32 of the tumors, but in some instances origin from epithelial mucus could not be entirely excluded. Areas of calcification were found in 10 instances and osteoid tissue was observed once. True formation of bone however was always lacking. Peripherally the connective tissue of the stroma was usually

condensed to form a capsule. Such condensation was demonstrated in all the primary tumors, but was absent in 8 of the 11 recurrent lesions. Tumor capsules varied greatly in thickness, and occasionally were incomplete. As stated previously in 18 instances there was invasion by epithelial tumor elements. In 10 cases ductule-like structures were present which probably were of salivary glandular origin. In 16 cases the capsule was adherent to the gland at multiple points and in no case in which the gland was available could it be considered as being entirely separate from the tumor. In the gland itself the only noteworthy

Fig 6 a, Submandibular gland as seen at distance from the main body of the tumor, an adenocarcinoma, cylindroma type, is growing around a duct, whether this represents origin or extension is questionable but in either case the observation serves to argue for radical surgical removal (hematoxylin and eosin $\times 70$). b, Adenocarcinoma, grade 2, in which the intimate relationship of the glandular to the tumorous elements is evident (hematoxylin and eosin $\times 70$)

considerably greater than is the case with mixed tumors. In both, however, it appears to be a relatively late phenomenon.

Group 3 The intermediate group was small and merits little in the way of special comment. Suffice it to say that the neoplasms microscopically exhibited the characteristics of the mixed and the cylindromatous patterns, so that separate classification seemed justifiable. The incidence of recurrence was higher in this group than it was in the mixed group, and the microscopic picture of the recurrent nodules tended to reproduce the cylindromatous fraction of the original lesion with invasion of nerve sheaths in 6 of the 7 cases (Fig 9).

Group 4 In the miscellaneous group was a number of tumors which were difficult of classification. In 3 instances the salivary gland appeared to be the seat of a primary papillary adenocarcinoma, and in 2 of these the regional lymphatic nodes were metastatically involved. In 2 cases the tumors were examples of primary (?) squamous cell carcinoma of the submaxillary gland, either by direct origin or through metaplasia in a pre-existing mixed tumor. In 1 case a grade 1 mixed tumor and a grade 4 adenocarcinoma were found in separate nodules of the same lesion (Fig 10a and b). The nodes were involved metastatically by the high-grade lesion. In 1 case the primary submaxillary neoplasm was rhabdomyosarcoma which promptly recurred after removal. There was no evidence that it was glandular in origin. One of the tumors was of the nature of an epignathus.

CLINICAL DATA

Incidence The incidence of mixed tumors was approximately one in every 20,000 clinic admissions (51 cases among slightly more than 1,000,000 patients). Such an incidence is considerably lower than that reported by Stein and Geschickter, who in a recent large series recorded 1 mixed tumor in every 208 hospital admissions, with submaxillary tumors constituting 10 per cent of the entire group. Adenocarcinomas of the cylindroma type constituted 18 per cent of the entire series of 81 cases. This figure agrees well with that of the group reported by Stein and Geschickter, in

which "adenocystic basal cell carcinomas" comprised 17.4 per cent of a series of 241 cases. Seven, 8.7 per cent, of our cases were of the intermediate group and 8, 10 per cent, were classified as "miscellaneous."

Sex of patients It is generally stated in the literature that mixed tumors show no predilection for persons of either sex. In the present series mixed tumors occurred 31 times in females and only 20 times in males. In addition, in 9 of 11 cases recurrence took place in females. Cylindromas afflicted 10 females and only 5 males. In the intermediate and miscellaneous groups the tumors were found to have a 2:1 preponderance for the male sex.

Age of patients Stein and Geschickter and others have pointed out that mixed tumors occurred among young persons and that cylindromas occurred among middle-aged persons. According to McFarland (10), 50 per cent of mixed tumors occurred among persons between the ages of 20 and 40 years, the peak of incidence being noted late in the third decade. In the present series of 51 mixed tumors, 46 per cent of the patients were between 20 and 40 years of age, the average age for the entire series being 39 years. The youngest patient was 12 years old and the oldest was 79 years old. Of the 15 patients who had cylindromas, 11 were between 40 and 50 years of age, the youngest was 27 years old and the oldest was 76 years old. The average age in the "intermediate" group was 48.7 years and in the "miscellaneous" group it was 44.4 years. In the former group the majority of the patients were in the fifth decade and in the latter group, the sixth decade. Recurrence was related to the age of the patient only in the mixed tumor group, where the average age of patients who had recurrent lesions was 32 years, or 7 years less than the average for the group in which no previous operation had been performed. Family and personal histories were carefully scrutinized in every instance for possible clues as to the etiology of these tumors. Results of such investigation were, not surprisingly, fruitless.

Symptoms The only constant symptoms complained of was the presence of a tumor, and this complaint was elicited in all except 2 cases in which "discovery" of a tumor was

Fig. 9. Grade 4 adenocarcinoma, from the intermediate group. Note again the tendency toward invasion of nerve bundles (hematoxylin and eosin $\times 131$).

the submaxillary gland at a distance from the main body of the tumor (Fig. 6a). In fact these tumors, in general exhibited a more intimate relationship to the salivary gland than did neoplasms of the true mixed type, a relationship which on the basis of our observations could not be entirely explained on the basis of direct extension (Fig. 6b).

The stroma of the cylindromas, although it was not so variable as in the case of mixed tumors, was nevertheless fully as characteristic. In general it was fibrous or hyaline and usually large in amount. Usually concentrated in zones between the islands or nests of epithelium, in many cases it was intracellular compressing and sometimes almost fusing with the cytoplasm of the parenchymatous cells (Fig. 6b). In such instances the epithelial

cells appeared to be small and atrophic, and the irregular anastomosing bands of hyaline stroma presented a mosaic pattern that was highly characteristic.

Perhaps the most important observations made in this entire series of tumors were the infiltrative tendencies of tumors of the cylindroma group. Capsular invasion was observed almost regularly. Infiltration of the salivary gland was commonly found this infiltration being particularly evident in the periductal lymphatic spaces. But perhaps of greater importance was the pronounced tendency of the tumors to grow in perineural lymphatic spaces (Fig. 7a). In some instances there was actual invasion of nerve bundles—veritable carcinomatous neuritis so to speak (Fig. 7b). In the cases in which the tumors were recurrent the reappearance took the form of multiple nodules and almost invariably within these nodules the process of nerve involvement appeared as a sort of nucleus. Even in primary tumors, nerves in the capsule often were invaded. In the later stages, especially in recurrent lesions muscles and adipose connective tissue also exhibited malignant invasion (Fig. 8a). In our opinion this was probably secondary to perineural spread of the disease.

Regional lymphatic nodes were identified in 9 of the 15 cases. In 4 instances these were involved by carcinoma (Fig. 8b). In all 4 cases the lesions were examples of recurrent neoplasms. The tendency of cylindromas to involve lymphatic nodes appears therefore to be

Fig. 10a and b. Combination of grade 4 adenocarcinoma, mixed tumor type, with squamous cell metaplasia and grade 4 adenocarcinoma. Both lesions are found in the same tumor nodule (hematoxylin and eosin $\times 70$).

the miscellaneous group of cases as previously detailed. The right side was involved 43 times and the left side 38 times. Bilateral involvement was not observed.

McFarland (11) has pointed out an apparent paradox in connection with the size of surgically removed mixed tumors. This author, referring chiefly to parotid tumors, stated that small tumors recurred more frequently than did large ones. In the present series the average diameter of the lesions was 3.1 centimeters. Data on the size of tumors were not available in the 11 cases in which operation was performed for recurrence. However, 10 patients who had primary mixed tumor were living 5 to 20 years after operation (at the time of our report) and in each the diameter of the tumor was less than 1.5 centimeters. It may be possible that the performance of conservative "enucleation" has been responsible for the reported high rate of recurrence of small tumors. There was no evidence in our series that "ripening" of the tumor was related to age of the patient or indeed to magnitude of the lesion. In the cylindroma group the average size of the lesion was 4.5 centimeters, the average size of the primary lesion being 2.8 centimeters and that of the recurrent lesion being 5.4 centimeters. In the "intermediate" group tumors averaging 4.4 centimeters were presented, and miscellaneous tumors averaged 4.7 centimeters in diameter.

Surgically, cases of mixed tumor were divided into those in which a primary tumor was presented and those in which the neoplasm was recurrent. For 38 of the 40 patients who had primary mixed tumor all or part of the submaxillary gland was surgically excised, along with the neoplasm. Eight of the 40 patients were operated on recently, and recurrence may or may not develop. Of the 32 remaining patients, 3 died of causes unrelated to their submaxillary lesions, 21 were living without recurrence from 4 to 25 years after operation (at the time of this report), whereas the 8 remaining patients have not been heard from. Of the 11 patients who had recurrent lesions, 5 were seen and treated too recently to permit final analysis to be made. Of the 6 remaining patients in this group of 11, 1 died of renal insufficiency 16 years after operation.

There had been no return of the lesion. For 4 patients arrest of the carcinoma was effected for periods varying from 4 to 10 years. The sixth patient suffered recurrence nine times over a period of 10 years, and was last heard from in 1934.

We believe it to be of some significance that all or part of the submaxillary gland was present in 9 of the 11 patients who came to the clinic for treatment of recurrent lesions, indicating that a conservative type of primary operation had been performed. Although a second operation appeared to eradicate the disease in nearly all instances, it is believed that primary radical surgery would have furnished some insurance against recurrence of the lesion.

In the group of cylindromas the tumor was primary in 5 and recurrent in 10 instances. In all cases in which the lesion was primary, gland and tumor were removed *en bloc*. One of the patients was living 26, and another 5, years after operation at the time of this report. The rest succumbed from recurrence of metastasis, 2 of them died in spite of repeated operations. In the second group 1 patient was living, at the time at which we write, 5 years after operation for a second recurrence. Two patients were treated recently and cannot be included in a statistical analysis of end-results. Concerning 2 patients we have no data other than that they were suffering from recurrence when they were last heard from. The 5 remaining died from carcinoma. In all but 2 of the recurrent tumors it was possible to find remnants of the submaxillary gland and it is possible if not probable that in these cases also the original "tissue sacrifice" had not been adequate.

In the "intermediate" group of neoplasms, tumor and gland had been removed in 4 instances. Two of the patients were living 20 and 4 years, respectively, after operation, at the time of this report. In one the gland was extensively infiltrated, and this patient succumbed in a year to spinal metastasis. Another died from recurrence in 15 months. In 3 instances only a part of the gland was removed. Two of these patients died from recurrence. We have no subsequent data on the third patient.

made during the course of examination. Among patients who had mixed tumors, the average duration of this symptom was 7 years when the tumor was primary and 4-7 years when the neoplasm represented a recurrence. Extremes of 40 years and 1 month were found. Among the 11 instances of recurrence in this group the average time elapsing between the first operation and the onset of the recurrent lesion was 2 years, with extremes of 6 months and 7 years. The average time elapsing between the first instance of recurrence and the second operation was 3.8 years. These figures, although they are based on a small number of cases, tend to indicate that the more rapidly growing tumors are the ones which usually recur. The evidence shows on the other hand that the behavior of the primary tumor does not necessarily serve to predict the behavior of the recurrent lesion.

In the cylindroma group 5 of the patients came to the clinic for consideration of their primary lesion. In this small group the average duration of symptoms was 3 years, with extremes of 6 years and 6 months. Of 10 patients who came for treatment of a recurrent tumor the average duration of the primary symptoms had been 5.6 years, with variations of from 12 years to 1 year. The duration of the recurrent lesion on an average was 1 year.

In the "intermediate" group only 1 patient came to the clinic for the treatment of a recurrent tumor. This person had had primary symptoms for a year and recurrence took place 18 months after operation. The average duration of the swelling in the remainder of cases was 6.3 years (4 years, if we disregard 1 case in which the duration was unusually long, 20 years). The shortest duration of the swelling was 6 months.

In the group of miscellaneous cases 3 patients presented themselves with primary lesions. One patient gave a history of the presence of a "lump for 20 years" and was free from recurrence after 7 years at the time of our writing. In another patient the tumor had been present for 50 years, but it had grown very rapidly for 6 months. This patient succumbed within 2 years, death being caused by the unusual combination described herein in the section called Pathologic Data—a grade

4 adenocarcinoma engrafted on a grade 1 adenocarcinoma of the mixed tumor type. The third patient who had a 6 month history was living at the time of this report, with recurrence after 2 operations for the removal of a grade 2 papillary adenocarcinoma had been carried out.

Of the 5 patients presenting themselves for treatment of a recurrent neoplasm of the "miscellaneous" type, 4 had short histories, and there was a rapid return of the neoplasm after removal. One of these patients died after a second recurrence, 1 was treated only recently and 2 have not been heard from. In the fifth case the diagnosis was epiglottic tumor and the patient probably is living and well at the time of our report.

Pain and tenderness. A perusal of the literature on mixed tumors leaves one with the impression that pain is not an outstanding symptom. This observation was confirmed in the present study. Only 4 of the 51 patients complained of pain and tenderness in the region of the tumor and in no instance was either severe. In the cylindroma group, however, pain was a prominent feature in 11 of the 15 cases. Pain usually was moderate in severity and of shorter duration than the swelling. It appeared to be more or less directly related to fixation of the tumor clinically and pathologically to involvement of nerves. This rather high incidence of pain we believe may be of importance in the making of a correct preoperative diagnosis.

In the intermediate group, pain was not a common symptom. It was present in 3 cases, in 2 of which extensive microscopic invasion of nerves had occurred. In the miscellaneous group of cases pain was present in only 2 of the 8 patients.

Miscellaneous symptoms, not previously mentioned herein occasionally were encountered but did not appear to be of diagnostic significance. In a number of instances the tumor was said to fluctuate when the patient caught cold, and in 4 instances of tonsillitis. In the first noted after attacks of tonsillitis. In general growth of the tumor was steady but in 8 cases there was a history of an accelerated rate of growth which however did not appear to be of serious significance except in 1 case in

was extremely high, and the outlook generally unfavorable

4 An "intermediate" group of cases was found in which the tumors pathologically shared the features of the mixed tumors and the cylindromas. Clinically, also, the histories of the patients justified separation of the tumors into a special category

5 Eight patients, 9.5 per cent, had atypical tumors described as "miscellaneous." Prognosis depended partly on the type and grade of the lesion and partly on the extent of lymph nodal involvement

6 Clinical follow-up studies have demonstrated the usefulness of the microscopic classification we have presented, in relation to prognosis

7 Throughout the study we were impressed by the disappointing results which followed conservative operation on malignant tumors of the submaxillary gland

In the miscellaneous group at least remnants of the submaxillary gland were found in all 4 recurrent tumors indicating that a conservative operation had been performed for removal of the primary tumor. Results were better in the 4 remaining cases in which gland and tumor were included in the operative resection. Throughout the entire series it may then be stated that the best results were obtained when in the primary surgical operation the submaxillary gland was removed. The difference in end-results in this particular respect was fairly striking in all groups except the group of cylindromas. The discrepancy in this group is probably to be explained by the fact that the tumors frequently infiltrated even beyond the confines of the gland itself.

RESULTS OF STUDY

Before this problem was undertaken we shared what we believe to be a general impression, namely, that all submaxillary tumors are mixed tumors and of a low grade of malignancy. Nearly all of our earlier cases were so labeled and in these cases the rate of recurrence seemed unduly high. Not until we had reviewed the macroscopic pathology did it become apparent that the term "mixed tumor" indeed covered a multitude of sins so to speak. Many were cylindromas which had produced no unusual features in the clinical history (except for a high incidence of pain) but which did produce an entirely different outlook from the standpoint of ultimate recovery of the patient. To be sure 7 cases belonged to an "intermediate class," but even in this class "cylindromatous" features usually predominated to such an extent that a separate grouping seemed advisable. A miscellaneous group was created to include tumors not belonging to the types we have just listed.

On the basis of this classification we are in agreement with Ewing and McFarland (11) that true mixed tumors are of epithelial origin and that they are inherently malignant—adenocarcinomas of low grade. We have shown that recurrence of these mixed tumors is not uncommon, particularly when in the surgical attack the tumor is "enucleated" a procedure which frequently leaves tumor cells behind. We have seen that removal of a recurrent

tumor is not so successful as performance of a complete primary radical procedure from the standpoint of avoidance of further involvement. It is felt, furthermore, that the surgeon cannot possibly distinguish at operation the simple mixed tumor from the highly dangerous cylindroma in which recurrence frequently follows, even after radical operation for removal of the primary lesion. For these reasons we are in complete disagreement with those who advocate local enucleation for submaxillary tumors. The disease can be thoroughly eradicated only by removal of the tumor en bloc the salivary gland and the regional lymph nodes. In the case of the cylindroma even this procedure may not be effective. Microscopic extension beyond the limits of gross invasion has been repeatedly demonstrated in our cases, this extension having a peculiar affinity for perineural lymphatic structures. (Existence of the perineural spread of carcinoma has been known for years, but it has not received the attention it deserves. It was emphasized by Kahler in a recent paper on carcinoma of the prostate gland.) In the intermediate and miscellaneous groups of tumors as we have classified them, the prognosis is only fair but to these groups, again, the same surgical principles should apply and the surgeon should not be deceived by apparent encapsulation of the tumor.

SUMMARY

1. Eighty-one primary submaxillary malignant tumors have been reviewed from the clinical and pathological aspects.

2. True mixed tumors constituted 63 per cent of the series. They represented low grade slowly growing adenocarcinomas usually not associated clinically with pain or local fixation. The tendency toward recurrence was not pronounced except when inadequate "tissue sacrifice" had been carried out.

3. Adenocarcinomas of the cylindroma type accounted for 18.5 per cent of the tumors. These cylindromas as a rule were associated with a short clinical history in which pain and local fixation were prominent features. Pathologically the lesions, although they were of a moderate degree of malignancy, presented pronounced infiltrative tendencies with selective invasion of nerves. The rate of recurrence

skin incision should be covered with laparotomy sponges or towels carefully. If it could be remembered that the surface of the skin, only, has been rendered free of live organisms, not its deeper layers, nor the hair follicles, the sweat glands nor the sebaceous glands, more rigid protection would be diligently carried out in protecting the delicate peritoneal surfaces from these ever present dangers of bacterial contamination. It is well understood that trauma must take place to peritoneal surfaces no matter how gently the manipulations are carried out. That trauma can be minimized by gentler handling, gentler packing off of viscera, gentler retraction of the parietal peritoneum and viscera, is easily understood, especially when one realizes that the peritoneum is nothing more than a single layer of delicate flattened cells with a very delicate basement membrane. It can offer not a whit of resistance. The peritoneum cannot resist exposure to air for many moments without drying. Drying produces death of this delicate surface rapidly as proved long ago by Walther. He advocated soft, warm, moist gauze packs as a preventative. These should be changed frequently to prevent cooling. In order further to minimize trauma, both Coffey and Gellhorn object to the use of gauze packs, moist or dry, and advocate thin rubber sheeting instead. The modern rubber glove is an excellent agent to employ in the handling of viscera. When moistened with warm saline it is difficult to conceive that many pavement cells are devitalized by its gentle application. Instruments of steel are difficult to devise in order to make them trauma proof. They are usually too rigid, toothed, corrugated, or lined too deeply. The hemostat, the Allis forceps, the usual run of thumb forceps, smooth or toothed, and even the Percy-Allis forceps are mentioned only to be condemned. A rubber-covered thumb forceps, the resilient type of Babcock forceps or its modification advocated by one of us (17) may be employed assuring a minimum of trauma—yet trauma nevertheless.

Many cases of postoperative adhesions can be attributed to poor operative techniques other than those which have been mentioned. Most glaring of them all is the peculiar

practice of neglecting to peritonealize injured, lacerated, or crushed surfaces. It has been the visual experience of many in the past to have witnessed this grave omission. Apparently, the guilty operator has inherent faith in the ability of the peritoneum to withstand not only the extensive trauma of the operative procedure at hand but also that it will always be able to "cover up," his errors of denudation, laceration, and cut surfaces.

Much research and clinical experimentation has been carried out in the past generation in an effort to guard the peritoneal cavity against the formation of adhesions as well as to guard it from postoperative infections. The scope of this paper is too limited to attempt a discussion of the numerous prophylactic agents employed. A number of them have enthusiastic clinical, as well as research, reports to substantiate them.

THE ATTACHED OMENTUM

The ubiquitous omentum has not received the support it should as an agent in adhesion prevention. There are many uses to which it may be harnessed. Mann advocates its use in adhesion prevention, as do Sweet, Chaney and Willson (23). The latter group carried out a long series of excellent experiments with free and attached omental grafts. Springer also used attached omentum freely. Many good surgeons use attached omentum to cover the repair of ruptured peptic ulcers, the damaged areas following cholecystectomy and choledochostomy. Over intestinal anastomoses, duodenal stumps, denuded parietal or visceral peritoneum, around enterostomy tubes, beneath abdominal incisions, the omentum is freely employed to good advantage. In checking hemorrhage from parenchymatous organs, Loewy suggests its use in liver, spleen, and kidney damage. Clark and Byford, however, warn against its use because its attachment to the denuded or inflamed area may interfere with normal physiology of the stomach and transverse colon. This may be true especially in its use in pelvic denudations or infections. Pirone, Wilkie, and Bost recommend, and have used, attached omentum as a "wrapping" about a strangulated portion of the intestine the viability of which

THE FREE OMENTAL GRAFT

A Clinical and Experimental Study

J. L. McGEHEE, B.A. M.D. F.A.C.S. and M. J. TENDLER, B.S. M.D. F.A.C.S.,
Memphis, Tennessee

THE past generation has witnessed a tremendous increase in the number of operations within the abdominal cavity. Concomitantly ever multiplying numbers of cases of acute and chronic intestinal obstruction and postoperative adhesions have arisen with this increase. With the myriads of surgical invasions within the peritoneal cavity not only in the many large surgical centers but also in every rural hospital it is remarkable to note that the number of cases of adhesive obstruction and postoperative adhesions is comparatively and indeed very small. In a series of 511 cases of acute intestinal obstruction studied at Charity Hospital New Orleans, over a 6 year period Moss and McFetridge found 26.8 per cent were due to adhesions. At the John Gaston Hospital Memphis, 581 cases of acute intestinal obstruction were studied over a 10 year period by us (17) and 17.2 per cent were found due to adhesions, either inflammatory or postoperative. The two hospitals mentioned have a large general surgical service, particularly in abdominal surgery. The total number of cases of obstruction due to any cause is but a fraction of total number of celiotomies performed in comparative periods.

The reactions incident to inflammation of the peritoneum, due to bacterial invasion have played a considerable part in the cause of intestinal obstruction of the adhesive type. A large percentage of obstructions, however can be traced to traumas other than infection. The most common of these are rough handling of the viscera, too much instrumentation, poor choice of abdominal sponges and packs, exposure and drying. It is also common to

find errors in operative technique that lead to adhesions. The main offender here is the operator who does not peritonealize traumatized surfaces sufficiently whether they be cut, crushed lacerated, or torn.

During the past few years free omental grafts have been used in 13 cases of adhesive obstruction, and in areas of potential obstruction, where relatively large areas of denudation of visceral or parietal peritoneum resulted. In none of the cases reported have the clinical results required further abdominal surgery. In an effort to determine parallel results in animals, dogs were subjected to laparotomy, free omental grafts were applied to scarified areas, and then explored 3 months later.

THE PREVENTION OF ADHESION FORMATION

The advent of the aseptic era in surgery has done by far the most good in aiding in the prevention of adhesions after operation. In this present age of surgery infection should not follow clean surgical cases if the usual diligent care is assumed by the operating room supervisor, her assistants, or nurses, in the routine, but ever careful preparation of the linens, drapes, sponges, and instruments. The word routine is dangerous. But eternal vigilance is the price of peace, and this vigilance requires frequent checks of sterilizers, temperatures, autoclave pressures, etc. Breaks in sterile technique occur among the best operating room teams. Should there be any question or doubt as to a break the very fact that there is a question or a doubt about the break, rectification should be made without any hesitation. This would be an excellent routine. It would save time, temper, and sometimes lives. The use of skin antiseptics should be carefully guarded, as well as any other chemical compounds when the peritoneal cavity and contents are exposed. The

which runs something like this: 'Oh I've applied free grafts now and then and I've seen Dr So-and-So apply them. When conversation continues, and we wish to learn what happened in those patients who were subjected to the grafts, the answers become extremely vague. Witness the dearth of detailed clinical reports. The last, and only report worthy of mention is Graham's published in 1934. Excellent reports such as his probably lie tucked away, embryonically, in the cortex of many a surgeon, and in his office records. We hope the following tabulation of our 13 private patients will stimulate more than a few to put their office force to work, as we did, to help substantiate the fine experimental data of the literature on this interesting subject. We would be delighted to learn of Dr So and So's experience with free grafts. Probably a summary of these collected personal observations and records could be published in a few years hence.

The authors regret that re-explorations or autopsy material have been unavailable in this series, but the clinical results have certainly proved most encouraging to us.

verse colon to the region of the gall bladder 10 sa were noted. The first portion of the duodenum was markedly contracted. Operation consisted of sharp dissection, releasing the stomach, duodenum and transverse colon from the liver and the gall bladder fossa. Grafts were applied (1) 8 by 6 centimeters, to the liver and gall bladder fossa (2) 10 by 8 centimeters to the stomach and duodenum and (3) 6 by 6 centimeters, to the transverse colon and mesocolon. There has been no recurrence of "gall bladder colic" to date. The gastrointestinal series is normal.

CASE 2. S. S. female, aged 28 years, was operated upon August 17, 1937. In 1930 she had had an appendectomy and right salpingectomy. She complained of colic like pain, nausea and vomiting. The terminal ileum was completely blocked by adhesions, the result of right chronic pelvic inflammatory disease. The left adnexa were normal. Operation consisted of right oophorectomy. A graft 10 by 6 centimeters was applied to the denuded terminal ileum. No recurrence of symptoms to date.

CASE 3. W. B. female, aged 31 years, was operated upon October 2, 1937. In 1930 appendectomy had been done. Patient complained of lower abdominal pain, nausea and vomiting, dysuria, frequent and a loss of 15 pounds in weight during 12 months previous to admission to the hospital. There was a profuse vaginal discharge, bilateral adnexa enlarged and tender. At operation the following was noted: a chronic bilateral tubo-ovarian abscess, the terminal ileum completely adherent to the right

is doubtful or when the patient's condition does not warrant resection. One other danger of the attached graft is that of intestinal obstruction. This may occur in one of two ways the most common, the volvulus-like loop of small bowel which becomes twisted about the omental pedicle the other the contracted "wrap" of greater omentum often seen in complete and chronic obstructions of terminal ileum or in ileocecal valve region. Binne warns against the possibility of internal hernia in the use of attached grafts.

THE FREE OMENTAL GRAFT

Senn in 1883 was the first to advocate the use of the free omental graft. Experimentally he found the grafts adhered firmly to the surfaces to which they were applied. They had become well vascularized in a very short time. He used 4 dogs in his experiments, observing his results in 36 hours to 8 days. His results were better with those grafts placed upon scarified intestine. Brocq, Ducastaing and Reilly (5) established the fact that free grafts not only were successful, but in addition that the surface endothelium of the transplanted omentum persists. Peet and Finton studied omental grafts histologically determining that in dogs the grafts survive unchanged for at least 6 months. They recommend that the thinner the graft used the better. Bennett covered a perforated peptic ulcer successfully with free grafts. Adversely Springer and Wilkie, though they do not consider free grafts unsatisfactory believe they lead to further peritoneal adhesions. Both in an extensive histological study found that the surface endothelium of the free graft not only persists but at the end of 2 weeks is continuous with the endothelium of the recipient organ. Sweet Chaney and Willson found that free as well as attached omental grafts were efficacious in covering suture lines—and remain free from other adhesions. Freeman, in a purely clinical report recommends enthusiastically the use of free grafts to replace lost portions of peritoneum, to prevent adhesions to strengthen suture lines and to check hemorrhage from parenchymatous organs. Another detailed and accurate experimental report is one by

Davis, who transplanted free grafts to stomach, intestine, liver spleen, kidney bladder and denuded areas of peritoneum, with excellent results. He found that the grafts survived well throughout his experiments. Mann, though not very enthusiastic about free grafts, states if however infinite care was used in handling the transplant, so that the delicate cells would not be injured, and in tucking in the edges so that none of the cut surface was exposed, it was found possible to cover a traumatized area so that few if any adhesions occurred. Graham, in 1934 presented a detailed clinical report of 20 cases of free omental grafts collected from the Methodist Hospital records in Brooklyn, New York. The grafts were used in a variety of conditions including terminal ileum, mesentery suture line, liver and duodenum, abdominal wall defect, leaking ureter gall-bladder fossa, and pylorus and duodenum, etc. The results warrant Graham's concluding that free omental grafts will live they are hemostatic they aid in preserving peristalsis they strengthen weak suture lines they resist infection.

In the technique of omental grafting, Freeman recommends the following. The pedicle should not be puckered by ligation the free border of the omentum should be used to avoid large vessels the graft should be carefully sutured in place with fine catgut, the transplant must extend beyond the raw surface. To these precepts should be added Mann's admonition to roll or tuck under the cut edges of the graft.

Clinical reports are still too meager concerning the ultimate fate of the omental graft. In 3 of Graham's case records was there an opportunity to examine the grafts. Although all three grafts were found intact, this number is entirely too small from which to draw conclusions containing final conviction. We must await more clinical reports which will contain data of grafts examined at re-explorations or at autopsies.

CLINICAL REPORT OF 13 CASES TREATED WITH FREE OMENTAL GRAFTS

Hardly a conversation with any surgeon, when the subject of free omental grafts is brought up, does not bring forth a statement

Fig 3 Case 4 a, Chronic bilateral tubo-ovarian disease Sigmoid and terminal ileum both densely adherent to adnexal masses and uterus b, Bilateral salpingo oophorectomy and supravaginal hysterectomy, complete peritonealization of lesser pelvis but denudation of sigmoid and terminal ileum c, Free omental grafts to sigmoid and terminal ileum

graft, 10 by 6 centimeters, was applied to cover the area of denudation in the left broad ligament's posterior leaf Patient made a complete recovery and has no gastrointestinal symptoms

CASE 7 L E T, female, aged 33 years, was operated upon on December 27, 1940 Patient complained of marked pain and tenderness in the right lower quadrant, of 2 months' duration A tumor was found in the lower abdomen 4 months ago A preoperative diagnosis of fibromyoma of the uterus and chronic pelvic inflammatory disease was made Operation revealed multiple myomas of the uterus, chronic bilateral salpingo oophoritis, and the terminal ileum densely adherent to right adnexa Operation supra vaginal hysterectomy, bilateral salpingo-oophorectomy, and appendectomy A graft, 8 by 6 centimeters, was applied to denuded terminal ileum Patient made complete recovery and has remained well to date

CASE 8 J A S, female, aged 41 years, was operated upon on January 4, 1941 Examination revealed lower abdominal pain, low grade fever, of 3 months'

duration, profuse vaginal discharge A preoperative diagnosis was made of chronic pelvic inflammatory disease Pathological examination revealed a right pyosalpinx, left chronic salpingitis, marked diffuse cystic degeneration of both ovaries, 12 centimeters of terminal ileum densely adherent over right pyosalpinx, and suppurative endocervicitis Operation consisted of bilateral salpingo oophorectomy, appendectomy, and coagulation of cervix A graft, 14 by 6 centimeters, was applied to denuded terminal ileum Patient has remained cured to date

CASE 9 J G C, female aged 34 years, was operated upon on January 13, 1941 She had previously been operated upon, in 1933, at which time a right salpingo oophorectomy and appendectomy had been performed Examination revealed lower abdominal pain, excessive menstruation, habitual constipation since last operation A preoperative diagnosis of chronic pelvic inflammatory disease and chronic intestinal obstruction was made When the abdomen was opened a left chronic pyosalpingitis and oophor-

Fig. Case 1. a, Chronic bilateral tubo-ovarian masses. Terminal ileum densely adherent to right adnexal mass. b, Bilateral salpingo-oophorectomy. decapsulation of terminal ileum. c, Free omental graft to terminal ileum.

III and pain throughout the lower abdomen of colic like nature which had been present for 6 days before admission to the hospital. No gas or feces had been passed for 7 hours. When the abdomen was opened thick layers of adhesions were noted throughout the right iliac fossa as well as chronic bilateral tubo-ovarian disease. The sigmoid was adherent to the uterus and left adnexal mass. The terminal ileum was densely adherent to the right adnexa. Bilateral salpingo-oophorectomy and supravaginal hysterectomy were done. Grafts were applied as follows: (1) 6 by 5 centimeter graft to cover decapsulation of left broad ligament and anterior sigmoid. (2) a 6 by 6 centimeter graft to cover decapsulation of terminal ileum. Patient gained in weight and had no gastrointestinal disturbances since discharge from hospital.

CASE 5. H. C. female aged 30 years, was operated upon January 8, 1910. Bilateral salpingo-oophorectomy had been done in 1906. Patient complained of colic like pain vomiting and distention grade II. No feces had passed for 4 days, no gas for

24 hours. When the abdomen was opened the terminal ileum was found to be densely adherent to the right broad ligament posteriorly for 6 centimeters, kinked, and completely obstructed. Operation consisted of resection of the posterior wall of the right broad ligament. A graft, 8 by 5 centimeters, was peritonealized of the posterior wall of the right broad ligament. The terminal ileum. Following operation bowel movements have been normal for first time in 4 years, and there has been no recurrence of the colic.

CASE 6. V. C. W. female aged 23 years, was operated upon April 23, 1910. Patient complained of alternating constipation and diarrhea. Peristalsis was visible distention grade II. Scout film showed much gas in small intestine. The preoperative diagnosis was left ovarian cyst, infected with chronic intestinal obstruction. When the abdomen was opened a large left cystic tubo-ovarian mass as noted wedged into the pelvis minor; also right chronic salpingitis. At operation the left adnexal mass was excised and right salpingectomy performed.

Fig 6 Technique of peritonealizing omental stumps and vessels a, First knot tied upon anterior or posterior leaf of intact omentum b, Ends of ligature rethreaded Edge rolled, then with blunt end of needle passed through omentum 1 to 2 centimeters above rolled edge, the second knot is tied c, Completely peritonealized omental stump

it and to the cecum. A total of approximately 20 centimeters of parts of the ileum was adherent to the uterus and left adnexa, burying the uterus completely. The right adnexa were absent. Operation consisted of appendectomy, supravaginal hysterectomy, left salpingo oophorectomy and complete peritonealization of the pelvis. Grafts were applied as follows: (1) a 9 by 6 centimeter graft to the terminal ileum and cecum, (2) a 10 by 6 centimeter graft to one portion of the pelvic ileum, (3) a 6 by 6 centimeter graft to another portion of the pelvic ileum. Since operation, bowel movements are regular and there have been no gastrointestinal symptoms.

CASE 11 B R W, female, aged 26 years, secundipara, was operated upon June 8, 1941. Patient presented the textbook picture of chronic cholecystitis following marked digestive disturbances through both pregnancies, colic like attacks suggestive of stone. A cholecystogram was positive for cholecystitis but no stones were visible. A gastrointestinal series was positive for duodenal ulcer after complete atropinization. When the abdomen was opened there was revealed a strawberry gall bladder with thick percholecystic adhesions involving the gall bladder and entire anterior wall of the first portion of duodenum. There were no stones in gall bladder or ducts. Cholecystectomy was performed and first portion of duodenum was completely denuded. A graft 8 by 6 centimeters, was applied to the denuded duodenum. Since operation patient has had complete relief from digestive attacks and pain, is on regular diet, and has no distress after eating.

CASE 12 C B K, female, aged 26 years, was operated upon on August 3, 1941. She had previously had a cesarean section in 1939, and in 1940 adhesions between the small intestine and the uterine scar were broken up to relieve an acute intestinal obstruction. Examination revealed colic-like pain, vomiting

Fig 7 Omental graft as applied in dog experiments. Grafts measured 10 by 5 centimeters. Intestine completely encircled. Number 50, J & P Coats cotton sutures used, every 2 centimeters. Edges rolled under. Sutures clipped short.

latio graft. This graft is sharply demarcated b, Sketch showing mirror image of photograph

intestine, were used as a base for the grafts.

In 5 dogs, free grafts 10 by 6 centimeters, were detached from the free border of the omentum. These grafts were attached without any injury to the intestine whatsoever (except for the needle punctures) to the entire circumference of the terminal ileum, about 30 centimeters, from the ileocecal valve. For fixation, 50 cotton sutures were used approximately every 2 centimeters. In order to ensure future mesenteric blood supply the grafts were run on both sides, upon the mesenteric borders of the ileum. The edges were carefully tucked under and the sutures were clipped very short (Fig. 7).

In 5 more dogs, the surface of the terminal ileum, about 30 centimeters, from the ileocecal valve, was scarified over an area roughly 8 by 3 centimeters. Scarification was done with the cutting edge of a dull scalpel. Complete macroscopic denudation was easily accomplished. After the scarified surface was rubbed with a dry gauze sponge the graft was then applied as in the first series.

From 90 to 100 days after the application of the grafts, the dogs were relaparotomized. In Table I are tabulated the results of the experiments upon the unscarified intestine and in Table II are the results upon the scarified group.

In all of the dogs (5) where the grafts were laid upon the unharmed ileum (Table I) the omentum had completely wrapped itself around the segment operated upon in such a way that it was impossible to tell graft from enveloping omentum (Fig. 8 a and b). The only identifying remains of the grafts were the

cotton sutures used in securing the grafts in place. There were no other adhesions to intestines or to the omentum. The area of the omentum from which the free grafts had been excised had smoothed out completely though the ligatures were still loosely in place in several instances.

TABLE I.—FREE OMENTAL GRAFTS APPLIED TO UNSCARIFIED ILEUM (Relaparotomized after 3 months)

Dog 1	Normal omentum envelops grafted area throughout its length. Sutures in place, glistens through omentum. No other adhesions.	Part of graft fixed
Dog 2	Graft enveloped as in Dog 1 completely. No omentum. No other adhesions.	
Dog 3	Same as Dog 1	
Dog 4	Same as Dog 1	
Dog 5	Same as Dog 1	

In 4 of the dogs in which the grafts had been applied to scarified intestine (Table II) the resulting patch was identified by the sutures still in place. The graft in all 4 dogs mentioned required careful inspection in order to outline it at all from normal ileum, so smooth and glistening was the surface (Figs. 9 a and b, 10 a and b, 11 a and b, 12 a and b). The only irregularities consisted of blood vessels which had grown into the grafts from the mesentery and the remaining suture knots. Peristalsis continued normally through the grafts. Fine long white strands could be detected running veil like, through the length and breadth of the patch. They resembled strands of replacement fibrous connective tissue. Very little of the original fat of the graft remained. Roughly estimating it, not more than 25 per cent of the original fat in any of the grafts, remained after 3 months. The circumference and the diameter of the patched

THE RÔLE OF HYPERTENSION AND PANCREATIC EROSION IN MASSIVE FATAL HEMORRHAGE FROM GASTRIC AND DUODENAL ULCERS

JOHN R. SCHENKEN, M.D. EDWARD L. BURNS, M.D. and
URBAN MAES, M.D. F.A.C.S., New Orleans, Louisiana

MANY factors influence the prognosis of massive hemorrhage from a gastric or duodenal ulcer. Among those most frequently mentioned in reports on this subject are (1) age, (2) number of hemorrhages, (3) arteriosclerosis, (4) chronicity, (5) sex, and (6) location.

The factors which are less frequently mentioned are (1) hypertension, (2) erosion of the pancreaticoduodenal artery, and (3) bleeding from granulation tissue buds in the base of the ulcer.

In a review of postmortem examinations of cases of fatal gastric and duodenal ulcer we were impressed by the high incidence of hypertension and pancreatic erosion in those patients who died of massive hemorrhage.

MATERIALS AND METHODS

In the Charity Hospital of Louisiana during the period from 1935-1941 the bodies of 81 patients who died as the result of gastric or duodenal ulcer were subjected to postmortem examination. Multiple ulcers were found in 11 cases, but only the ulcer which was responsible for the patient's death was used for the purpose of analysis.

The cases were divided into gastric and duodenal ulcer groups and in each group analyses were made concerning (1) the distribution of ulcers according to sex and color, (2) the primary cause of death, (3) the age range and average age of the patients at death, (4) the incidence of hypertension, and (5) the incidence of pancreatic erosion.

The presence of hypertension was established by reviewing the clinic and hospital

From the Departments of Pathology and Bacteriology and the Department of Surgery of the Louisiana State University School of Medicine, and the Department of Pathology of the Charity Hospital of Louisiana at New Orleans.

history records and the postmortem protocols. Because some patients were in a state of shock throughout their last hospital stay previous blood pressure readings taken when shock was not present, were reviewed on all cases.

Nineteen patients had hypertension. In 12, there was a diastolic blood pressure of 90 or more millimeters of mercury and a cardiac hypertrophy. Most of these patients also showed nephrosclerosis. In 5 the diagnosis of hypertension was based largely on the record of an elevated blood pressure. Four of these 5 patients showed diastolic blood pressures of 100 or more millimeters of mercury and one maintained a blood pressure of 130/76 millimeters of mercury in the presence of a gastric hemorrhage so severe that physical signs of shock and subjective symptoms of cerebral anemia were present. In 2 cases, cardiac hypertrophy alone formed the basis of the diagnosis. Causes of hypertrophy other than an elevated blood pressure were excluded.

Ten patients were classified as questionable cases of hypertension because the data obtained in the clinical and postmortem records, although suggestive of hypertension, were incomplete. These were counted as patients without hypertension in the calculation of percentages. The 32 remaining patients showed no clinical or postmortem evidence of hypertension.

With one exception (patient in shock with a blood pressure of 130/76 millimeters of mercury) the classification into the three groups was made without knowledge of the cause of death.

RESULTS

Distribution of gastric and duodenal ulcers according to sex and color. Forty-six, 56.7 per cent, of the 81 ulcers occurred in white patients

and 35, 43.2 per cent, occurred in negroes. Of the 46 ulcers found in white patients, 44 were found in males, and of the 35 ulcers found in colored patients, 31 occurred in males.

Thirty-three, 40.7 per cent, of the 81 ulcers were gastric and 48, 59.2 per cent, were duodenal. In white patients the ratio of duodenal to gastric ulcers was almost 2:1, whereas in negroes the ulcers occurred with almost equal frequency in the two sites.

Cause of death. Hemorrhage was the cause of death in 11 gastric and 8 duodenal ulcers, a total of 19 cases, 23.3 per cent. Perforation with ensuing localized or generalized inflammation in the peritoneal cavity caused death in 19 gastric and 36 duodenal ulcers, a total of 55 cases, 67.9 per cent. Miscellaneous causes accounted for death in 3 gastric and 4 duodenal ulcers, a total of 7 cases, 8.6 per cent. Among these cases there were 3 deaths from obstruction, 2 from operative procedures, and 1 each from bronchopneumonia and postoperative peritonitis.

Colored patients predominated in the group in which death was due to hemorrhage, and white patients in the group in which perforation was the cause of death.

Analysis of age. The average age of the colored patients in each group was less than that of the white patients in the corresponding group. The average age of patients who died of hemorrhage was 59.7 years, in those who died of perforation it was 50.1 years.

Relation of hypertension to cause of death. The incidence of hypertension in the entire group of 81 patients was 23.4 per cent. Of the 19 whose death was due to hemorrhage, 11, 57.8 per cent, had hypertension and of these 8 were colored and 3 were white. The incidence of hypertension among patients who bled fatally from gastric ulcers was essentially the same as the incidence among those who bled fatally from duodenal ulcers. Among the 55 patients whose death was due to perforation, 6, 11.1 per cent, had hypertension, and among the 7 patients whose death was due to miscellaneous causes, 2, 28.5 per cent, had hypertension.

Pancreatic erosion. In 7 patients the ulcer had eroded into the substance of the pancreas.

Hemorrhage was the primary cause of death in each instance. Two ulcers were located on the posterior surface of the pyloric portion of the stomach and 5 were located on the inferior surface of the first portion of the duodenum. All of these patients were males. Three patients in this group also had hypertension.

IMPORTANT FACTORS IN FATAL HEMORRHAGE

The predominance of duodenal ulcers over gastric ulcers, the average age of the patients in the hemorrhage group and the predominance of males over females is in accordance with the observations of many other investigators, even though 43.2 per cent of our patients were negroes. A finding which differs from that of other authors, however, is the presence of hypertension or erosion of the pancreas in 78.9 per cent of the hemorrhage cases.

In reports by other workers, hypertension has not received a prominent place among the factors which produce fatal hemorrhage. Jordan and Kiefer in 1932, in analyzing the factors which influence prognosis in the medical treatment of duodenal ulcer, noted that hypertension was present in 9 per cent of 53 patients in whom treatment was successful, whereas the incidence among 43 unsuccessfully treated patients was 33 per cent. In 12 of their patients treatment was considered to be unsuccessful because of hemorrhage. 4, 33 per cent, of these patients had hypertension. The authors did not relate the hemorrhage directly to the elevated blood pressure but stated that "the prognostic significance of hypertension appears to be related to the intolerance of alkalis." Pfeiffer and Meyer, Rosi, and Steigmann, in their reviews on bleeding ulcers, include hypertension as one of the factors which increases the mortality from hemorrhage, but they give no data to support their statements.

In our group, hypertension was associated with massive fatal hemorrhage in 57.8 per cent of the cases, as compared to an incidence of 23.4 per cent in the entire group and 11.1 per cent among the patients whose death was due to perforation. It should be emphasized that the actual incidence of hypertension in the hemorrhage group could not have been detected if only the blood pressure readings

taken during the final hospital stay had been considered. Only 5 of the 11 cases of hypertension in this group showed an elevated blood pressure during the time of their fatal hemorrhage. The clinic records, the records of previous hospital admissions, and the postmortem findings enabled us to establish the presence of hypertension in the 6 remaining cases.

The hospital record of 1 patient with massive gastric hemorrhage illustrates how blood pressure readings taken at the time of the hemorrhage may be misleading. The lowest reading taken during the time of the hemorrhage was normal 138/80 millimeters of mercury. A reading obtained one day prior to the severe hemorrhage was 180/106 millimeters of mercury and 5 days after the hemorrhage ceased the blood pressure was 144/110 millimeters of mercury. This patient was not included in the hemorrhage group because he subsequently died following a subtotal gastrectomy.

It is interesting to note that among the various factors which different investigators have found to be influential in the outcome of hemorrhage from gastric or duodenal ulcers there are several which are commonly associated with hypertension. It is commonly stated that fatal hemorrhage is more likely to occur in patients beyond the age of 50 or 55 years; the incidence of hypertension is higher in this age group. Arteriosclerosis is also mentioned as an important factor in fatal hemorrhage; vascular disease is common in patients with hypertension. The relatively high incidence of fatal hemorrhage in the colored as compared to the white race is probably correlated with the greater frequency of hypertension among negroes.

In our series, all 7 of the patients with erosion into the substance of the pancreas bled to death. We were not able to demonstrate the erosion of a large vessel such as the pancreaticoduodenal artery in any of these cases. It is probable that the action of digestive ferments on the walls of smaller blood vessels was largely responsible for these hemorrhages.

Our studies suggest that hypertension is an important factor in the causation of fatal hemorrhage from gastric and duodenal ulcers. We cannot be certain of the pathogenesis of the hemorrhage but it seems likely that injured vessels in the ulcer base may rupture more easily and bleed more profusely in the presence of an elevated, than in the presence of a normal blood pressure. The accepted explanation of spontaneous cerebral hemorrhage in patients with hypertension is based upon this same principle.

SUMMARY

1. Nineteen, 23.3 per cent, of 81 patients with gastric or duodenal ulcer died of hemorrhage as shown by postmortem examination.
2. Eleven, 57.8 per cent of these 19 patients had hypertension.
3. Four of these 19 patients had erosion of the pancreas without hypertension and 3 had both hypertension and pancreatic erosion.
4. Fifteen, 78.9 per cent of the 19 patients had either hypertension or erosion of the pancreas, or both.

SIGNIFICANCE OF CHANGES IN SUBDIVISIONS OF THE LUNG VOLUME IN THE TRENDELENBURG POSITION

MARK D. ALTSCHULE, M.D., and NORMAN ZAMCHECK, A.B.,
Boston, Massachusetts

COMPARISONS of the volumes of the various subdivisions of the total lung volume in patients in the sitting and in the recumbent position have been made by several authors (1, 3, 7, 9, 11, 14), their findings have been analyzed by McMichael and McGibbon. No data are available, however, on the changes which occur when the patient assumes the Trendelenburg position. Since this position is employed routinely in certain surgical operations and with great frequency in the treatment of shock and peripheral vascular disease, it appeared desirable to study the effect of the head-down position on pulmonary volume and dynamics.

Studies were made 1 to 3 hours after the last meal on 6 normal subjects, 3 male (subjects 1, 2, 3) and 3 female (subjects 4, 5, 6), aged 20 to 35 years. A tilting table was used in these experiments. All the measurements were made 15 to 20 minutes after a given position was assumed. Measurements of the subdivisions of the pulmonary volume were first made with the subject flat, after which the table was tilted so that the subject's body, with head down, made an angle of 22.5 degrees with the horizontal. Following this, studies were made with the subject in the head-up position at an angle of 25 degrees with the horizontal. Two to 8 measurements were made in each position. Estimations of tidal air, respiratory minute volume, and oxygen consumption were also made. The method of Christie (4), slightly modified as described previously (10), was used in these studies.

RESULTS OF STUDY

The *functional residual air* was uniformly smallest with subject in the head-down position, intermediate with subject in the flat position, and largest with subject in the head-

From the Medical Service and the Medical Research Laboratories of the Beth Israel Hospital and the Department of Medicine Harvard Medical School, Boston, Massachusetts.

up position. The functional residual air ranged between 280 and 500 cubic centimeters, or between 9.5 and 23.8 per cent less with subject in the head-down position than in the flat position, the average difference was 363 cubic centimeters, or 17.2 per cent.

The *reserve air*, one of the two components of the functional residual air, was uniformly smallest with patient in the head-down, intermediate in the flat, and largest in the head-up positions. The reserve air with subject in the head-down position varied from 185 to 360 cubic centimeters, or from 19.4 to 51.9 per cent less than that in flat position, average difference, 253 cubic centimeters, 39.8 per cent.

The variation in the volume of the other component of the functional residual air, the *residual air*, with subjects in the three positions was no greater than the variation in successive measurements made with patient in any one position. The residual air in patients in the head-down position ranged between 20 and 165 cubic centimeters, or between 1.0 and 14.6 per cent less than that in the flat position, the average difference was 100 cubic centimeters, or 7.3 per cent.

The *complemental air* in 5 instances was greater with subjects in the head-down than in the flat position, in the sixth subject this relationship was reversed, but the difference between the two values was only 35 cubic centimeters. The complemental air was uniformly lowest with subject in the head-up position. The values in the head-down position were between 35 cubic centimeters less and 200 cubic centimeters greater than the values in the flat position, or minus 1.2 to plus 5.7 per cent of the latter value, average difference, 93 cubic centimeters, 2.9 per cent.

The *vital capacity* was uniformly smaller with patients in the head-down position than in the head-up position. However, it was intermediate in only 4 of the 6 subjects in the

flat position, being identical in the 2 others with the vital capacity in the head-down or the head-up position. The vital capacity in the head-down position was from 0 to 395 cubic centimeters, or from 0 to 10.3 per cent less than the vital capacity in the flat position the average difference was 164 cubic centimeters, or 4.6 per cent. The greatest difference between the head up and the head down positions was observed in the subject in whom the complemental air was not increased in the head-down position. The tidal air respiratory rate respiratory minute volume and oxygen consumption showed no consistent changes in the various positions studied.

EVALUATION OF STUDY

The changes in the various subdivisions of the pulmonary volume in the Trendelenburg position are due entirely to variations in the volume of the reserve and complemental air, since the residual air is essentially unchanged. Other authors have observed a decrease in the reserve air and an increase in the complemental air in the recumbent as compared

to the sitting position (1, 9, 11, 14). McMichael and McGibbon have demonstrated that these changes are due to the cephalad shift of the diaphragm which occurs in recumbency. It appears therefore that the further decrease in reserve and increase in complemental air in the Trendelenburg position result from a more marked cephalad diaphragmatic shift. This is apparently due to the pressure of the abdominal viscera on the diaphragm.

The complemental air increases less than the reserve air decreases in changing from the head-up to the flat and then to the head-down position. Accordingly the vital capacity and total pulmonary volume decrease slightly. This has been ascribed to an increase in the amount of blood in the lungs (11) but the evidence in this regard is not conclusive. Certainly these changes are too small to be considered significant. It is to be noted that insignificant decreases in vital and total capacities fail to reveal the important changes in pulmonary dynamics which result from the head-down position. These are revealed only by consideration of the variations in the func-

Fig 1 Changes in the lung volume and its subdivisions in various positions

tional residual air Changes in functional residual air are significant because they may be correlated with changes in the intrapleural pressure Christie and McIntosh (5) observed a decrease in the volume of the functional residual air of 230 to 440 cubic centimeters accompanied by a decrease in the negativity of the intrapleural pressure of 2.0 to 3.2 centimeters of water in the flat, as compared to the sitting position In the present study a further diminution in the volume of the functional residual air of almost the same magnitude occurred in patients in the head-down, as compared to the flat, position, presumably this change was accompanied by a still further decrease in the negativity of the intrapleural pressure of 2.0 to 3.0 centimeters of water Decrease in the volume of the functional residual air indicates a state of partial collapse of the lungs, with a reduction in respiratory space averaging approximately 20 per cent, this interferes with the aeration of blood flowing through the lungs A further impediment to respiration in patients in the head-down position is related to the necessity for moving the weight of the abdominal viscera upward during inspiration Judging by the

sensations experienced by the subjects of the present study in the head-down position, the interference with respiration is not important in normal individuals However, in the case of patients in shock or under the influence of depressing sedatives, it might be appreciable Shallow respiration and cyanosis are frequently noted in patients in whom paralysis of the lower intercostal muscles has occurred as a result of spinal anesthesia and it is not unlikely that this respiratory embarrassment is due in part at least to the changes in the lungs resulting from the Trendelenburg position frequently used in patients receiving this type of anesthesia It has been noted by anesthetists that patients operated upon in an extreme Trendelenburg position may breathe inadequately and become cyanotic, this is relieved by restoring the position of the patient to, or toward, the horizontal

Diminution in the negativity of the intrapleural pressure interferes with the return of blood to the heart and should give rise to an increase in peripheral but not in intrathoracic venous pressure Significant increases in antecubital venous pressure have been described in the head-down position by Henderson and

Haggard, Asmussen et al and Schott and Spatz. If this elevation of venous pressure were present also in the great veins within the thorax, an increase in cardiac output should occur in patients in the head-down position. However Asmussen et al found no change in the cardiac output in patients in the head down position, and Donal et al reported a decrease of 23 per cent in subjects in this position. The finding of a marked decrease in pulse rate (2.8) beginning immediately on the subject assuming the head-down position, further suggests that a fall in venous return occurs. It is doubtful whether the slightly decreased venous return in subjects in the Trendelenburg position exerts any deleterious effect in normal man in patients in shock, however when the venous return is already diminished it would appear that further interference with the return of blood to the heart resulting from the Trendelenburg position may be definitely harmful.

It has been assumed that the Trendelenburg position causes the drainage of significant amounts of blood from the lower part of the body and also favorably influences circulation through the brain. Data bearing on the former were reported by Asmussen et al. who showed that only 100 cubic centimeters of blood are drained from the legs after the head-down position at an angle of 22.5 degrees is assumed. Similarly it is unlikely that the circulation through the brain is increased in subjects in the head-down position, since the cerebrospinal fluid pressure within the cranium is increased, and it has been shown in animals that this results in a brief slowing of the circulation followed by a return to normal (15).

It appears therefore that the Trendelenburg position obtains no advantages for the circulation of the brain over the flat position and may well be less favorable so far as respiration and circulation are concerned. In patients in shock or under the influence of sedatives or spinal anesthesia, it may be harmful.

SUMMARY AND CONCLUSIONS

1. Measurements of the subdivisions of the total lung volume and of the pulmonary dy-

namics were made in 6 normal subjects in the Trendelenburg, flat and head-up positions.

2. The residual air was unchanged in the various positions studied, and the vital and total capacities varied only slightly. The vital and total capacities were lowest in the Trendelenburg. Intermediate in the flat, and greatest in the head-up positions.

3. Striking changes in reserve and complementary air volumes occurred. The reserve air was lowest in Trendelenburg and greatest in head-up positions; the complementary air varied inversely with reserve air. These changes were interpreted as due to a cephalad shift of diaphragm in patients in head-down position.

4. The changes in the functional residual air are significant in that they afford information on changes in the intrapleural pressure. Decrease of the functional residual air in the Trendelenburg position suggests that changes in intrapleural pressure occur in this position which tend to make respiration more difficult and impair return of venous blood to heart.

5. No consistent changes in respiratory dynamics were observed in the various positions studied.

STONE IN THE URETER

Clinical Data Based on 500 Cases

HERMAN L. KRETSCHMER, M.D., F.A.C.S., Chicago, Illinois

THIS paper is based on a study of 500 unselected patients with stone in the ureter, covering a period from 1917 to 1941. The 500 unselected cases do not represent all the patients seen, but I believe the number is large enough for purposes of study, since, being unselected, they are fairly representative of the cases seen in the average urologic practice.

Sex. The question of sex is of little aid in the diagnosis. It is the general consensus that this condition occurs much more frequently in men than in women, and my experience is in keeping with this general point of view, since of the 500 patients studied 400 were males and only 100 were females.

Age. It is a well known fact that stone in the ureter is rare at the extremes of life. The youngest patient in this series was 2 years old and the oldest, 80. Stone occurred with the greatest frequency in the third, fourth, and fifth decades. This is in keeping with experiences in general. The age incidence in our group was as follows: 2 patients in the first decade of life, 9 in the second, 74 in the third, 131 in the fourth, 137 in the fifth, 82 in the sixth, 32 in the seventh, 9 in the eighth, 1 in the ninth, and 23 patients whose ages were not stated.

Location. So far as being an aid in the diagnosis, the question of whether stone occurs more frequently on the right or left side is of little moment, except when the stone occurs on the right side it is frequently confused with appendicitis. There was not much variation in the two sides in my series, as the stone was located on the right side in 229, or 45.8 per cent of my patients, on the left side in 259, 51.8 per cent, and on both sides in 12, or 2.4 per cent of my patients.

THE STONE

Number of stones. In the largest number of instances the symptoms are due to the presence of a single stone. In this series, 447, or 89.4 per cent, of the patients had a single stone, and only 53, or 10.6 per cent, had multiple stones. Nevertheless, the question as to whether the patient is suffering from multiple stones is of importance as regards prognosis and management, and will be considered under treatment. I always make it a point to call the patient's attention to the fact that multiple stones are present. Unless this is done, the patient may be less vigilant as regards a search for the passage of the second stone.

Multiple stones may vary greatly in number from 2 to 100 or more. In one instance, a patient, who was a physician, passed 28 stones after a very severe attack of colic. In another instance the ureter harbored stones from the vesical end to the fourth lumbar vertebra (Fig. 1). Multiple stones, in one patient, were left behind after a nephrectomy which was performed elsewhere. Because of grave symptoms it was necessary to perform a ureterectomy (Fig. 2).

Size. Fortunately, most stones in the ureter are small. They may vary in size from a grain of wheat to a stone of enormous size and weight (5). The size has a direct bearing on prognosis and treatment (Fig. 3). This will be discussed under these headings.

Chemical composition of stones.¹ The results of chemical examinations of stones are available in 102 patients. This number is deemed sufficient to serve as a cross index of the chemical composition of the stones in this series. One is impressed by the fact that in only 9 cases, only 1 element was present. Analyses in the 102 cases are given in Tables I and II.

Read before the Western Surgical Association, St. Paul, Minnesota, December 6, 1941.

¹The chemical analyses were made by Dr. M. R. Freeland, chemist to the Presbyterian Hospital.

SYMPTOMS AND SIGNS

Pain. Pain may be either the first symptom or it may occur during the course of the disease. Pain was the first symptom for which relief was sought in 440 cases or 88.0 per cent. But the onset of the illness is not always

ushered in with pain since a number of patients have other initiating symptoms. For instance when a stone becomes engaged in the intramural part of the ureter or when it forms in a cystic dilatation of the ureter the onset of symptoms may be vesical in character (Fig. 4). Besides the presence of initiating pain pain occurring at some time during the illness was recorded in 468 patients, or 93.6 per cent.

The character of the pain is generally typical for stone, although there are exceptions. But not always does the pain radiate downward along the course of the ureter to the internal or external genitalia nor upward into the renal area.

The severity of the pain deserves careful analysis. The question which should arise is: Was the attack relieved by simple measures or was it necessary to resort to a hypodermic of morphine? A sudden onset of severe abdominal pain requiring morphine for relief should at once suggest either urinary or biliary stone colic. Not to weaken this statement thought should be given to the fact that the tabetic may have equal severe pain.

Hematuria. Hematuria may be the first and only symptom of which the patient complains. Furthermore, it should be remembered that stone is one of the five common causes for blood in the urine. In practically all the patients in this series the hematuria was followed by pain. But not infrequently hematuria and pain occur simultaneously. Hematuria was present in 81 patients or 34.2 per cent at some time during the illness and it was present in 23 patients, or 4.6 per cent as the first symptom noted by the patient. Every patient routinely is specifically asked whether he or she has ever noticed blood in the urine.

Nausea and vomiting. Reflex nausea and vomiting occur with renal and ureteral stone colic. Some of the patients in this series complained of nausea alone but, on the other hand, both nausea and vomiting occurred in 231 patients, or 46.2 per cent.

Previous passage of stones. The history of a previous passage of stones is most important and one must never fail to ask the patient the specific question as to whether sand, gravel, or stone has been previously passed. Naturally, if a patient gives a history of having passed stones on one or more occasions, the odds are in favor of passing stones again; hence the benefit of watchful waiting should be the order of the day before cystoscopic manipulation or advancing operation. Because of the importance in prognosis as well as in outlining treatment, I make it a rule to ask this specific question of each patient. Seventy-one patients, 14.2 per cent in this series, gave a history of having passed stones previously; therefore, observation and study were of prime importance before instituting treatment.

Other symptoms Backache, so common in lesions of the urinary organs, was present in 186 patients, or 37.2 per cent. Frequency of urination was present in 42 per cent, and burning in 30.4 per cent. One hundred eighty patients, or 36 per cent, stated that pus had been previously found in the urine either by physicians or by laboratory bureaus, to which they were subscribers, advising that they should consult their family physicians. This is a relatively high percentage, and a significant one as far as the patient is concerned. Chills and fever were present in 88 patients, or 17.6 per cent.

In Table III are recorded the symptoms which occurred most frequently

TABLE III

	No. patients	Per cent
Pain	468	93.6
Hematuria	171	34.2

Pyuria	180	36
Backache	186	37.2
Burning	152	30.4
Chills and fever	88	17.6
Passage of stones	71	14.2

THE EXAMINATION

Urinalysis Next in importance to the history and physical examination is the urinalysis. If we bear in mind the ease with which this examination can be carried out and the invaluable information it gives, one cannot help but stress its importance, especially when coupled with the history. As previously stated, many patients were seen because of the fact that pathological elements were found in the urine. It should be emphasized here that one negative report is not indicative that pathology is nonexistent. The number of positive findings were truly amazing, since a study of the patients in this series revealed that the findings were positive in 393 patients and negative in only 78. In 29 patients no data were available. In other words, the findings were positive in 83.43 per cent and negative in 15.56 per cent. In some of the patients of the group more than one pathological element was found.

The results of the urinary examination were as follows: albumin in 122 patients, or 24.4 per cent, sugar in 4 patients, or .8 per cent, red

blood cells in 215 patients, or 43 per cent, white blood cells in 346 patients, or 69.2 per cent, casts in 38 patients, or 7.6 per cent.

In a case of suspected stone one should never be satisfied with the results of a single examination, especially if it is negative, which occurs not at all infrequently when the stone produces a temporary block on the affected side, hence the importance of repeated examinations cannot be overemphasized. Examination of a number of specimens pertaining to the same patient may yield only negative results, when unexpectedly the next examination will show many fresh red blood cells, pus cells, or both.

Culture studies of the urine Cultures, unfortunately, were not obtained in each case due to the fact that some of the patients were seen before bacteriological studies of the urine were a matter of routine, a procedure now followed to the letter. However, cultures were made in 385 patients of which 133 were positive, an incidence of 34.54 per cent, and 252, or 65.43 per cent, were sterile.

Blood pressure studies In this study, blood pressure findings were normal except in patients in the older age group—a group at a time of life when an increase in blood pressure is not uncommon—and were not considered of special significance so far as the diagnosis or treatment was concerned.

Roentgen-ray observations With the results of a careful history and physical examination coupled with the urinary findings, strong, presumptive evidence of stone is at hand. The next logical procedure is the roentgen-ray examination which begins with a plain film, or set of films, that includes the entire urinary tract. The two essentials are films of good quality and the correct interpretation of the shadows shown.

Of these two essentials, quality of the films at the present time is above reproach. But, on the other hand, correct reading and proper interpretation are most important. I am sure that everyone has had the experience of receiving a negative report only to have the patient pass a stone a few days later, which, in the light of events, leads to a review of the films with the result that a previously overlooked shadow is seen that corresponds in shape and

Fig. 5, left: Showing the shadow in apparent contact with the shadowgraph catheter after the shift in the x-ray tube. (See Fig. 6)

Fig. 6. Retrograde pyelogram showing the shadow outside the ureter

size to the stone brought in by the patient and is absent in subsequent films. The importance of careful film reading cannot be overemphasized.

In some of the patients in whom the roentgenogram failed to demonstrate the stone shadow the cystoscopic examination disclosed the stone in or protruding from the ureteral orifice. In others the orifice was edematous and swollen clearly indicating a pathological

condition. In others still the mucosa was red due to the presence of blood which, in turn, was the result of trauma inflicted by the stone in its passage.

Peterson and Holmes, in a study of 100 roentgen reports of patients suspected of having ureteral stones found that 21 films gave no indication of any shadows which might be interpreted as calculi. These films were then carefully restudied abetted by the clinical data in each case and shadows, which as questionably represented the calculi, were seen in 1 of the 21 cases.

A study of the roentgen findings in this series disclosed that positive reports for stone were recorded in 455 patients, while the reports were negative in only 20 patients. Twenty-three passed their stones before or during the time they were under my observation and in 2 patients the roentgen reports were missing. A review of these cases therefore reveals positive roentgen reports in 95.79 per cent and negative reports in 4.21 per cent.

The presence of a shadow along the course of the ureter warrants further investigation to determine whether one is dealing with a stone or with an extraureteral shadow (Figs. 5-6). This can be done by the use of a shadowgraph catheter with a double exposure film and shift in the tube a procedure previously described (6).

In the case of very stout patients the films may not be clear and the shadow under study may be lost. Because of this possibility it is advantageous to use two films, a point which

Fig. 7. Showing the presence of shadow in the region of the right kidney. Such are confused with calculi. They were due to enteric coated pills of ammonium chloride.

was recently mentioned by Peterson and Holmes

Possible sources of error in this procedure (shadowgraph catheter) are the presence of a stone in a diverticulum of the ureter or a stone in a double ureter, only one of which has been catheterized

Confusion with extraureteral shadow-producing bodies has been discussed so often that I shall refrain from doing so here. I wish only to call attention to a new factor that may lead to confusion in diagnosis—namely, the presence of shadows produced by enteric coated pills. I know of one instance in which a patient was recently operated on for stone, when the shadow was actually due to an enteric coated pill. Because of the prevalent use of these pills, this possibility must always be borne in mind. To substantiate the truth of this statement, only recently a patient was sent in with the diagnosis of multiple kidney stones, the shadows having been caused by enteric coated pills (Fig 7)

Intravenous urography. The intravenous urogram is of much aid. In the largest number of instances it reveals dilatation of the ureter and of the kidney pelvis. Stone in the ureter is probably the most frequent cause of hydronephrosis. Although dilatation (except when the stones are very small) is the rule, I have seen a number of patients in whom the urograms disclosed no dilatation, despite the fact that the stones were far from small. The urogram not infrequently reveals the ureter down to the bladder or the outline may stop at the site of the stone, disclosing a complete block. This should cause no undue alarm, since the block, as the stone changes its position, is relieved.

In some instances the urogram fails to visualize the outline of the pelvis and ureter. When this occurs an increased density of the kidney outline is shown, therefore the kidney is more definitely outlined than its mate on the opposite side. The density is probably due to a temporary inhibition of function. I have seen this in several patients who were advised to have an immediate operation in one instance a nephrectomy. Subsequent study after the passage of the stone disclosed a complete return of function. Likewise in patients

Fig 8 Retrograde movement of ureteral calculus

studied after stones were passed, the dilatation of the ureter and kidney pelvis disappeared except of course in those patients in whom some other pathological condition was present.

Retrograde movement of stone. In a previous publication (7) I called attention to the possibility of retrograde movement, which was not generally recognized at that time, and reviewed the cases in the literature. Because of this possibility a roentgenogram should be made on each patient just before operation, thereby avoiding the embarrassment of operating only to find that the stone had wandered up the ureter or into the kidney pelvis (Fig 8). This phenomenon occurs in children (8) as well as in adults and more frequently than is generally appreciated. Retrograde movement of the stone occurred in 10 patients in the present series.

A review of these 500 case histories reveals that 442 are available for study. The 58 remaining cannot be used because some of the patients were seen but once, others refused to follow advice, some discontinued treatment and others still could not be located to determine the ultimate result of treatment. The results are recorded as follows: stones passed without instrumentation in 128 patients or 28.9 percent; stones passed with instrumentation in 106 patients or 23.9 percent; stones removed by operation in 112 patients or 25.3 percent; still under observation and treat-

Fig. Bilateral multiple ureteral calculi. They are passed spontaneously

ment in 4 patients, or 9 per cent (3 patients are under observation because the stone had wandered back into the kidney but caused no symptoms 2 patients are under treatment)

TREATMENT

The treatment of stone in the ureter naturally falls into three groups: watchful waiting, instrumental manipulation, operative treatment.

Watchful waiting. It is to be borne in mind that many of these patients pass their stones without the use of instruments by the simple expedient of drinking large quantities of fluids, with or without the administration of diuretic drugs.

A careful history will reveal the fact that a significant number of these patients have previously passed stones, sometimes an indeterminate number of years ago and not seldom more or less recently. This has been the case in this series since the records show 14.3 per cent under the head of patients who have passed stones before coming under observation. It goes without saying that instrumentation in these patients is to put it mildly superfluous.

The statement of a patient that attacks of renal colic were followed by the passage of stones, should not go unheeded, and justifies a period of "watchful waiting." To subject a patient to cystoscopic manipulation just because of an attack of renal colic, unless immediate relief of obstruction is indicated, is not only unnecessary but condemnatory. Because a stone does not move a certain amount each day does not, in my opinion, justify manipulation. I have seen patients in whom no movement of a stone occurred for weeks or

months without any untoward symptoms, to be followed by the passing of the stone without medical aid just when my advice was forthcoming that an operation was necessary (Fig. 9).

In this series there were 128 patients or 28.9 per cent, who passed stones without manipulation of any sort.

Instrumental manipulation. It might be well to emphasize the fact that manipulation of a stone with instruments is not entirely free from danger and this phase has recently received attention in the literature (Wesson, Stevens, Lynch and Thompson, Woodruff, Henline, and others). Rusche and Bacon have emphasized the fact that the incidence of ureteral injuries has increased since the advent of a multiplicity of instruments designed to aid the passage of or to extract the ureteral stone. They report a series of 16 patients who suffered from injury to the ureter due to cystoscopic intraureteral instrumentation. Interestingly, too, is the fact that in the discussion of papers dealing with the danger of injury, individual experiences are related by the discussants, which lead one to the inevitable conclusion that injury is far more frequent than one suspects.

I should like to state here that in this series there is no record of injury to the ureter in a single patient.

That injuries may occur from the use of the various types of stone extractors seems reasonable enough when we consider that their use depends mostly upon force and less upon dilatation. The stone if left to its own machinations dilates the ureter in its progress downward, a similar process being found in the realm of obstetrics. It seems to me that dilatation as a factor is most important and, while it is not without triumph to remove the stone at the first treatment, nevertheless it is advisable to exercise a considerable degree of caution when this type of procedure is undertaken.

Apprehensive of the danger of injury I made it a point to rely on simple dilatation and to use a sterile oil in practically all the patients in this series. Some of the various "stone extractors" were used in a few patients mindful always of the possible injury to the

ureter, a possibility fraught with danger that has militated against their use. While the dilatation and injection of oil is slower and requires more manipulations than the extractive methods, in my opinion the former procedure is decidedly less dangerous to the patient.

The patient, as well as the physician, it should be stated here, is desirous of a cure to be effected as soon as possible, and this brings up the question of how frequently manipulation should be resorted to. There is danger in manipulations that are too frequently repeated. The possible trauma produced by one treatment should be completely healed before the next manipulation is carried out. That ureteral catheterization may cause traumatism is evidenced by the fact that in simple cases, bloody urine occasionally occurs, or a small clot may be seen hanging from the ureteral orifice at a subsequent cystoscopic examination. These patients should not be subjected to manipulation again until the effects of trauma resulting from the previous instrumentation are no longer evident. If one adds to this picture the additional trauma produced by impacted stones, plus local inflammatory changes in the ureter around the stone, the danger of injury is not a remote possibility. It is for these reasons that I have always taken the position that manipulations should not be carried out too frequently and that they should be effected with a minimum of force so as to prevent trauma.

The treatment of stone by manipulation deserves careful consideration in each case. Not seldom, but, I regret to state, too often, the advice given is embarrassing, to say the least, since many of us have had the experience of treating a relatively large stone by manipulation without beneficial results, and then urging the patient to be operated on, advancing all the arguments in favor of an operation and stating the reasons why further use of instruments would be of no avail, only to have the patient pass the stone without further local treatment. The use of instrumentation for a small stone is, in my opinion, never justified, if the stone progresses down the ureter with each attack of pain, and especially if the patient, as mentioned, has previously passed stones.

Fig. 10. Small calculus in the pelvic ureter which led to complete hydronephrotic atrophy of the kidney.

In case a patient is suffering from pain and the roentgenogram discloses a stone in the pelvic ureter, I am firmly convinced that cystoscopic examination and manipulation should not be resorted to immediately. The fact that the stone has progressed so far downward is one point in its favor for passage without instrumentation.

In this series of patients 44.3 per cent passed the stone after manipulation.

Operative treatment. As may be seen by a perusal of the literature, during the past 25 years there has been a definite trend away from open operation in favor of cystoscopic manipulation. Among some of the recent publications reporting the successful removal of stone by cystoscopic manipulation may be mentioned Alyea, 82 per cent, Fowler and Champion, 76 per cent (patients having been treated in the office), Grant, 45 per cent, Mathe, 78.3 per cent, and Thompson and Kibler, 91.3 per cent.

On the other hand, some authors report a large number of open operations Higgins, 65 per cent Rockstra 47.7 per cent

The percentages will naturally vary according to one's personal point of view and also the condition of the patient and the underlying pathology will play no small part in affecting their rise or fall

1 *Large stones* In patients with a very large stone it is perfectly obvious that manipulation is useless and that ureterolithotomy should be done at once

2 *Multiple stones* In case the patient has only 2 or 3 stones without complications one might wait or try manipulation before resorting to open operation However when complications are present operation is probably the best procedure although I have seen patients with multiple stones pass them spontaneously (Fig 9)

3 *Location* A relatively large stone high in the ureter had best be operated on whereas, if it has descended into the pelvic ureter operation may be deferred awaiting developments

4 *Duration of symptoms* If the onset of the symptoms is recent one may wait, but if there have been recurrences without signs of remission, operation is clearly indicated

5 *Reaction to instrumentation* In case severe reactions such as pain, chills, fever, hematuria, etc. occur following each instrumentation, the patient should be operated on To persist with manipulations under such circumstances is poor surgical judgment

6 *Repeated attacks of hematuria* Operation is the only procedure in case of severe attacks of hematuria, either with or without colic, accompanied by a marked secondary anemia. On the other hand, when the patient has only an occasional loss of blood and a mild secondary anemia operation may be deferred to a later date

Associated infection Severe infection in the kidney clearly indicates operation. Chronic pyelonephritis persists in these patients because of poor renal drainage and should manipulation fail operative removal of the stone is in order Acute infection, unrelieved by ureteral catheter drainage necessitates operation at once

8 *Anuria* If the stone is large, this condition should be met with immediate removal If small ureteral catheter drainage should be the procedure In case catheter drainage does not give prompt relief operation must be performed at once

9 *Suppression of function above the stone* This does not call for immediate operation, since the opposite kidney is able to carry on. I recently saw a patient who had no secretion of dye above the stone for days. She subsequently passed the stone without manipulation and the gratifying result was a complete return of function

10 *Function of the kidney* When a complete hydronephrotic atrophy exists above the stone, operation should be performed (Fig 10) When a moderately advanced hydronephrosis is present the stone should be removed to prevent further progress of the hydronephrosis but this statement should not be construed as a demand for immediate surgical removal of a stone because of the concomitant hydronephrosis which is so commonly noted in such cases

11 *Age of patient* In the older group operation is naturally deferred unless some of the previously mentioned acute, complicating conditions are present which make operation imperative

As previously stated the number of operations performed in a reported series depends upon many factors as does the type of operation that is done

In this series 114 patients, or 35 per cent, had surgical procedures as listed in Table IV

TABLE IV

Procedure	No. patients	Per cent
Ureterolithotomy	74	64.9
Pyelotomy		10.5
Suprapubic cystostomy		9.6
Nephrectomy	9	7.8
Nephroureterectomy	3	2.6
Heminephrectomy and ureterectomy		7
Resection of kidney		6
Type of operation not stated (performed elsewhere)	—	7
Total	4	90

SUMMARY

1 A series of 500 unselected patients with stone in the ureter is reported.

2 Roentgen-ray findings were positive in 95.79 per cent

3 Attention is called to the danger of certain types of manipulation

4 The advantages of the use of the ureteral catheter for dilatation and the injection of oil are considered

5 The study discloses that 128 patients passed their stones without treatment, 106, with manipulation, and 114 were operated on

6 Dangers of too frequent manipulation are stressed

7 Policy of "watchful waiting" in the average case is still desirable

THE PHENOMENON OF ASPHYXIAL RESUSCITATION

I Resuscitation with Inert (Asphyxiating) Gas in Advanced Asphyxia

SAMUEL A. THOMPSON M.D. F.A.C.S. and GEORGE I. BIRNBAUM M.D. F.A.C.S.
New York, New York

RESUSCITATION in asphyxia is of considerable and mutual interest to physiology and medicine. From the practical standpoint the problem is important in the operating room—cessation of respiration and of circulation or both—in industrial surgery—electric shock, cave-in gases and fumes—in civilian life—carbon monoxide asphyxia, drowning—and military surgery—crushing injuries, air raid casualties, war gas poisoning thoracic trauma.

Yet much controversy still exists on methods of resuscitation. For this reason we have carried out an experimental investigation in an attempt to clarify this important problem. During this work we observed a phenomenon (3) to our knowledge hitherto not described, which bears directly on the practical aspects of resuscitation. We wish now to elaborate on this phenomenon. Its mechanism is the subject of a paper to follow. Briefly, the phenomenon of asphyxial resuscitation consists in the ability quite regularly to restore the circulation and respiration in advanced asphyxia, *without benefit of oxygen* through the use of rhythmic inflation of the lung with an inert gas alternating with rhythmic suction. That is to say in the third stage of asphyxia—cessation of respiration and rapidly falling blood pressure—resuscitation of the heart and respiration can be produced by rhythmic alternating inflation and suction with an inert gas—nitrogen helium—which has just been previously used to produce the asphyxia. Resuscitation with neutral gas by the inflation and suction method is also possible after obstructive asphyxia (Table I Figs 1 2 3 and 4)

Asphyxia has been divided into four stages (1) initial apnea, dyspnea, cessation of respiration or terminal apnea, and arrest of the heart. Although it is convenient to consider the total duration of acute asphyxia is approximately 4 minutes, with each stage occupying about a minute, the duration of each stage and the total time may vary. The stages can be summarized as follows

1st stage initial apnea The breath is held and the blood pressure rises.

2nd stage dyspnea Breathing is labored. The blood pressure continues to rise. At the end of this period consciousness disappears. Tonic and clonic convulsions occur.

3rd stage terminal apnea The respiration ceases. Reflexes and muscle tonus disappear. The animal is relaxed and limp. The blood pressure falls progressively toward the end of the stage the character of the pulse changes the heart beat is irregular and the blood pressure rapidly approaches zero. The sphincters are relaxed and the corneal and glottis reflexes are absent.

4th stage arrest of the heart

It should be kept in mind that due to the fact that anesthesia was given and asphyxia produced in some cases by inhalation of inert

Fig 1 The phenomenon of asphyxial resuscitation *A*, Control tracing, *B*, nitrogen inhalation asphyxia, by way of leakproof intratracheal tube, begun, *C*, respiration has ceased, *D*, resuscitator—suck and blow, plus 14 millimeters

of mercury, minus 9 millimeters of mercury with nitrogen started, *E*, blood pressure is rising rapidly and spontaneous breaths occur. Resuscitator is discontinued and tracheal tube is opened to the atmosphere

gases, the stage of initial apnea may not be very evident or may even be absent

It is pertinent to consider the question of spontaneous resuscitation in asphyxia and at what point after the asphyxial procedure is stopped spontaneous recovery is still possible. Coryllos considered that if submersion is interrupted before the middle of the third stage, spontaneous resuscitation is always possible, he considered that in obstructive asphyxia "Removal of the obstructing agent before the

end of the third phase is followed as rule by immediate spontaneous resuscitation"

Since he considered his stages to occupy about a minute, this would place the critical point for spontaneous recovery under 30 seconds from the time respiration ceased in the case of submersion asphyxia and under 45 seconds from the cessation of respiration in the case of obstruction asphyxia. Lougheed, Janes and Hall, in a study on asphyxia by drowning and tracheal obstruction, have found that

Fig 2 Asphyxial resuscitation by rhythmic pressure and suction on the lungs after failure of rhythmic inflation alone. The animal has been asphyxiated by mechanical obstruction of a specially fitted face mask, 1, Respiration has just ceased, 2, rhythmic inflation of the lung (14 millimeters of mercury) is begun. Since an amply large pharyngeal airway is in place, failure of the intratracheal pressure

to return to the base line may indicate a lack of tonus or adequate elastic recoil of the chest on release of the inflating pressure. 3, Rhythmic inflation has failed to sustain the blood pressure or to initiate spontaneous respiration and the positive negative resuscitator with nitrogen is there fore applied, 4, resuscitator discontinued, 5, spontaneous respiration begins

Fig. 3. *A*, control; *B*, helium inhalation asphyxia by way of intratracheal tube, is started; *C*, respiration has ceased; *D* and *E*, Agonal asphyxial gasps; *F* to *G*, re-

suscitator with helium in action; *G*, tracheal tube opened to atmosphere; *H*, spontaneous respiration begins; *I*, sharp rise of the blood pressure occurs.

after cessation of respiration there is a critical point at which the heart beat ceases to be expellable. In general the period between the point at which respiration ceased and the point at which the asphyxial procedure was stopped could not exceed 18 seconds if spontaneous recovery were to take place. If this period was extended even a very few seconds longer resuscitation even with manual artificial respiration together with inhalation of oxygen-carbondioxide was impossible.

Asphyxial resuscitation with inert gas, however, is effective far beyond the point at which spontaneous recovery could take place by the cessation of the asphyxial procedure. Generally we have started asphyxial resuscitation well over 45 seconds after cessation of respiration at the variable critical point at which the heart action becomes markedly altered and irregular. The length of time which may elapse after respiration ceases before asphyxial resuscitation is successfully

Fig. 4. *A*, control; *B*, mechanical obstruction asphyxia begun by clamping intratracheal tube; *C*, respiration ceases; *D*, resuscitator with nitrogen begun; *E*, resuscitator dis-

connected but between *E* and *F* the lung is connected only with an atmosphere of nitrogen; *F*, spontaneous respiration begins and tracheal tube opened to the air.

Fig 5 The vagus nerves were exposed in the mid neck and surrounded for a distance of 1 centimeter with pledgets of cotton soaked with 2 per cent procaine, for a period of 20 minutes A, Control curves, B, mechanical obstruction asphyxia begun by clamping intratracheal tube, C, respiration ceases, D, obstruction released and resuscitator with nitrogen started, E, resuscitator discontinued and the

tracheal tube opened to an atmosphere of nitrogen only, F, a spontaneous respiration is taken, F to G, lung is still connected only to nitrogen Resuscitator with nitrogen started again at G and continued to H H to I, Lung connected only to nitrogen At I, a spontaneous respiration is taken and tracheal tube opened to atmosphere Vagal fibers probably partially anesthetized in this experiment.

instituted varies with different experiments, the longest interval was $2\frac{3}{4}$ minutes Lastly, although in a classical asphyxial resuscitation the resuscitator¹ is kept in action not only until the circulation has recovered but also until spontaneous respiration is taken, this is not always imperative Once the resuscitator has produced recovery of the circulation as indicated by a marked or progressively rising blood pressure, spontaneous respiration can follow after the resuscitation is discontinued (Figs 2, 3, and 4)

TECHNIQUE

Dogs weighing 8 to 12 kilograms were anesthetized by the intraperitoneal injection of veterinary nembutal, 1 cubic centimeter per 5 pounds The animal was then placed on its back In some experiments, a pharyngeal airway was inserted and a specially fitted metal face mask with inflation cuff on its rim was applied In others, there was inserted an intratracheal tube surrounded by an inflatable rubber cuff to make the trachea leak-proof Asphyxia was produced either by obstructing the face mask completely or clamping the intratracheal tube In other experiments

asphyxia was produced by inhalation of inert gases such as nitrogen or helium

Tracings on the kymograph were produced by recording mercury manometers which registered the blood pressure, respiration (intrapleural pressure), intratracheal pressure and resuscitator pressures Blood pressure was recorded from the cannulized femoral artery Intrapleural pressure or respiration was recorded by means of a fine brass intrapleural cannula

For mechanical resuscitation the Emerson resuscitator was used This apparatus inflates to 14 millimeters' mercury pressure and aspirates to minus 9 millimeters' mercury pressure, it was usually regulated to make 16-20 complete excursions or respiratory strokes per minute It was connected when needed to the face mask or intratracheal tube, as the case might be Where it was desired to use rhythmic pressure alone or rhythmic suction alone on the lungs, the desired pressures were regulated by under-water glass tubing Rhythmic pressure with a gas was given at plus 12 to 14 millimeters' mercury pressure with release to 0 millimeter mercury pressure—atmospheric pressure—of the gas Rhythmic suction on the lung was carried out at

¹Emerson model

minus 8 to 12 millimeters mercury pressure with release to 0 millimeter mercury pressure—atmospheric pressure—of the gas. Manual artificial respiration was done by bilateral manual compression of the chest by the four fingers and palms of the hands at the same time that the thumbs and thenar eminences compressed the abdomen over the epigastric region. It was carried out moderately vigorously, the lungs being in communication with an atmosphere of the particular gas in question.

Inhalation asphyxia by inert gas was carried out with an arrangement to prevent re-breathing carbon dioxide since this latter gas would make the problem more complex. We called this "blow-off" inhalation asphyxia and it was accomplished by leading the expired air through the expiratory tube of the inhalator under a 1 centimeter depth of water.

ANALYSIS OF STUDY

As a precaution against the possibility of spontaneous resuscitation it was seen that asphyxial resuscitation was carried out well past the points designated as critical for such recovery by Loughreed, Janes and Hall and Coryllos. Moreover our own control experiments have showed us that asphyxial resuscitation is possible far beyond the period at which spontaneous recovery is possible. What is more when the respiration has ceased in asphyxia, if the lungs are left in communication with 100 per cent inert gas, asphyxia will proceed to a fatal conclusion yet, the same inert gas administered by suck and blow to the lungs insures a high percentage of recovery. Such recovery is, therefore essentially inherent in the method itself for the application of other resuscitative procedures yields only a small percentage of success (Table I).

Asphyxial resuscitation with the same inert gas previously used to asphyxiate appears the more remarkable but it is also possible after mechanical obstruction asphyxia (Figs. 2, 4).

While the mechanism of the phenomenon will be discussed in a later paper it can be

surmised that the success or failure of the procedures used (Table I) bears a definite relation to the ventilatory excursion of the lung both above—inflation—and below—suction—the phase of passive expiration of the chest. In advanced asphyxia there is loss of muscle tonus and elastic spring of the chest. Manual artificial respiration is the least effective of all the procedures probably because it, more than the other procedures used, depends chiefly on the elastic spring of the chest for pulmonary ventilation. On the other hand positive—negative resuscitation, which gives the most effective ventilatory excursion independently of the state of tonus of the chest, also gives by far the greatest percentage of successful resuscitation with inert gas.

Perhaps most surprising of all is the fact that suck and blow resuscitation with inert—asphyxiating—gas is more effective than manual artificial respiration with oxygen inhalation. We do not mean to infer by these observations that inert gas should be used clinically. For clinical purposes the use of oxygen or oxygen-carbon dioxide is indicated as preferable.

SUMMARY

Advanced asphyxia was produced experimentally by tracheal obstruction or inhalation of inert gases—nitrogen helium. When, in such asphyxia the respiration has ceased it is possible to resuscitate with a suck and blow apparatus, inert gas being used. Such resuscitation is possible in a high percentage of cases and far beyond the period at which spontaneous recovery could occur by discontinuing the asphyxial procedure. With other methods of resuscitation—manual artificial respiration rhythmic inflation rhythmic suction—recovery of the circulation and respiration is the exception rather than the rule.

In this phenomenon of asphyxial resuscitation the heart and circulation recover first, the respiration later. Typically applied in experimental asphyxia the positive-negative resuscitator with inert gas, is kept in action until the blood pressure has definitely recovered and spontaneous respiration is taken when the lungs are let in communication with

¹As the paper is to follow blood oxygen levels simply verify the outcome experimental asphyxia produced.

THE SIGNIFICANCE OF THE GALACTOSE TOLERANCE TEST IN HYPERTHYROIDISM

MARVIN C SMITH, M D, WILLIS JONDAHL, M D, and ALTON OCHSNER, M D, F A C S,
New Orleans, Louisiana

THE galactose tolerance test has been used by a few investigators to confirm the diagnosis of hyperthyroidism. Our interest was directed toward the correlation of this test with the clinical and pathological diagnosis of hyperthyroidism and the basic metabolic rate.

Althausen and his co-workers (1, 3) and MacLagan and Rundle (8) found the results of this test very much in accord with both the clinical and pathological diagnosis. Althausen, on the basis of animal experiments and clinical investigation with galactose tolerance tests, states that the principal factor in high galactose readings in hyperthyroidism is due to increased intestinal absorption resulting from stimulation of the intestinal mucosa by thyroxin. The investigations of MacLagan (7) and Lichtman lead them to believe that hepatic dysfunction is the basis for abnormal tolerance. From our observations certainly the latter is true, for positive findings occurred in patients with known liver damage and without hyperthyroidism. The hypothesis of Althausen is also true to some extent as verified by a few of our findings, namely that in 4 cases of myxedema the galactose tolerance was below normal in all, and in 6 out of 18 cases with hyperthyroidism there was some galactose in the blood between the 5 and 15

minute intervals after the administration of galactose.

That increased intestinal absorption is not the underlying factor is stated by Lichtman inasmuch as 54 per cent of his patients with thyrotoxicosis gave normal galactose curves. His test consists in the oral administration of galactose and the analysis of the urine for the presence of this sugar. In response to this technique MacLagan and Rundle agree that in patients with known liver damage this analysis gives many negative results. Lichtman's theory for the liver being the sole factor in elevated galactose readings is that the glycogen and the carbohydrate reserves, and to some extent the protein reserve of the liver, are exhausted. The hepatic cells are then left without protection and are vulnerable to various toxins, intermediate products of metabolism, and thyroxin.

In a discussion of the various tests of hepatic function, Snell and Plunkett believe that the galactose tolerance test, because of its simplicity and the relatively satisfactory results, is an exceptionally good test in determining liver functions. There are, however, good reports in the literature concerning the use of the hippuric acid test in hyperthyroidism (4, 5, 10). Mann is of the opinion that inasmuch as the utilization of galactose appears to depend mainly on the liver, it should be possible to indicate hepatic injury by the tolerance test. But others (11) have stated that the galactose tolerance test is of

From the Department of Surgery, School of Medicine, Tulane University, New Orleans, Louisiana.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

little value in determining hepatic damage. We agree with Haines and associates that the test is not of great value in the management of hyperthyroidism, since it interprets liver damage in terms of liver function.

The galactose tolerance test is based on the fact that galactose is removed from the blood stream chiefly by the liver and is presumably converted into glycogen (Mann). Galactose is used in preference to glucose because it is much more readily and easily determined in the blood.

The technique of this test, as used by us, consists in the oral administration of 40 grams of galactose dissolved in water to a patient who has fasted for 12 hours. Specimens of venous blood are obtained before the administration of the sugar and 30 and 60 minutes afterward. In most of our cases the 150 minute specimens were also taken but infrequently the 5 and 15 minute specimens. The glucose fraction is removed by fermentation after the method of Folin Wu and the remaining filtrate is titrated as glucose. This quantity in the fasting specimen is then subtracted from the corresponding figure in subsequent specimens. Inasmuch as the galactose has a lower reducing power than glucose 24 per cent must be added to the readings of the nonfasting specimens.

Our series was composed of 98 consecutive cases manifesting some or many of the symptoms of thyrotoxicosis. These patients had been admitted to the Hutchinson Memorial Clinic of Tulane University Medical School the Tulane Surgical Divisions of Charity Hospital, and Touro Infirmary. After completion of the clinical and laboratory studies, 75 of these patients were advised to undergo a thyroidectomy. Eleven of these patients have not been operated upon as yet and as long as the diagnosis has not been established by pathological examination these cases are not included except to mention that all had elevated galactose readings and all but 3 had elevated basal readings.

The average normal as taken from 10 medical students tested was 16 or milligrams per cent at 30 minutes, 7 to milligrams per cent at 60 minutes and 1.61 milligrams per cent at 90 minutes. The highest reading was

41 milligrams per cent and the lowest was 9 milligrams per cent.

The following 87 cases are listed as to their final diagnosis. Those with positive galactose tolerance test hyperthyroidism 41 cases nontoxic goiter after iodine 3 cases hypertensive cardiovascular disease 2 cases menopausal syndrome 1 case syphilitic cirrhosis of the liver 1 case urticaria, 1 case amebiasis, 1 case catarrhal jaundice 1 case dyncbondroplasia, 1 case.

Galactose below the normal level occurred in myxedema 4 cases nontoxic nodular goiter 4 cases arteriosclerotic heart disease 1 case peptic ulcer 1 case neurocirculatory asthenia, 1 case.

Normal galactose curves were found in nontoxic nodular goiter 8 cases nontoxic diffuse goiter 3 cases thyroid adenocarcinoma, 2 cases familial jaundice, 1 case hypertensive cardiovascular disease 2 cases amebiasis, 1 case anxiety hysteria, 1 case manic depressive psychosis, 1 case cystic goiter 1 case colloid goiter 1 case toxic nodular goiter 1 case.

Of the 64 patients operated upon the histopathological report was diffuse toxic goiter 28 cases nodular toxic goiter 14 cases nontoxic nodular thyroid 12 cases nontoxic diffuse thyroid 3 cases adenocarcinoma (thyroid) 2 cases nontoxic (after iodine) 3 cases cystic goiter 1 case colloid goiter 1 case.

Relationship of the preoperative test 1 cases of toxic goiter are listed in Table I.

TABLE I

Pathological diagnosis	Cases	Basal metabolic rate	Galactose tolerance test
Toxic diffuse goiter	43	+50	50
Toxic nodular goiter		Mean +45	Mean 50
Nontoxic (after iodine)		+4	55
		+	6

case with normal basal metabolic rate and galactose tolerance.

The 3 cases reported as nontoxic after iodine are recorded here under the toxic cases because the pathologist's report stated that the gland showed a histopathological picture characteristic of remission. The adiol were

dilated with colloid but there was no marked hyperplasia present

Of the 42 cases of toxic goiter there were 10 cases in which the basal rate was within or below the accepted limits or normal. The lowest basal metabolic rate of this group was -4 , and the highest $+71$. All of the cases of toxic goiter except one had a positive galactose tolerance curve. This was a case of toxic nodular goiter with a basal metabolic rate of $+5$, and galactose readings of 20 milligrams per cent and 39 milligrams per cent at the 30 and 60 minute intervals, respectively. This patient had been taking iodine and sedatives for 3 months prior to admission to the clinic. Operation was advised in this instance on the basis of the clinical manifestations.

Pathological diagnosis of nontoxic goiter as related to preoperative tests are given in Table II.

TABLE II

Pathological diagnosis	Basal metabolic rate	Galactose tolerance test	
		30 min	60 min
Cystic goiter	-2	37	30
Colloid goiter	$+30$	75	41
Nontoxic diffuse goiter	$+3$	32	26
	$+12$	14	22
	-3	12	12
Nontoxic nodular goiter	$+8$	16.5	13.5
(Mean of 12 cases)	$+27$	23.5	2.3
Adenocarcinoma	$+24$	5	12

In the 1 case of cystic goiter the patient presented all of the symptoms of hyperthyroidism. The basal metabolic rate was low but the galactose readings were on the upper border of normal. The case reported as colloid goiter gave high readings for both the basal metabolic rate and the galactose tolerance. In each of these cases a preoperative diagnosis of diffuse toxic goiter had been made, and it is our opinion that premedication had changed the pathological picture.

There are 2 cases in which the efficacy of the galactose tolerance test is particularly revealed. The first case is that of a 33 year old white female who entered Touro Infirmary with the complaint of frequent headaches and the progressive loss of weight for about a year. Physical findings revealed only evidence of weight loss and tremor of the fingers. There was no exophthalmos or apparent enlarge-

ment of the thyroid. The pulse rate was 100 and the basal metabolic rate -4 . The galactose tolerance test readings were 116 milligrams per cent at 30 minutes and 85 milligrams per cent at 60 minutes. After diligent study the patient was subjected to a thyroidectomy. The pathologist's report after examination of the gland was toxic nodular goiter. Since the operation the patient has been free of symptoms and has gained weight. This case showed the most marked discrepancy between the basal metabolic rate and the galactose tolerance test.

It is here that the test has its greatest significance, i.e., the test will aid in confirming the diagnosis in patients with symptoms suggestive of thyrotoxicosis and who have a normal basal metabolic rate.

The other example which illustrates the value of this test is that of a 42 year old female who 2 years previously had had a thyroidectomy. The clinical and pathological diagnosis was toxic goiter. However, the patient had no relief of symptoms following the operation. She was again admitted to the hospital. The basal metabolic rate was slightly elevated and the galactose tolerance test was high. It was suggested that the patient might have a mediastinal goiter. Roentgen examination of the chest and subsequent operation confirmed this diagnosis. Following the last operation the patient had no more toxic symptoms.

The galactose tolerance test should not be used to replace the basal metabolic determinations in patients with suspected hyperthyroidism for in most instances the basal metabolic rate and the galactose test will be elevated above the normal and the basal metabolic rate will be more likely to indicate the severity of the toxicity, especially when the readings are high. Two examples of this occurred in our series. One fatality due to postoperative thyroid crisis had a preoperative basal metabolic rate of $+64$ and tolerance readings of 57 milligrams per cent and 79 milligrams per cent. Whereas a comparatively uneventful convalescence following hemithyroidectomy (first stage) was manifested by another patient whose preoperative tests revealed a $+27$ basal metabolic rate and galactose readings of

167 milligrams per cent and 200 milligrams per cent. The last mentioned galactose test had the highest reading of the series. The lowest was 44 milligrams per cent at 30 minutes and 6 milligrams per cent at 60 minutes.

In the toxic group of cases there was no correlation between the basal metabolic rate and the galactose tolerance test. There was also no correlation between the duration of the disease and the galactose tolerance test, for in some instances the galactose readings were high when the hyperthyroidism had been clinically of short duration and in other instances the test was low when the disease had been present for a long period of time. When the patient with hyperthyroidism shows a good clinical response to preoperative management and premedication the galactose curve tends to approach the normal but not in direct proportion to the basal metabolic rate. Following thyroidectomy the galactose curve gradually returns to normal, which suggests that in thyrotoxicosis liver dysfunction is not as a rule permanent.

In summarizing this investigation, it may be stated that the galactose tolerance test used in conjunction with the basal metabolic rate can be of definite aid in confirming the diagnosis of hyperthyroidism. Too much confidence can not be placed in any one test, nor can a test replace clinical experience or diagnostic ability. The responsibility for decision as to the course of therapy depends not on the results of the tests *per se* but does depend on the judgment of the physician.

In 41 of 46 cases, in which the preoperative diagnosis was toxic goiter the diagnosis was confirmed by the galactose tolerance test. All of the 5 exceptions had a preoperative diagnosis of toxic goiter. It is our opinion that in these 5 cases, because of premedication or prolongation of the disease the pathological picture had changed from typical toxic characteristics to a modification of this state. The cases of nontoxic nodular goiter after iodine cystic goiter and colloid goiter in all of which the preoperative diagnosis was toxic goiter probably showed the pathological condition as the result of premedication or in the case of cystic goiter prolongation of the disease.

In conclusion it is well to stress the fact that wherein the basic metabolic readings are within normal limits in patients manifesting symptoms of thyrotoxicosis, the galactose tolerance test will be of great aid in confirming a diagnosis of hyperthyroidism.

CHRONIC IDIOPATHIC ULCERATIVE COLITIS

Report of Seven Cases of Patients Operated Upon

MAURICE KAHN, M D , F A C S , and MAX W BAY, M D , F A C S , Los Angeles, California

THERE is an ill defined but important group of patients who present ulceration of the large bowel with no recognizable causal agent. For this condition there is at present no specific therapy.

The disease varies in violence within wide limits. Its onset may be sudden, and its severity so great as to cause death within a short time. Or its severity may be less, with few symptoms present, despite decided pathological changes. The most common and striking clinical characteristic is the tendency to chronicity with recurrent mild to severe exacerbations. McKittrick and Miller, in their analysis of 149 cases, describe one case with five separate recurrences in 1 year, and another patient who had 12 years of freedom between attacks. It is small wonder then that a wide difference of opinion exists as to the relative merits of various modes of therapy and as to the results obtained in any particular type of treatment.

The disease tends to involve all of the bowel wall, so that the muscularis becomes markedly thickened and the serosa is edematous and injected. The mucosal surface is denuded to greater or less degree and healing results in scar, with or without "heaping up" of islands of mucosa (to which the term pseudopolyposis has been applied), and in strictures. Healing of the muscular coat also results in fibrosis with loss of muscular tone and narrowing of the lumen of the bowel.

The disabilities of the disease are serious. Some patients suffer recurring attacks of fever and prostration, others are handicapped by continuous symptoms, of greater or less severity, and loss of weight and strength over prolonged periods. The loss of normally functioning mucosa causes faulty absorption, and, together with loss of food by diarrhea, results in nutritional deficiency. The infected colon acts as a focus of infection, frequently causing

multiple arthritis, and eye complications such as keratitis, iritis, and corneal ulcers. We have seen a young woman who lost the sight of one eye as a result of the disease.

Complications are common.

1 *Perforation* usually leads to death from generalized peritonitis. Abscess and fistula formation are fairly frequent. Barger (5) reports the incidence of perforation as 3.4 per cent in a total of 647 cases. In 10 of 18 cases, the perforation was located in the sigmoid. Perforation also occurred in the cecum, rectum, and splenic flexure. Multiple perforations were found in 2 cases. He reports a case of colojejuno-gastric fistula in a case of infantilism. He attributes the infantilism to the onset of the disease at an early age with lack of absorption of vitamins and mineral substances. Studies ruled out other known forms of infantilism.

2 *Massive hemorrhage* has been encountered by all writers. McKittrick and Miller report an incidence of 5 per cent in their cases.

3 *Strictures and narrowing of the lumen* occur in cases of long standing. Cattell (10) reports 2 cases in which complete obliteration of the lumen occurred at one or more points. In 4 of his patients stricture formation in the rectum was so extensive that a digital examination beyond the anal sphincter was impossible. We observed the same condition in one of our cases.

4 *Pseudopolyposis*. There is some difference of opinion as to the relationship of pseudopolyposis to chronic ulcerative colitis. Barger and Comfort (4) report an incidence of 10 per cent pseudopolyposis in 693 cases of chronic ulcerative colitis. They state that of every 5 cases of multiple polyps of the colon studied at the Mayo Clinic, 4 are on the basis of chronic ulcerative colitis. Barger (2), in another communication, reported an incidence of 13 per cent in 200 cases. Bancroft believes

that polyposis may be a part of the healing process, but David contends that it is definitely not part of the healing process. Bagen (2) states that the development of polypos is noted proctoscopically in the course of progressing as well as healing chronic ulcerative colitis. The possibility of malignant degeneration in these polyps is a matter for serious concern. Rankin (21) reports 25 cases of carcinoma in 1100 cases of colitis, an incidence of 2.3 per cent. Brust and Bagen report an incidence of 2.5 per cent in 800 cases. In contrast they quote the statistics of the United States Department of Commerce which indicate that 0.011 per cent of persons die from carcinoma of the intestine, and those of the Mayo Clinic which indicate an incidence of 0.88 per cent of carcinoma of the large intestine in all patients registering at the Mayo Clinic.

5. *Thrombophlebitis and mesenteric thrombosis and 6. colonic intussusception.* Among the rarer complications which have been reported are thrombophlebitis and mesenteric thrombosis (Cave 12) and colonic intussusception (Bagen 5).

It is important that we consider two other features of the disease namely its diffuse nature and its tendency to spontaneous remissions and exacerbations. Bagen and Mayo (6) report that in 95 per cent of 1500 cases of chronic ulcerative colitis the disease process began in the lower portion of the rectum and spread upward to involve the remainder of the large bowel. McKittrick and Miller report an involvement of the terminal ileum in 1.3 per cent of their cases and state that segmental colitis was rarely found. Cave and Nickel (13) found the terminal ileum apparently involved in 15 per cent of their cases yet on subsequent examination after ileostomy only 4 cases remained involved. Cattell (10) performed a loop colostomy well above the involved portion of bowel in 2 cases in which the disease was limited to the sigmoid and rectum. The disease spread through the colostomy to the proximal bowel. In one of the cases, extension occurred within 2 months. It is known that lesions may seemingly clear up entirely either spontaneously or following ileostomy, yet may become reactivated spon-

taneously or with re-establishment of the intestinal continuity. Stone (25) Lahey Rankin (21) and Cave and Nickel (13) report reactivation of the disease in cases in which re-establishment of the intestinal continuity was made following apparent cure resulting from ileostomy. In view of these reports it is difficult to reconcile the seemingly excellent results reported by Rienhoff Strauss and Stone (25, 26) unless it be that their cases had not been followed for a sufficient period before the reports were published.

Since no specific etiological factor has ever been proved a great many differing forms of conservative medical therapy have been attempted. Because the disease varies so greatly in its pathological findings and the severity of its symptoms widely differing results from the use of any given method of treatment have been reported. Several optimistic reports have been published which command consideration. Thus Crohn and Rosenak report a series of 90 cases, 75 of which were followed for an ample period. They claim that 75 per cent of their cases were cured or improved by medical means alone. Most of these patients were in their first 2 years of illness. Eleven per cent of their cases were unimproved, and 15 per cent died as a result of the disease. Bagen Brown and Rankin (3) also report a similar degree of success with medical management.

The acceptance of these statistics brings us to the conclusion that medical therapy is in sufficient in about 25 per cent of these cases. We concur with Lahey, Cave, and others, that the management of this disease demands close co-operation between the internist and the surgeon. Surely no one would suggest that surgical treatment be tried before the patient has been amply treated medically, the response to such treatment evaluated, and the extent of permanent damage to the colon determined. One must also bear in mind that some patients with marked pathological changes appear to have few symptoms. We, in common with the medical enthusiasts, hope the future may bring us knowledge of the etiology of the disease and a more specific therapy. But, for the present, it is our feeling that the pathology of the disease is in many

instances irreparable Mackie in an analysis of medical management, states that when extensive anatomical changes have occurred it is vain to hope for restoration to normal Brown (8) urges surgical treatment before the ulcerations have become so deep that complete restoration of the gut to normal function is less probable Cave (12) believes it unreasonable to assume that a disease which has caused such extensive infiltration in the deeper layers of the colonic wall could be reached by any known medical procedure

We believe that surgery finds a definite place in two groups of cases, namely, the acute fulminating type, and the chronic intractable type, complicated by sequelae which in themselves are serious conditions

Strauss, Stone (25), McKittrick and Miller, and Cave and Nickel (13), have advocated the use of ileostomy in the acute fulminating cases before the patient's condition has been too greatly impaired Single-barreled ileostomy, first advocated by Brown (7), completely diverts the fecal current from the diseased bowel, and thus gives complete physiological rest to the large bowel Striking clinical improvement is seen following ileostomy, yet in most instances the toxemia, although temporarily diminished, persists We cannot expect this procedure to be curative, notwithstanding contrary isolated reports in the literature (Stone, 24, 25, Strauss, Rienhoff) Ileostomy has gained a reputation for a high mortality rate McKittrick and Miller report a rate of 28 per cent in 54 cases Kunath reports 83 per cent in 12 cases and advocates appendicostomy or cecostomy as the procedures of choice, these have resulted in a mortality of 21 per cent in 19 cases Cattell (11) reports a mortality of 22 per cent, and Cave and Nickel (13) report a mortality of 45 per cent in 11 emergency ileostomies and of 11 per cent in 19 elective ileostomies Borgen, Brown and Rankin (3) report a 66 per cent mortality in 9 emergency ileostomies and of 50 per cent in 82 elective ileostomies, 30 per cent of which were immediate, and 20 per cent late It is possible that the rapid and excessive loss of fluids immediately following surgery is a factor in producing mortality, but the more likely reason for mortality in many

instances is that surgical aid is invoked too late Cave and Nickel (13) no longer advocate ileostomy in the presence of massive hemorrhage They believe that vitamins K and C are competent to control the bleeding and that surgery in these cases almost always results fatally

We urge surgery in the chronic intractable type, in cases constantly handicapped by chronic symptoms, in cases presenting progressive extension of the pathological changes, in cases showing periods of activity and remission with extension of pathology, and in those complicated by the sequelae previously discussed

There are a number of surgical procedures which we need to discuss briefly

Appendicostomy and cecostomy have been advocated chiefly for the doubtful value of irrigation These procedures fail to divert the fecal current completely and are inadequate

Colostomy, with distal partial colectomy, is applicable only to cases of segmental colitis, which have been estimated to constitute only 10 per cent of the whole A colostomy is more desirable than an ileostomy but is very rarely indicated

Ileosigmoidostomy, with or without proximal subtotal colectomy, has been enthusiastically advocated, but we must bear in mind that 95 per cent of cases begin with rectal involvement, and that apparently healed lesions may become reactivated with re-establishment of continuity Our experience with a recent case which will be described, and with another patient treated elsewhere, who retains active lesions in the remaining bowel with multiple fistulas and widespread arthritis, and who has lost the sight of one eye, convinces us that this procedure is very limited in its applicability

Total colectomy we believe to be logical because it completely disposes of the diseased bowel, results in no permanent damage to the patient, and is attended with a reasonable mortality

Cattell (11) has reported 24 total colectomies with 3 deaths, Rankin (21, 22), 7 total with no deaths, 4 subtotal with 1 death, Cave (12) 3 total and 3 subtotal with no deaths, McKittrick and Miller 2 total and 8 subtotal

with 1 death. The aggregate totals 51 cases with 5 deaths or a rate of approximately 10 per cent. We realize that the combined group represents a small series from which to draw extensive conclusions but, granted proper management it seems that mortality should be within reasonable limits for this type of surgery.

The operation should be done in multiple stages. We will not attempt to describe in detail all of the steps. The first stage of the operation entails ileostomy the second, subtotal colectomy from the terminal ileum around to the lower sigmoid the omentum being preserved. On occasion it may be necessary to conduct two stages for this portion of the procedure, as we found in one of our cases. The third stage consists of combined abdominoperineal or posterior resection of the remaining sigmoid and rectum.

Different forms of ileostomy technique have been described by Brown (7) Rankin (21) MacGaire Cattell (11) Cave and Nickel (13) and Stone (26). These vary from an ileostomy combined with appendicostomy to implantation of the terminal stoma in the abdominal wall as a mucous fistula. We prefer the single barreled or end ileostomy turning the distal limb in and dropping it. We are not unmindful of the warning voiced by some, that stricture in the distal bowel might result in opening of the closed ileum. We have so far left the clamp on the proximal limb for 36 to 48 hours. Recently immediate tube drainage has been advised by many. We have decided to adopt this procedure in the future. We do no exploration of the abdomen at the time of performing ileostomy since little information can be gained and trauma might complete an impending perforation. The complications of ileostomy have been completely described by Cave and Nickel (13) bleeding from mucous membrane prolapse retraction narrowing of stoma, secondary openings proximal to the stoma, intestinal obstruction, pronounced collapse due to loss of sodium chloride from suden and rapid ejection of fluid from the stoma. We try to guard against prolapse by suturing the mesentery to the anterior peritoneum, but encountered this complication in one case.

Ileostomy may on occasion be an emergency procedure. The succeeding stages need never

be done in haste. Sufficient time must elapse following ileostomy to permit water balance to be re-established and general improvement of the patient's condition. A minimum of 5 to 8 weeks has been advised. Whittaker's observations on ileostomy indicate that water and mineral balance begin to be established at the end of 1 month, and that average weight and strength are regained in about 3 months. We waited 2½ years on our first patient because repeated acute exacerbations with massive hemorrhages, precluded earlier intervention.

We performed the second stage in two procedures on our second patient because she had previously suffered a perforation at the splenic flexure with abscess formation. In the first of these we resected to the splenic flexure. In the second we resected to the lower sigmoid.

We believe that at least 1 month should be allowed between the second and third stages for proper preparation of the patient. Cave (12) advocates a period of 2 to 6 months.

Our surgical experience is based on 7 patients operated upon 2 ileostomies without further surgery 4 total colectomies, and 1 ileosigmoidostomy with resection of the proximal colon.

The complications encountered were as follows (1) prolapse of ileostomy in 1 of the 5 ileostomies, which necessitated surgical correction (2) partial dehiscence of the wound following the second stage operation in 1 of the 4 total colectomies (3) dehiscence of the wound with fecal fistula following resection of the proximal colon in the patient on whom an ileosigmoidostomy was done (4) completely dysfunctioning neurogenic bladder following the third stage in the first total colectomy performed.

Since then, Dr. A. A. Kutzmann, of our urologic department, has instituted total drainage on all of our cases immediately after operation and has been successful in obviating serious bladder disturbance.

Management of the ileostomies has presented some difficulties. It has been stated that when colectomy has been completed, the terminal ileum has taken on the function of the large bowel with absorption of fluid and solidification of the stool resulting in less frequent movements. Dr. William Bachrach,

Fig 1 Diagram of cecum and ascending colon Wall markedly thickened and lumen narrowed Previous destruction of mucosa Some active ulceration Case 3, S.L

of our resident staff, made some interesting observations independent of the work of Whittaker previously mentioned. He found the intestinal passage time to be about 4 hours. Protein in the form of meat and starch in the form of potato were readily digested. Leafy vegetables, and those with distinct membranes such as peas and corn, left considerable residue. Seeds were, of course, not digested. There was no significant effect from varying the water intake. Milk resulted in a more acid, more liquid stool. Dr. Bachrach suggests the following dietary regulations: (1) No restriction of amount, but food to be taken at conventional meal times, (2) meat and potatoes as desired, (3) moderate amounts of nonleafy, nonmembranous vegetables, (4) daily intake of strained orange juice, (5) vitamin supplements may be added. By applying these rules our patients have been able to restrict the movements to three or four in 24 hours. One of the patients has been able to dispense with the wearing of a bag on most occasions.

Whittaker, in his observations on the human being following colectomy or colonic exclusion with ileostomy, has demonstrated that there are few temporary and no permanent effects on mineral metabolism, no change in the motor activity of the small intestine, some physiological dilatation of the terminal ileum, and that in 3 months patients may regain average weight and strength.

Our results in the 4 totally colectomized patients have been very gratifying to the

patients who express enthusiasm over the results and are not at all unhappy with their ileostomies.

REPORT OF CASES

CASE 1 E. R., female. Illness began in 1925 at the age of 20, with bloody diarrhea which lasted 5 weeks. In 1930 she had an attack which lasted 2 months. In January, 1934, she had an attack of influenza, and 1 month later developed bloody diarrhea which continued until her admission to the hospital on May 18, 1934. For 1 month previous to the hospital ad-

Fig 2 Showing complete replacement of mucosa by chronic inflammatory changes. Note increased submucosal fat. Case 3 S.L. X 95

Fig. 5. Barium colon enema roentgenogram reveals narrowing below the splenic flexure with dilatation of proximal bowel. Loss of mucosal pattern and haustration in the descending colon. Case 4. F. P.

mission she had 5 bloody rectal movements daily a great deal of abdominal pain, and some vomiting. She had lost great deal of weight and felt very weak. She was given whole blood transfusion on May 20, days after hospital admission she appeared to have had perforation of the bowel. Exploratory laparotomy as done through a McBurney incision under local anesthesia. There was a great deal of clear serous peritoneal fluid which on culture grew *Streptococcus viridans*. A cecostomy was done. A blood transfusion was given and repeated on June 1. On June 9, there was hemorrhage from the cecostomy and rectum. The blood count dropped moderately and two days Sigmoidoscope were given in a period of days. Sigmoidoscopic examination revealed good many active ulcerations extending to 9 1/2 inches, there being a few ulcers in the rectum. In August she was transferred to convalescent home. The improvement continued to be very slow. She was readmitted to the hospital and an end ileostomy was done on September 7, 1934. Retraction of the ileostomy gradually took place and a new ileostomy was done on November 23, 1934. She improved steadily following this, gaining great deal of weight and having few rectal passages

of mucus and pus. In May 1938 sigmoidoscopic examination revealed acutely injected rectal mucosa which bled readily on touch. In May, 1939, prolapse of the ileostomy necessitated resection of the prolapsed ileum. She was last seen in January 1940. Her general appearance was very good. There was marked contrast between her emaciation in 1934 at the time of her first illness, and the obesity in 1940. She continued to pass mucus and pus rectally however, and sigmoidoscopic examination revealed continued ulceration. She has refused total colectomy and we have refused to re-establish bowel continuity.

Almost continuous fluid drainage from the ileostomy has rendered her useless for employment and a burden on society. Despite the very evident improvement in the patient's condition activity of the disease continues.

CASE 3. M. G. male. Illness began in 1931 at the age of 31 years, with fever, painful swelling of the knees and ankles, lower abdominal cramps and bloody diarrhea. The attack lasted only a few days. He was placed on an ample medical regimen and suffered only a few mild exacerbations. In August, 1935, when he had a severe exacerbation characterized by abdominal pain, nausea, vomiting, and 4 to 6 bowel movements daily, swollen tender knee joints, and great weakness. He lost 10 pounds in eight or a few weeks, and weighed 135 pounds when admitted to the hospital. His previous normal weight had been 165 pounds. Ileostomy was performed on August 4, 1935. He enjoyed remission of his illness for a year, weighing 80 pounds at the end of that period. For the following 5 months he again suffered from chills, fever, anorexia, vomiting, and bloody rectal movements. Multiple arthritis again became evident. Under more active medical care he improved and enjoyed another remission of 6 months duration. At the end of that time he had a mild exacerbation during which an ischio-rectal abscess developed. Since that time he has remained well except for short periods of mild exacerbation. When last seen by us in January 1940, he weighed 90 pounds and felt very well. An attempt to do sigmoidoscopic examination revealed that a small finger could not be inserted into the anus. Total colectomy has been advised but refused by the patient.

Ileostomy has resulted in virtual cure of the disease from the patient's point of view. We feel, however, that in view of the anal stricture, eventual re-establishment of bowel continuity is impossible.

CASE 3. S. L. female. Illness began in 1931 at the age of 20 years, characterized by cramps, bloody diarrhea, and vomiting. There were rare periods of remission except for persistent complete relief during pregnancies in 1933 and 1935. About 1935, she developed multiple arthritis, involving practically all joints, at times necessitating the use of crutches. She

Fig 4 Diagram of section of colon reveals complete loss of normal mucosa with scarring. Some surviving islands of mucosa appear to be proliferative, producing pseudopolyposis. Case 4, E P

had an exploratory laparotomy and appendectomy in 1933. In 1934, a cecostomy was done elsewhere. She improved for 1 year and again developed cramps, bloody diarrhea, and arthritis of moderate severity, with periods of remission. She had been cared for by a great many physicians in this community. We saw her in 1936 and performed an ileostomy in March of that year. Her symptoms and general condition improved. She gained some weight, but her arthritis continued to be bothersome, and she began to have more purulent and bloody drainage from the bowel, in addition to a good deal of abdominal pain. In the spring of 1937 she was sent into the hospital and was being prepared for colectomy, when she developed a most acute exacerbation, having massive hemorrhages from the bowel and much pus. She was treated conservatively. She weighed 80 pounds when she left the hospital. Her normal weight had been about 130 pounds. During the illness she had weighed on the average 95 to 100 pounds. She improved and gained weight but continued to pass pus and blood by rectum.

On July 26, 1938, first stage colectomy was done, the bowel being resected to the sigmoid. One month later, on August 25, 1938, the abdominoperineal resection was done. This patient developed the bladder difficulty previously mentioned. It has been considerably improved under treatment. It is now 28 months since the completion of colectomy. The patient feels extremely well. She has had to restrict her diet because she now weighs 146 pounds, which is approximately 16 pounds over her previous normal weight. The ileostomy is satisfactorily controlled.

The specimen revealed marked thickening of the wall with narrowing of the lumen (Fig 1). The mucous membrane appeared to be almost completely absent and there was some active ulceration in the remaining mucosa. The microscopic sections revealed severe chronic inflammatory change, with ulceration of the mucosa and hypertrophy and fibrosis of the muscularis (Fig 2).

This patient had had repeated exacerbations and remissions for 14 years before ileostomy. The most severe exacerbation occurred 1 year after ileostomy was performed, and at the completion of total colectomy, 2 years after ileostomy, active ulceration was found in the specimens. She remarried 2 months ago.

CASE 4 E P, female. Illness began in 1929 at the age of 21 years, characterized by severe bloody diarrhea. She had rather frequent attacks of moderate severity. In 1931 she was delivered by cesarean section and shortly developed a right tubo ovarian abscess which necessitated surgery. Although the colitis was particularly bothersome during the pregnancy, there appeared to be a remission until the next pregnancy in 1933, when she was again delivered by section. The colitis was moderately active during this pregnancy. In 1936 she suffered a severe attack which necessitated hospitalization. This was the fourth severe attack. The illness continued mild until July, 1938, when she developed pain in the left loin and flank accompanied by high fever. This subsided after several weeks. Subsequent x-ray study revealed narrowing below the splenic flexure with penetration at this point (Fig 3). The evidence of obstruction with cramps accompanied by visible peristalsis became more marked and for a matter of 2 weeks the patient was in great distress. In September she developed a diarrhea, having about 6 or 8 watery stools daily, and she became nauseated. She was admitted to the Hospital in October but continued to lose ground, her weight dropping from a normal of 110 pounds to 65 pounds, a loss of 45 pounds in a period of 3 months. The hemoglobin dropped to 50 per cent, red blood cells, 3.6 million. Two whole blood transfusions were given and ileostomy was done on November 10, 1938. She improved gradually following this procedure. In January, 1939, an abscess surrounding the splenic

Fig. 5 Barium colon roentgenogram, November 1930, reveals well demarcated lack of illustration limited to the ascending, transverse, and descending colon. Case 6, P.C.

Fig. 6 Barium colon roentgenogram taken July 1931. There is no essential change from condition shown on previous film. Case 6, P.C.

flexure pointed in the left lumbar region and was drained. Her improvement continued for 3 months and she then developed moderately severe exacerbation passing good deal of mucus and blood per rectum. On July 7 1930, first stage colectomy was done resection being carried to the splenic flexure. Six weeks later on September 1930, the resection was carried to the lower sigmoid. She got along well and gained some weight, but continued to have bloody drainage rectally. Ten months later on November 6, 1930, abdominoperineal resection was done. Now 1 year since completion of colectomy she is feeling well. The ileostomy is satisfactorily controlled. Her weight is normal.

The specimen revealed the following: There was marked narrowing of the lumen in two places with thickening of the wall. There were numerous areas of complete ulceration of the mucosa. Some surviving islands of mucosa appeared to be proliferative producing pseudopolyps (Fig. 4). In the remainder the mucous membrane was diffusely hyperemic to hemorrhagic and showed scattered match-head size ulcers with hemorrhagic bases. The microscopic examination revealed evidences of acute and chronic inflammation.

This patient was practically invalided for years before surgical treatment. Ileostomy resulted in some improvement but did not prevent the occurrence of a rather severe exacerbation 3 months later. Her invalidism resulted in a great deal of marital discord as she was greatly opposed to having a permanent ileostomy thinking that this might further estrange her husband. She has been restored to health and happiness.

CASE 5 M.G. female. Illness began in 1911 at age of 20 years. She had severe attacks characterized by abdominal pain, bloody diarrhea, with restlessness, movements daily, vomiting, and fever. She was hospitalized for 6 months during which time no blood transfusion was given. Ten months following the hospital discharge she suffered milder attacks but again necessitated hospitalization. There were moderately severe attacks in February 1933 and February 1934. She was admitted to the Cedars of Lebanon Hospital in August, 1934, on the fifth attack of moderate severity during a period of

Fig 7 Above, descending colon to line of resection. Below, ascending colon with cecum and attached terminal ileum and appendix reveal the longitudinal furrows which extended practically the full length of the bowel. These furrows were occupied by hemorrhagic membranes which,

when scraped away, revealed the presence of shallow almost continuous erosions. The distal 7 centimeters of bowel appeared to be relatively normal except for the extension of one of the linear furrows clear to the line of resection. Case 6, P C

3 years. After a month's conservative care, an ileostomy was performed in September, 1934. She had no severe exacerbations from this time on, except for a mild one in 1936, when she developed a perirectal abscess which was drained. She gained 30 pounds of weight and felt well, but despite the apparent remission she continued to pass blood and mucus and had lower abdominal cramping pain on frequent occasions.

On September 12, 1939, first stage colectomy was done, resection being carried to the lower sigmoid. Within several days, an unusual local heat wave, with a maximum temperature of 107 degrees F, took place, which lasted for 1 week. The loss of chlorides was increased due to vomiting. Partial dehiscence of the wound occurred. The blood chemistry was corrected and repair was not necessary. Three months later, on December 7, 1939, an abdominoperineal resection was done. It is now 1 year since the completion of the operation. The patient feels very well. She weighs 116 pounds which is about 5 pounds above the previous normal. The ileostomy is satisfactorily controlled.

The specimens showed diffuse marked narrowing of the lumen particularly in the sigmoid where the closed scissors were admitted with difficulty, being about 2 centimeters in diameter at the widest point. There was some thickening of the wall as well as increased firmness. There was atrophy of the mucous

membrane in many areas which appeared to be the result of healed ulcers with scarred bases. The mucosa was represented in a few areas by a few ridges of glistening hemorrhagic rugae, and elsewhere it consisted of hemorrhagic and hyperemic to gray granulation. In the first specimen, 6 centimeters of the bowel showed scattered active ulcers with hemorrhagic borders, the largest being about 1 centimeter in diameter. There were no areas of polyposis or malignancy seen.

Microscopic sections showed virtually complete absence of the mucous membrane which appeared to be replaced by granulation tissue which blended with thickened submucosa. There was connective tissue proliferation in the submucosa and streaking through the muscle fibers. There was infiltration of lymphocytes, plasma cells, and eosinophiles, through all layers, being indicative of chronic inflammatory reaction.

This patient had repeated exacerbations of varying severity for 3 years previous to ileostomy. Following this procedure she appeared to enjoy reasonably good health but continued to pass blood and mucus rectally. Progressive pathological change continued in the bowel despite the ileostomy.

Fig. 3. Section shows acute ulcerative process occurring in the longitudinal furrow at the line of resection. Case 6, P.C. X95

CASE 6. P.C. female. At 8 years of age this patient had diarrhea which lasted for months. At 6 years, she developed diarrhea following "food poisoning," she thought, consisting of 5 or 6 loose movements daily with no blood, and inconstant cramp-like abdominal pain. She vomited on occasion and lost 5 pounds in weeks. She had ample medical care. The diarrhea persisted for years but her general condition improved slowly. She weighed 74 pounds at 6, and 86 pounds at 8. She suffered moderately acute exacerbation in October, 1930, at the age of 8 years and as admitted to the hospital on October 4. Her immature appearance was noticeable. Menstruation had begun at 4 and had ceased at 6½ year and gained 3 months before her admission. She weighed 80 pounds on admission. She had moderate febrile reaction. Sigmoidoscopic examination revealed an essentially normal mucosa to 10 inches. Barium colon enema (Fig. 5) revealed a rather well demarcated lack of haustration limited to the ascending transverse and descending colon. She had a moderate secondary anemia. A whole blood transfusion and course of neoprontol were given with some improvement in her condition. She was discharged from the hospital on November 28, 1930. The disease continued only mildly active until

August, 1940, when there was an exacerbation of the symptoms with 8 to 10 movements daily, pain, fever and anemia. She was readmitted to the hospital on August 16, 1940. Sigmoidoscopy revealed some redness of the normal mucosa but no ulcerations to 10 inches. A repeat barium enema (ray taken in July (Fig. 6) had shown no progression in the findings. On September 3 blood transfusion was given, and on September 4 an end-to-side ileosigmoidostomy was done. Examination of the large bowel confirmed the x-ray findings which had indicated involvement of the ascending transverse and descending limbs of the colon. These portions of the bowel are thickened and lusterless. There was an abrupt line of demarcation at the sigmoid where the bowel appeared perfectly normal. The anastomosis was carried out 6 to 7 inches below this line of demarcation. Two blood transfusions were given during the week following surgery and the patient reacted well. She had on the average three liquid stools daily. The operative wound healed *per primam*. On October 17 subtotal colectomy was carried out the bowel being resected from the ileum 4 inches below the line of demarcation in the descending colon. A good many adhesions were encountered in the lower abdomen including fixation of the anastomotic area to the anterior parietal peritoneum. Freeing of the latter resulted in tear into the lumen of the ileum which was repaired. Sulfanilamide therapy was immediately instituted. A blood transfusion was administered following surgery and repeated in 6 days. Within 7 days there was purulent drainage from the wound, followed by fecal drainage and complete dehiscence of the wound. There was copious fluid loss from the wound. She vomited frequently and feeding became a real problem. There was great deal of albumin lost in the urine and the serum proteins steadily dropped. Another blood transfusion, the third following surgery, was given. On November 7 on month following the resection, massive hemorrhage from the wound occurred. A tampon had been administered regularly. She was given byzoxone parenterally. Two blood transfusions and 5 cubic centimeters of plasma were also given. The patient died on November 20. Postmortem examination as not permitted.

The surgical specimen revealed a somewhat thickened, narrowed bowel, the serosal surface of which was hyperemic (Fig. 7). The lumen was filled with bright bloody fluid. The mucous membrane was rather smooth and irradated out. There were several irregular but generally longitudinal furrows which extended practically the full length of the colon. These furrows were occupied by hemorrhagic membranes which when scraped off revealed shallow almost confluent erosions. In places there were larger ulcers, the margins of which were composed of overhanging slightly proliferating mucous membrane. This process 1 to 7 centimeters from the distal line of resection, the mucous membrane in this latter por-

(Gynerthe, William L. Abbott.)

tion of the bowel being more normal in appearance except for the extension of one of the linear furrows in an hemorrhagic erosive manner, clear to the line of resection. Microscopic sections (Fig 8) of the relatively uninvolved portion of bowel revealed mainly acute inflammation with some chronic change, but without involvement of the muscularis or definite ulceration. Sections of the involved area revealed involvement through the whole thickness of the wall.

This case clearly demonstrates the difficulty of ascertaining the extent of involvement by means of the gross, outward appearance of the bowel and x-ray examination. It further demonstrates the importance of proper nutrition and the difficulties one encounters in the postoperative management. We feel that the condition of the bowel contributed to the failure of healing. It now appears that the ileosigmoidostomy was ill-advised, since this was not a case of limited colitis.

CASE 7. C W, male. Illness began in January, 1939, at the age of 39 years, characterized by bloody diarrhea with 8 to 10 movements daily, nausea, vomiting, and diffuse abdominal pain. He lost 60 pounds during the course of 1 month, the previous normal having been about 120 pounds. He was given six blood transfusions. Ileostomy was performed elsewhere in February, 1939. He improved remarkably, regaining 35 pounds during the following 5 months. He was first seen in our out patient department in June, 1939. His weight was 118 pounds and he was having only 3 to 4 rectal passages of pus and mucus daily. He was placed on an ample medical regimen. In February, 1940, he had a mild exacerbation characterized by fever and by abdominal cramps and bloody rectal movements. His weight dropped from 114 pounds to 99 pounds. He was admitted to the hospital on September 27, 1940. Sigmoidoscopic examination revealed active inflammation in the lowermost 8 inches of bowel. He was given sulfathiazol and improved. On November 1, 1940, a subtotal colectomy was performed, resection extending from the ileum to the rectosigmoid. His postoperative reaction was excellent aside from a moderate degree of shock which responded adequately following transfusion. Combined abdominoperineal resection was carried out on December 6, 1940. There was slight postoperative reaction. The abdominal wound is healed and the posterior wound granulating nicely. The ileostomy drainage has noticeably thickened. He now weighs 90 pounds.

The specimens revealed a hemorrhagic appearance of the serosa and roughened hemorrhagic mucosa with numerous bleeding points and many

small ulcerated areas throughout, including the anal canal. The ulcerations involved the full thickness of mucosa and submucosa and a portion of the muscularis. The lumen as a whole was narrowed. Microscopic examination revealed evidences of acute and chronic inflammation.

Ileostomy no doubt was instrumental in saving this man's life. It has not, however, prevented progression of the pathological changes.

CONCLUSION

Surgery finds a place in the treatment of chronic idiopathic ulcerative colitis because of the serious complications of the disease. Total colectomy is logical because it completely eradicates the pathology. It is attended by a reasonable mortality.

PALE EPITHELIUM IN THE MAMMARY GLAND AND ITS EXPERIMENTAL PRODUCTION IN THE RHESUS MONKEY

HAROLD SPEERT M.D. Baltimore, Maryland

AMONG the vast number of authors who have contributed to the pathology of the human breast a few have interested themselves in certain cells sometimes encountered in the mammary gland remarkable because of their pallor after staining. Opinions concerning the origin, biological significance and practical importance of these atypical cells have been conflicting and almost as numerous as the authors who have written about them. Attempts at clarifying these problems have been based upon the study of pathological human breast tissue obtained either at autopsy or at operation for various types of mammary morbidity.

In a recent study of the effects of intense and prolonged estrogenic stimulation on the rhesus monkey (Hartman, Geschickter and Speert 1941) examination of the mammary glands revealed changes similar to those described and pictured as atypical epithelium or *Masses Zellen*. These observations are recorded here in detail, in the hope that they may throw new light upon an obscure subject.

This atypical epithelium was recognized as a constituent of pathological breasts long before it was specifically mentioned and described in the literature. If one may judge from the drawings accompanying some of the early articles on chronic cystic mastitis (Lewer 1858, Same, 1897, Roloff 1900, Tietze, 1900) In 1900 Wohlbecker a student of Borst, clearly distinguished between the normal darkly staining cuboidal cells of the mammary gland and the tall pale cells with eccentric nuclei which were seen lining different parts of the same cyst. Paul, in the following year described epithelial changes in chronic cystic mastitis which bore certain points of resemblance. But it was not until 1904 that Borst clearly called attention to these large pale cells lining mammary cysts and named them *atypische Epithelien*. They were further studied by von Sauer who in 1907 pointed out their similarity to sweat gland epithelium. Since then they have been variously

referred to in the literature as "*Masses Zellen*", "*fibroadenoid epithelium*", "*cellules claires*" (Dubet and Alendaro), "*oxyphile Epithelien*" (Przym), "*eosinophile Epithelien*" and "*hells rosige Epithelien*" (Askanazy).

The distinguishing cytological features of these cells are their size and the staining qualities and homogeneity of their cytoplasm. The cells are cuboidal to cylindric in shape and may under some conditions appear elongated. Their size varies from two to four times that of the normal mammary epithelium. The nuclei are round, vesicular, hypochromatic, and usually centrally located. The abundant pale cytoplasm stains a faint pink with eosin and yellow with van Gieson's stain. It is usually homogeneous and clear, sometimes faintly granular in appearance, and occasionally contains small clear vacuoles.

In describing the epithelial changes in chronic cystic mastitis in 1901 Paul called attention to the cystic arrangement of the "long-celled epithelium" and the intracytic growth frequently derived from it. The description of atypical epithelium by Borst in 1904 likewise concerned itself with the large pale cells lining mammary cysts. Subsequent studies have emphasized the cystic arrangement of the epithelium in regions where these cells are found. Krompecher (1931) found pale epithelial cysts in 21 of 293 mammary tumors which he studied. Semb (1935) has described cysts lined with pale epithelium as a constant feature in all cases of fibroadenomatous cystics, where they usually occur in large numbers and are more frequent than cysts lined with ordinary mammary epithelium. More recently Dawson (1931) has stated that although the size of the cyst may vary within wide limits, in all cases in which pale epithelium occurs in the breast it lines a definitely cystic structure even the smallest pale structures always appearing larger than normal mammary acini. Cheate and Cutler (1931) have attributed to these pale cells an important rôle in the genesis of mammary cysts, whose formation they described as follows:

"The first change from the normal epithelium of the acinus is the development of cells (cytoblasts) desquamative

From the Carnegie Institution of Washington, Department of Embryology, and the Department of Obstetrics, Johns Hopkins Hospital, Baltimore

epithelial hyperplasia) is a slight elongation of the cells. In the next state they become more cuboidal in shape and present a very delicate characteristic appearance. The essential characteristic of these cells is their pallor and they are described by some authors as 'pale cells'. The nuclei are round, hypochromatic, and centrally situated. The cytoplasm is homogeneous and perfectly clear. In the next stage these pallid cells increase in number to form two or three rows from which columns of three or four cells may spring and project into the lumen. It is from the upper cells of these columns as well as from the inner layers lining the acini that desquamation occurs. This process and the collection of fluid distend the acini, forming small cysts. It is the condition advances the walls which separate the neighboring acini disappear and a composite cyst is thus formed. These early states result in the later formation of the large cysts in the breast. "These cysts are the blue-dome cysts" of Bloodgood."

Although occurring predominantly in areas of cystic disease, small cavities lined with pale epithelium have been observed also in association with solid mammary tumors. Thus Krompecher reported 12 cases of pale epithelial cysts occurring with fibroadenomas among his previously mentioned 292 breast tumors, and Semb found 14 such cysts among 100 cases of fibroadenoma.

Pale epithelial cysts are most commonly met with in the fourth and fifth decades, at which ages the various forms of chronic cystic mastitis are most prevalent. However Kudji (1921) has reported such cysts in a 14 year old girl who died of pulmonary tuberculosis before puberty, and Cheatele and Cutler have stated that rarely mammary structures that resemble sweat glands can be found even in the breasts of infants at birth. In adults pale epithelium seems limited to the female in its distribution. Dawson has denied its occurrence in male mammary glands, as has Semb. The latter, however, has described true sweat gland cysts in the male, closely resembling the epithelial lining of fibroadenomatosis in the female breast.

ORIGIN OF PALE EPITHELIUM

The origin of pale epithelial structures in the mammary gland has been accorded various interpretations by different authors. These interpretations may be classified broadly into two groups first, that the pale structures represent sweat gland epithelium, and second, that they are derived from true mammary epithelium.

The mammary glands have long been regarded as modified sweat glands (Benda, 1894). When von Saar called attention to the histological similarity between the pale epithelium of the mammary glands and that of the sweat glands, he regarded this as further evidence for the phylogenetic development of the mammary glands from the sweat glands of the skin. Creighton, in

1902, wrote a detailed account of his extensive studies of the sweat glands of mammals and emphasized their relation to mammary development. He believed that tubular glands with the structure of sweat glands were very commonly found in normal breasts as developmental anomalies and that they represented a reversion to a lower type of mammary gland. Similar views concerning the histogenesis of pale epithelium have been expressed by Kuru (1909), who compared it phylogenetically with sweat gland epithelium, and by Krompecher (1913, 1916). The latter author regarded pale cysts as sweat gland cysts and viewed their occurrence in the mammary gland as a manifestation of reversion.

A larger group of authors has vigorously opposed the belief that pale epithelial structures are aberrant sweat glands. The entire subject has been reviewed by Dawson (1932) who concluded that pale epithelium in the breast is derived from normal mammary tissue (ductile or acinar). Her study of sections of mammary glands at various stages of development gave no support to the view that sweat glands are normally included in the breast. Cheatele and Cutler reported similar observations in 1931 and stated that whenever sweat glands resembling mammary structures were encountered they have always been in the extramammary subcutaneous tissue and not in the gland itself. These authors never failed to trace a direct anatomical continuity between the pale structures and the mammary ducts.¹ Dawson observed pale cells and normal mammary epithelium merging directly into each other in the same cystic acinus or duct, and in so doing confirmed the earlier observations of Wohlsecker, Semb, Delbet and Mendaro, and Kudji. This was interpreted as a strong argument for the mammary origin of the pale cells. Krompecher, in 1924, also described both normal and pale epithelium contiguously lining the walls of mammary ducts and cysts, sometimes with almost imperceptible transitions between the two types of tissue. These observations prompted a revision of his previously published views concerning the histogenesis of pale epithelium, which he now regarded as derived from normal mammary structures. Other authors who concluded that the pale epithelium arose from the acini and small ducts of the mature breast include Berka, Prym, and McFarland.

There is general accord among those authors who would derive pale epithelium from true mammary elements, concerning the processes by which the changes occur. Dawson attributes the altera-

¹Ewing (1940) likewise observed glands lined with pale epithelium which emptied into the intralobular lacteal ducts of the normal breast but he regarded the former as sweat glands.

PALE EPITHELIUM IN THE MAMMARY GLAND AND ITS EXPERIMENTAL PRODUCTION IN THE RHESUS MONKEY

HAROLD SPEERT M D Baltimore Maryland

AMONG the vast number of authors who have contributed to the pathology of the human breast a few have interested themselves in certain cells sometimes encountered in the mammary gland, remarkable because of their pallor after staining. Opinions concerning the origin, biological significance and practical importance of these atypical cells have been conflicting and almost as numerous as the authors who have written about them. Attempts at clarifying these problems have been based upon the study of pathological human breast tissue obtained either at autopsy, or at operation for various types of mammary morbidity.

In a recent study of the effects of intense and prolonged estrogenic stimulation on the rhesus monkey (Hartman, Geschickter and Speert 1934) examination of the mammary glands revealed changes similar to those described and pictured as atypical epithelium or *Blasse Zellen*. These observations are recorded here in detail, in the hope that they may throw new light upon an obscure subject.

This atypical epithelium was recognized as a constituent of pathological breasts long before it was specifically mentioned and described in the literature if one may judge from the drawings accompanying some of the early articles on chronic cystic mastitis (Leser 885 Sasse 1897 Roloff 1900 Tietze 1900). In 1900 Wohlbecker a student of Borst clearly distinguished between the normal darkly staining cuboidal cells of the mammary gland and the tall pale cells with circular nuclei which were seen lining different parts of the same cyst. Paul, in the following year described epithelial changes in chronic cystic mastitis which bore certain points of resemblance. But it was not until 1904 that Borst clearly called attention to these large pale cells lining mammary cysts and named them *atypische Epithelien*. They were further studied by von Saar who in 1907 pointed out their similarity to sweat gland epithelium. Since then they have been variously

referred to in the literature as *blasse Zellen*, *adenomalous epithelium*, *cellules claires* (Delbet and Mendaro), *atypical Epithelien* (Prym), *cantharophil Epithelien* and *belle rosige Epithelien* (Askanazy).

The distinguishing cytological features of these cells are their size and the staining qualities and homogeneity of their cytoplasm. The cells are cuboidal to cylindrical in shape and may under some conditions appear elongated. Their size varies from two to four times that of the normal mammary epithelium. The nuclei are round, vesicular, hypochromatic, and usually centrally located. The abundant pale cytoplasm stains a faint pink with eosin and yellow with van Gieson's stain. It is usually homogeneous and clear, some times faintly granular in appearance, and occasionally contains small clear vacuoles.

In describing the epithelial changes in chronic cystic mastitis in 1901 Paul called attention to the cystic arrangement of the "long-celled epithelium" and the intracystic growth frequently derived from it. The description of atypical epithelium by Borst in 1904 likewise concerned itself with the large pale cells lining mammary cysts. Subsequent studies have emphasized the cystic arrangement of the epithelium in regions where these cells are found. Krampecher (1913) found pale epithelial cysts in 21 of 292 mammary tumors which he studied. Semb (1918) has described cysts lined with pale epithelium as a constant feature in all cases of fibroadenomatous cystics where they usually occur in large numbers and are more frequent than cysts lined with ordinary mammary epithelium. More recently Dawson (1932) has stated that although the size of the cyst may vary within wide limits, in all cases in which pale epithelium occurs in the breast it lines a definitely cystic structure, even the smallest pale structures always appearing larger than normal mammary acini. Cheate and Cutler (1933) have attributed to these pale cells an important rôle in the genesis of mammary cysts, whose formation they described as follows:

"The first change from the normal epithelium of the acini into the desquamated state (cytoplasmic desquamation

From the Carnegie Institution of Washington, Department of Embryology, and the Department of Obstetrics, Johns Hopkins Hospital, Baltimore

epithelial hyperplasia) is a slight elongation of the cells. In the next state they become more cuboidal in shape and present a very delicate characteristic appearance. The essential characteristic of these cells is their pallor and they are described by some authors as 'pale cells'. The nuclei are round, hypochromatic, and centrally situated. The cytoplasm is homogeneous and perfectly clear. In the next stage these pallid cells increase in number to form two or three rows from which columns of three or four cells may spring and project into the lumen. It is from the upper cells of these columns as well as from the inner layers lining the acini that desquamation occurs. This process and the collection of fluid distend the acini, forming small cysts. As the condition advances the walls which separate the neighboring acini disappear and a composite cyst is thus formed. These early states result in the later formation of the large cysts in the breast. These cysts are the 'blue-dome cysts' of Bloodgood.²

Although occurring predominantly in areas of cystic disease, small cavities lined with pale epithelium have been observed also in association with solid mammary tumors. Thus Krompecher reported 12 cases of pale epithelial cysts occurring with fibroadenomas among his previously mentioned 292 breast tumors, and Semb found 14 such cysts among 100 cases of fibroadenoma.

Pale epithelial cysts are most commonly met with in the fourth and fifth decades, at which ages the various forms of chronic cystic mastitis are most prevalent. However Kudjı (1921) has reported such cysts in a 14 year old girl who died of pulmonary tuberculosis before puberty, and Cheate and Cutler have stated that rarely mammary structures that resemble sweat glands can be found even in the breasts of infants at birth. In adults pale epithelium seems limited to the female in its distribution. Dawson has denied its occurrence in male mammary glands, as has Semb. The latter, however, has described true sweat gland cysts in the male, closely resembling the epithelial lining of fibroadenomatosis in the female breast.

ORIGIN OF PALE EPITHELIUM

The origin of pale epithelial structures in the mammary gland has been accorded various interpretations by different authors. These interpretations may be classified broadly into two groups: first, that the pale structures represent sweat gland epithelium, and second, that they are derived from true mammary epithelium.

The mammary glands have long been regarded as modified sweat glands (Benda, 1894). When von Saar called attention to the histological similarity between the pale epithelium of the mammary glands and that of the sweat glands, he regarded this as further evidence for the phylogenetic development of the mammary glands from the sweat glands of the skin. Creighton, in

1902, wrote a detailed account of his extensive studies of the sweat glands of mammals and emphasized their relation to mammary development. He believed that tubular glands with the structure of sweat glands were very commonly found in normal breasts as developmental anomalies and that they represented a reversion to a lower type of mammary gland. Similar views concerning the histogenesis of pale epithelium have been expressed by Kuru (1909), who compared it phylogenetically with sweat gland epithelium, and by Krompecher (1913, 1916). The latter author regarded pale cysts as sweat gland cysts and viewed their occurrence in the mammary gland as a manifestation of reversion.

A larger group of authors has vigorously opposed the belief that pale epithelial structures are aberrant sweat glands. The entire subject has been reviewed by Dawson (1932) who concluded that pale epithelium in the breast is derived from normal mammary tissue (ductile or acinar). Her study of sections of mammary glands at various stages of development gave no support to the view that sweat glands are normally included in the breast. Cheate and Cutler reported similar observations in 1931 and stated that whenever sweat glands resembling mammary structures were encountered they have always been in the extramammary subcutaneous tissue and not in the gland itself. These authors never failed to trace a direct anatomical continuity between the pale structures and the mammary ducts.¹ Dawson observed pale cells and normal mammary epithelium merging directly into each other in the same cystic acinus or duct, and in so doing confirmed the earlier observations of Wohlsecker, Semb, Delbet and Mendaro, and Kudjı. This was interpreted as a strong argument for the mammary origin of the pale cells. Krompecher, in 1924, also described both normal and pale epithelium contiguously lining the walls of mammary ducts and cysts, sometimes with almost imperceptible transitions between the two types of tissue. These observations prompted a revision of his previously published views concerning the histogenesis of pale epithelium, which he now regarded as derived from normal mammary structures. Other authors who concluded that the pale epithelium arose from the acini and small ducts of the mature breast include Berka, Prym, and McFarland.

There is general accord among those authors who would derive pale epithelium from true mammary elements, concerning the processes by which the changes occur. Dawson attributes the altera-

¹Ewing (1940) likewise observed glands lined with pale epithelium which emptied into the intralobular lacteal ducts of the normal breast but he regarded the former as sweat glands.

tions in morphology and staining affinities to degenerative changes which occur following antecedent stimulation of the epithelium. She found pale epithelial cysts predominantly associated with the glandular involution of the menopause. Thus she regarded the pale change as evidence of receding epithelial activity supervening on the proliferative states of the normal epithelium. Berkha had expressed a somewhat similar view in 1912. This author apparently found pale epithelium only in the breasts of women who had borne children, and considered such tissue a result of incomplete involution after pregnancy. McFarland regarded pale epithelial cysts as residual lactation acini. The mechanism by which the pale change occurs has been explained by Kodji as a temporary increase in the blood supply with resultant growth, followed by a secondary decrease in blood supply caused by hormonal withdrawal with resultant degeneration of the parenchyma.

A modified interpretation of pale epithelium has been advanced by Theile. He regarded this tissue as a special degeneration form of the mammary elements, differentiated from the normal cells by virtue of its greater growth energy (papillary formations) secretory activity (vacuole formation) and shorter life span (no large masses of cells despite rapid multiplication desquamation into cysts).

RELATION TO CANCER

The greatest interest in the nature of pale epithelium has centered about the long waged controversy concerning its possible relation to carcinogenesis in the mammary gland. Opinion has been divided into two main groups which have championed opposite views: that pale epithelium indicates a change either of early malignant neoplasm or with a definite possibility of subsequent transformation into cancer; and that the pale change is essentially degenerative, rather than neoplastic, with little or no possibility of subsequent malignant tumor.

The earliest claims for the carcinomatous nature of the large atypical pale cells having mammary cysts are found in the writings of Borst in 1904. Berkha, Kromsperger, Askanazy and Fraser in subsequent publications, have regarded pale epithelium as a precancerous alteration of mammary epithelium. In the series of breast tumors reported by Kromsperger pale epithelium was observed in 9 cases of cancer. Seimb found pale epithelium in 35 of 111 cases of cancer of the mammary gland. Dawson succeeded in demonstrating pale structures in 6 of 20 breasts containing malignant tumors. These observations

were interpreted as corroborative evidence of the pathogenetic relationship between pale epithelium and mammary neoplasms.

Ewing has stated that 25 per cent of mammary cancers are of sweat gland origin, and Lee, Pack, and Scharnagel have described 81 so called "sweat gland cancers" from Ewing's laboratory. Their findings, while not in themselves indicating a specific malignant tendency of pale epithelium, have at least shown this tissue to be susceptible of carcinomatous change. Chentle and Cutler also agree that these cells are the frequent site of origin of cancer of the breast, in agreement with Cohnheim's theory of malignant change from misplaced cell rests. Dawson on the other hand, has denied the existence of true sweat gland carcinomas of the breast.

Attention has been called to the morphological similarity between atypical pale epithelium and Paget cells. Seimb found pale cells present in the excretory ducts and milk ducts under the nipple and in 6 cases of Paget's disease atypical pale epithelium was found in the mammary tissue of all. He was thus led to state in 1928 that "from my investigations I assume that the proliferation in Paget's disease primarily begins with the growth of the atypical pale epithelium in the large milk ducts under the nipple. From here the proliferation as a constant rule extends to the epidermis of the nipple, with formation of the cancer tumor."

Other authors have denied, with equal emphasis, that pale epithelium is a sign of malignant new-growth or that it is in any way related to carcinogenesis. Mueller found areas of early cancer in the vicinity of the pale epithelial cysts in his case but denied a relationship between the two. Kuru interpreted the presence of pale epithelium in the mammary glands of children as evidence against cancer. The absence of ulcers and of invasiveness were pointed out by Kodji as additional features of pale epithelium suggesting its benignancy. Theile and von Saar among others, likewise denied any malignant tendencies of pale epithelium.

Seimb has clearly distinguished between the significance of the pale epithelium seen in mammary fibroadenomas and that occurring in areas of fibroadenomatous cystica. He observed small cavities lined with pale epithelium in 14 of 100 cases of the former but felt that no importance for the tumor formation could be ascribed to this epithelium since it occurred in too scant quantities in the separate tumors. Furthermore since fibroadenomas seldom go over into cancer neither could this pale epithelium be regarded as a sign

of "malign degeneration" in the fibroadenoma. In the cases of fibroadenomatosis cystica, on the other hand, small cystic cavities lined with pale epithelium were observed, with atypical changes and penetration of the basement membrane and distinct infiltrating growth. These changes were found in 9 of 24 cases. Semb, therefore, concluded that in these cases pale epithelium served as the starting point for cancer development.

ANIMAL STUDIES

Study of the published opinions of the aforementioned authors does not permit of definite conclusions concerning the nature of pale epithelium in the mammary gland, nor its biological or pathological significance. Because of the lack of agreement resulting from studies based on human pathological material, it is desirable to obtain evidence from other species resulting from an experimental approach to the problem.

Observations on the occurrence of "pale epithelium" in the mammary glands of animals other than the human are very scant. Fifer (1934) described cysts with hyperplastic and metaplastic epithelium (possibly pale) in the breasts of rabbits during the postlactation interval but not during periods of functional activity (estrus, pregnancy, pseudopregnancy, and lactation). These findings are in agreement with the concept of pale epithelium advanced by Dawson, Berka, and by McFarland, namely, that the pale change occurs as a result of receding epithelial activity following upon antecedent stimulation. Fifer observed similar pale changes, however, in the breasts of males and virgin females also.

In 1936 Macdonald reported areas of intracanalicular hyperplasia in the mammary glands of castrated rabbits receiving 25 to 200 rat units of estrogenic hormone daily. Some areas of the hyperplastic growth resembled pale epithelium. The following year similar changes occurring in mammary cysts were reported by Herold and Effkeman, who injected normal and castrated male and castrated female rats for periods up to 3 months with amounts of estrogens ranging between 50 and 1000 international units daily. However, such changes were rarely produced in the glands of intact females which were similarly treated.

PERSONAL OBSERVATIONS

In collaboration with Dr. Carl G. Hartman and Dr. Charles F. Geschickter, the writer has recently made a study of the effects of the long term treatment of rhesus monkeys with very large amounts of estrogenic hormones. These ob-

servations have already been reported briefly¹ and will be described in detail elsewhere.

The animals were treated by subcutaneous implantations of two estrone pellets weekly, weighing 3 milligrams each, and subcutaneous injections of 10,000 international units of amniotin (Squibb) every other day. Studies of the mammary glands include 32 specimens obtained from 15 females ranging in weight from 2,180 to 3,970 grams. Eight of the animals were surgically castrated immediately before the institution of estrogenic treatment, in the 7 remaining the ovaries were left intact. The specimens represent material obtained at autopsy or by repeated biopsies after periods of treatment ranging from 2 to 29 months.

Soon after the onset of treatment a marked hyperplasia with resultant stratification of the duct epithelium occurred. At the end of about a month the ducts began to dilate as the epithelial hyperplasia began to wane, and budding of the duct system occurred. Within 2 months evidence of early lobule formation was detectable. Development of the gland progressed thereafter in an orderly fashion to complete unfolding of the lobule-alveolar system. These developmental changes have been observed in the same animal by repeated biopsies at different stages of treatment.

This pattern of mammary development in response to estrogenic stimulation was found to occur with fair uniformity in all the animals, and appeared not to be dependent upon their weight or the presence or absence of the ovaries. On the other hand, the pale changes to be described occurred predominantly among the castrates. Of the 5 animals in which pale epithelium was observed 4 were castrates, an incidence of 50 per cent among this group, whereas pale epithelium was found only once in the mammary glands of the 7 noncastrated monkeys, an incidence of only 14 per cent. This finding is in agreement with the observations of Herold and Effkeman, who failed to detect pale epithelium among their intact estrogen treated female rats, whereas the mammary glands of the castrates developed cysts lined with pale epithelium.

Concurrently with the orderly development of the mammary gland just described, the pale cells made their appearance. They were seen at various stages after the 10th week of estrogenic treatment. In contrast to the cystic arrangement of the pale cells which has been described in pathological human mammary glands, the pale epithelium in our experimental monkey specimens appeared as small islets of these atypical cells usually compactly arranged, although there was occa-

Fig. 2 G2—castrate. Mammary gland biopsy specimen after 15 months of estrogenic treatment. Islet of pale epithelium adjoins dilated duct, center. Hematoxylin and eosin, X60.

sionally a suggestion of acinus formation. These groups of cells were irregularly spaced among the normal mammary lobules, with which they formed a sharp contrast (Figs. 1 to 3). Less frequently the pale cells were seen in the linings of the mammary ducts, merging and contrasting with the normal mammary epithelium (Fig. 3).

The cells were two to three times as large as the normal mammary cells, cuboidal or polygonal in shape. The nuclei were large, round, vesicular, hypochromatic, and contained prominent nucleoli. They were usually centrally but occasion-

ally basally located. The cytoplasm was very pale, faintly eosinophilic and appeared perfectly clear at low power magnification. At higher magnification the cytoplasm was found to be very finely granular, and in some instances contained vacuoles of varying size.

ANALYSIS OF STUDY

The metaplastic change in the mammary gland represented by the appearance of pale epithelium is interpreted as a specific response to intensive estrogenic stimulation. Of 474 specimens obtained from the breasts of 304 male and female rhesus monkeys under all sorts of physiological and experimental conditions, pale epithelium was found in none outside of the series here mentioned. The occurrence of this atypical epithelium in the glands of only those monkeys which had been treated with large amounts of estrogens points strongly to this hormone as the causative agent. Furthermore, since 4 of the 5 cases manifesting pale epithelium were among the castrated animals (which group constituted only a small proportion of the monkeys in the Carnegie colony), it is suggested that the absence of the ovaries may have been an important prerequisite factor for the attainment of this change.

In explanation of the pathological changes noted in their estrogen-treated castrated rats and the failure of those with intact ovaries to develop similar mastopathies, Herold and Eklman have stressed the importance of the corpus luteum. Functionally test tissue persisted in the ovaries in response to estrogenic stimulation, a phenomenon which was first demonstrated in the rabbit (Allen

and Heckel, 1936) The mammary glands of the intact rats were thus regarded as being under the balanced influence of estrogen and progesterone. In the castrates, on the other hand, the estrogens were allowed to exercise an unopposed effect upon the mammary glands. It is possible that estrogens stimulate the monkey's ovary, either directly or through the mediation of the pituitary, to produce progesterone or some other hormone, which may help prevent the appearance of the pale change in the macaque's breast. Since little is known concerning the effects of estrogens on the structure of the monkey's ovary, and even less concerning the effects upon ovarian function, however, this suggestion is to be regarded as purely speculative.

The changes which occur in the anterior pituitary following castration provide an alternative explanation for the high incidence of pale epithelium among the castrates in contrast to the noncastrated animals. After bilateral ovariectomy, profound alterations occur in the functioning of this gland. In the human, for example, increased quantities of pituitary gonadotropic hormone appear in the blood and urine. Specific cytological alterations occur at this time in the pituitaries of several species, including the rhesus monkey (Severinghaus, 1939). During the past few years a large body of suggestive evidence has accumulated attributing to the anterior pituitary specific mammogenic activity. Perverted pituitary function, in conjunction with the estrogens administered in the present experiments, may thus be responsible for the changes observed in the mammary glands.

An additional channel through which altered pituitary function may affect the mammary glands involves the mediation of the adrenals. The adrenal cortex produces estrogens, androgens, and other steroid substances which are effective stimulators of mammary growth (Speert, 1940). Yet adrenal function is, in turn, under control of the anterior pituitary. Thus under conditions of pituitary hyperactivity, augmented secretion by the adrenal cortex may ensue with resultant effects upon the mammary gland.

In addition to the pale changes described, two other somewhat similar alterations have been observed in the mammary glands of castrated monkeys receiving smaller amounts of estrogens. One occurred following the daily administration of 100 rat units of amniotin (Squibb) for a period of 6 weeks. Examination of the breast at the end of this period revealed a marked hyperplasia of the pale staining sebaceous apparatus in the subcutaneous tissue (Fig 4). This change is probably comparable to the condition which Florentin and Binder (1939) succeeded in producing in the guinea pig mammary gland by the injection of 55,000 international units of estrogenic hormone over a period of 6 weeks, and referred to by them as "sebaceous metaplasia."

The second pathological change likewise was found after a 6 weeks' period of estrogenic stimulation, this animal having been treated daily with 5,000 rat units of amniotin. A small adenoma about twice the size of the average mammary lobule and consisting of typical sweat gland tissue was found embedded in the substance of the mam-

mmary gland. It is shown in Figure 5 in relation to a normal mammary lobule and two hyperplastic ducts. The relative pallor of the sweat gland epithelium affords a definite striking contrast to the more darkly staining cells of the mammary gland.

Sebaceous hyperplasia and sweat gland adenomas were not found in any other mammary glands of the large control series previously mentioned. Yet the appearance in the breasts of these epithelial overgrowths, of sebaceous gland cells on the one hand and of sweat gland cells on the other, makes possible a morphological comparison of these cells with those comprising the pale epithelium. It becomes immediately apparent that we are dealing with three distinct cell types, the only common characteristic being that the cytoplasm of each stains less intensely than that of the normal mammary epithelium.

There is little cytological similarity between the pale epithelium¹ and that of the sweat glands in the monkey's breast. The cells of the latter are smaller, the cytoplasm more eosinophilic, and the nuclei smaller and more darkly staining. More closely on the other hand, do the "pale cells" resemble the cells of the sebaceous glands, although the latter too have smaller and more darkly staining nuclei.

We are thus led to the conclusion that the pale cells represent variants of the normal mammary gland cells. The characteristic appearance of the former results from the metaplastic change stimulated by the continuous and unopposed action of very large amounts of estrogens. The view that these cells arise from the mammary epithelium is strengthened not only by their morphological contrast with the other possible precursors, but also by their intimate relation to the normal elements comprising the mammary lobules and ducts (Fig. 3).

It is by no means certain that the many published papers dealing with atypical or pale epithelium have concerned themselves with the same cell type, for the illustrations accompanying the articles have been neither sufficiently numerous nor clear. Conclusions drawn from the present studies are, therefore, of limited applicability to the problems of pale epithelium as they exist in the literature. Yet it seems safe to conclude that the present experimentally produced pale epithelium is comparable to at least some of the lesions described in the human mammary gland, so closely do our specimens resemble some of the published illustrations of this condition (cf. Deibel and Mendaro, Fig. 7, p. 22). The common failure of ovulation to occur in premenopausal women

may give rise to a condition in the human comparable to that of our experiments, namely the continued unopposed action of high estrogen levels.

Carcinoma of the mammary gland has been produced in susceptible strains of mice by several investigators by means of various estrogenic hormones (see review by Gardner 1939). Geschickter had recently succeeded in inducing mammary cancer in rats also after intensive estrogenic treatment. Although the amounts of estrogens required for the production of malignant changes in the breasts of rodents are proportionately many times greater than the doses ordinarily used clinically in the treatment of patients, these studies have naturally brought into question the complete safety of prolonged estrogenic therapy in the human. Indeed isolated case reports (Allaben and Owen, 1939; Auchincloss and Haagemen, 1940; Parsons and McCull 1941) have suggested a possible carcinogenic action of estrogens on the human breast.

The present experiments were originally begun by Dr. Geschickter with the view of determining the possibility of producing cancer of the mammary gland in the rhesus monkey with estrogenic hormones. All the mammary specimens are therefore studied in great detail and pathological changes carefully sought. Aside from the transitory hyperplasia and dilatation of the ducts, the appearance of pale epithelium was the only pathological change noted in the breasts. The pale cells were of uniform appearance, gave no evidence of invasiveness, and no mitotic figures were seen among them. Among the animals that came to autopsy there was no suggestion of metastases. Thus no support can be offered for the view that pale epithelium, at least as it is observed in the mammary gland of the monkey, is in itself a malignant tumor type of epithelium or that it has any malignant tumor potentialities.

SUMMARY

The literature on "pale epithelium" in the human mammary gland has been reviewed. Changes resembling this condition have been produced in the breasts of rhesus monkeys by the administration of very large amounts of estrogenic hormones. These changes are observed predominantly among the castrated animals. Evidence indicates that pale epithelium represents a metaplastic alteration of normal mammary gland cells, but no support is offered for the belief that this change in the cells has a significance for the subsequent development of carcinoma of the breast.

PERSISTENCE OF TUMOR AFTER PREOPERATIVE RADIUM TREATMENT FOR CANCER OF THE CORPUS UTERI

M. S. DONOVAN, M.D. and SHIELDS WARREN, M.D. Boston, Massachusetts

RADIATION therapy has come to occupy a position of great value in the treatment of carcinoma of the body of the uterus. Aside from the fact that this is the only effective treatment available for patients who are inoperable because of local extent of the growth or for constitutional reasons, intrauterine radium therapy with or without external irradiation with roentgen rays, has been accepted in most large centers in this country and in Europe as an important preoperative measure. However the French cancer therapists in general do not subscribe to this view using radium and roentgen rays for palliation only of endometrial cancer. German radiologists have treated carcinoma of the uterine body since 1912 (9) and by 1915 this method was in use at other European clinics and in America.

Originally many cancer therapists felt that irradiation of endometrial cancer was unwise since surgical methods gave quite a satisfactory number of cures, and there was a widespread opinion that adenocarcinoma was not radiosensitive. However because many women with this type of cancer were inoperable some form of radiation therapy was used, and it soon became apparent that this type of treatment would effect a fair percentage of cures.

In 97 Heyman published a report from the Radiumhemmet in Stockholm which tended to give radiation as good a standing as surgery in the treatment of cancer of the uterine body (5). He first tabulated the reports of 38 patients treated by operation alone in 6 different European clinics, with an average 5 year cure of 4.8 per cent. Counting only the strictly operable cases the recovery was 58.8 per cent. He then reported 46 patients treated at the Radiumhemmet with intrauterine radium alone, with a recovery rate of 43.5 per cent. Twenty five of these patients were technically and clinically operable and of

these, 15 or 60 per cent recovered after radium therapy.

By 1933, Hurdon and Chambers were able to collect reports from Stockholm, Berlin, Munich, New York (Memorial Hospital) and Baltimore (Howard Kelly Hospital) totaling 359 operable cases of endometrial cancer treated by radiation methods. One hundred and ninety-six patients survived 5 years, 54.5 per cent, and of 381 inoperable cases, 42 or 11 per cent, lived 5 years.

Heyman, in reporting the technique of treating corpus carcinoma at the Radiumhemmet in 1935 (6) stated that he filled the uterus with small containers of radium, giving 2600-4000 milligram hours in treatments, plus one vaginal treatment to prevent metastasis in this location. If symptoms did not disappear or if new symptoms appeared such as bleeding, discharge, or an increase in size of the uterus, a total hysterectomy was done. In this paper he reported that in 48.7 per cent of 56 cases, patients were cured by radium therapy.

A year later Heyman (4) summarized the results of treatment in carcinoma of the body of the uterus for a 16 year period and showed that in both the technically and clinically operable groups the survival rate was better in those who had a hysterectomy than in those who were not operated on. He therefore advised that this operation be done on all patients who were suitable risks.

Irradiation, chiefly by intracavitary radium, followed in 4 to 8 weeks by panhysterectomy and salpingo-oophorectomy has been recommended in many recent publications as the treatment of choice for cancer of the uterine body (1,2,3,4,5). Miller agrees that a combination of irradiation and surgery is better than operative treatment alone but he believes that preoperative roentgen treatment is more efficacious than intrauterine radium and uses the latter only for obese patients and those who are inoperable. He reports 70 per cent of 34 patients as surviving 5 years after irradiation followed by surgery or 82 per cent if corrected for noncancer deaths. Healy and Brown reported 75 per cent of 8 patients well and free of cancer 2.5 years after a dosage of 3000-4000 millcurie hours of radon followed by panhysterectomy 1 to 4 months later.

From the Laboratories of Pathology, New England Deaconess Hospital, Collis P. Huntington Memorial Hospital, and Poughkeepsie Hospital.

We are indebted to the chief of the division of gynecology at the Palmer Memorial Hospital and Collis P. Huntington Memorial Hospital, Dr. George A. LeGrand, Jr. for permission to refer to the clinical data used. Dr. Joe V. Meyer will report later on the clinical aspects of the cases from the Poughkeepsie State Hospital for Cancer.

Masson and Gregg have reported that among 42 technically operable patients treated by irradiation alone, they obtained 50.5 per cent 5 year survival. They also stated "In our series the difference in five and ten-year cure after operation with and without irradiation is too small to be of significance."

The method of treating uterine corpus carcinoma at the Palmer Memorial Hospital has usually been an intrauterine radon treatment, followed by hysterectomy in the operable cases after an interval of 6 to 10 weeks. Dr. Meigs will report later on the type of treatment used at the Pondville Hospital. Because of the frequent presence of active carcinoma in these irradiated uteri when removed at operation, it occurred to us to check over the survival of tumor tissue in the specimens received in the pathological laboratories. In all, 46 cases are included. The various dosages of radon which were used are shown in Table I.

In all cases the diagnosis was made by microscopic examination of curettings prior to the insertion of radon. The latter was applied by means of various types of single applicators, of a length conforming to that of the uterocervical canal. In only 4 cases was there more than one application. Only those cases have been included in which the hysterectomy and salpingo-oophorectomy were done 6 weeks or more after the irradiation, so that there was adequate time for the full effect of the irradiation to become manifest. In one case the interval was 1 year because the patient was a poor operative risk due to obesity, but later lost weight. The longest interval was 2 years, as the patient refused operation and later changed her mind. Three patients had roentgen ray treatment in addition to the local radon, the reason in 2 of them being that they were originally diagnosed as carcinomas of the cervix.

Of the 46 cases summarized in Table I, it will be seen that only 5 uteri were free of carcinoma at the time of hysterectomy, 11 per cent. It is interesting to note that this figure of 11 per cent corresponds very closely to the average 5-year survival of 381 inoperable and irradiated cases reported by Hurdon and Chambers.

In our cases there was no special effort to find carcinoma in any of the uteri. Routine sections taken from what appeared grossly to be representative areas were examined and reported as showing carcinoma or no carcinoma. No further sections were made in any case which failed to show cancer in the first slides examined. The amount of tumor which was present varied from large amounts to scattered small foci of cancer in the

TABLE I—DOSAGE USED IN PREOPERATIVE RADIUM TREATMENT OF CARCINOMA OF CORPUS UTERI

Dosage in mc-hrs	Number treated	Uteri free of carcinoma when removed
1700-2000	1	1
2000-2500	6	1
2500-3000	6	0
3000-3500	18	1
3500-4000	13	2
4000-4500	2	0
Total	46	5

myometrium which would obviously have been sources of recurrence had the uterus been left *in situ*. In a few cases the cancer showed no detrimental effect from a radon dosage that clearly had damaged the myometrium and its vessels.

There is but little to be found in the literature on the persistence of carcinoma in preoperatively irradiated uteri. Arneson states that "Six patients received more than 3000 mg-hrs of radium. In 4 of these no tumor could be demonstrated in specimens taken 2 to 8 months after the intrauterine treatment. Active disease was found in every instance if the dose had been less than 3000 mg-hrs." But only 4 cases were included in the latter group. Healy and Brown studied 75 uteri after operation and said that "of six patients who received roentgen rays only, all showed residual carcinoma. In twenty-four cases in which the intracavitary radon dosage varied from 1200 to 2700 mc-hrs, complete regression occurred in only 12 per cent. In twenty-five cases in which the dosage was from 3000 to 3300 mc-hrs, there was complete disappearance of carcinoma in 52 per cent, while in twenty patients receiving 3400 to 4000 mc-hrs, 60 per cent showed no residual carcinoma." Thus, 40 per cent of their patients receiving the largest dosage showed residual carcinoma and this was an important factor in their conclusion that the uterus should be removed in all operable cases. In the discussion of this article, Dr. J. A. Corscaden said that of 21 uteri removed at his clinic following irradiation for carcinoma of the corpus, 8 were free of cancer.

There is no longer the unanimity of opinion about the merits of using intrauterine radium as a preoperative measure in the clearly operable patients which apparently existed a few years back. Miller states that the problem of adequately treating an endometrial cancer by radium has not been solved by multiple applications or by multiple applicators. He gives this as an important reason for preferring preoperative roentgen

TABLE II A—SUMMARY OF CASES

No. Patient, Age	History	Diagnosis on smears	Radon dosage in cc. hrs.	Interval between radon and operation	Operation	Laboratory report	Result
E. S. 52	Normal bleeding for years	Adenocarcinoma	700	8 mos.	Partial hysterectomy and bilateral salpingo-oophorectomy	Uterus 3 by 3 by 3 cm. Endometrium negative, radiation reaction of myometrium. Hydrosalpinx, left. Chronic cervicitis.	Well yrs. later
A. S. 56	Bleeding for 3 yrs	Adenocarcinoma	1412 plus 1000 for each of 4 periods	8 wks.	Same	Uterus 3 by 4 by 3 cm. Cervix negative. No radiation reaction with no radiation reaction, radiation reaction of myometrium, metastases to ovary.	Recovered from radiation; no later for metastases
S. C. 64	Bleeding for 3 yrs	Adenocarcinoma	52	8 wks.	Same	Uterus not measured, endometrium thickened to 1 cm. found 3-4 clusters of carcinoma cells in myometrium of myometrium, radiation reaction. Negative tubes and ovaries.	Well 10 yrs. later
A. W. 52	Discharge and bleeding for yr	Adenocarcinoma	2236	12 hrs.	Same	Uterus normal size. Endometrium greatly negative except for one slightly elevated area. Microscopic examination, negative and radiation reaction of uterus, negative tubes and ovaries.	Well yrs. later
L. C. 58	Irregular bleeding for yrs	Adenocarcinoma	1404	1 yr. mos.	Same	Uterus 3 by 3 cm. Radiation reaction and atrophy of endometrium. No malignancy negative tubes and ovaries.	Well 4 yrs. later
M. W. 51	Irregular bleeding during menopause	Adenocarcinoma	2076	6 wks.	Same	Uterus not measured. Larynx, one area of carcinoma with radiation reaction. Ovaries and tubes negative.	Well yrs. later
C. L. 54	Menstruating for years	Adenocarcinoma	136	mos.	Same	Uterus 3 by 3 by 3 cm. Adenocarcinoma with radiation reaction, endometrial myometrium, negative ovaries.	Improved 10 mos. later by treatment of radiation. Poor condition.
M. A. 54	Bleeding for yrs	Adenocarcinoma	150	mos.	Same	Uterus 3 by 3 by 3 cm. Adenocarcinoma with radiation reaction. One of uterus, larynx, negative tubes and ovaries.	Dead 10 mos. later
M. H. 61	Bleeding for mos.	Adenocarcinoma	1504	mos.	Same	Uterus 3 by 3 by 3 cm. Adenocarcinoma with radiation reaction.	Dead on 17th postoperative day. Tubes, peritoneum and ovaries negative.
A. M. 50	Bleeding yr	Adenocarcinoma	3600	wks.	Same	Uterus 3 by 3 by 3 cm. Adenocarcinoma with radiation reaction of uterus and superficial parts of vagina.	Well 10 mos. later
F. S. 56	Bleeding during menopause	Adenocarcinoma	177	8 wks.	Same	Uterus 3 by 3 by 3 cm. Adenocarcinoma with radiation reaction. Tubes and ovaries negative.	
M. K. 45	Bleeding for mos.	Adenocarcinoma	2150	wks.	Same	Uterus 3 by 3 by 3 cm. Atrophy of endometrium, one area of adenocarcinoma and early radiation reaction. Negative tubes and ovaries.	
M. T. 47	Bleeding for mos.	Adenocarcinoma	3600	8 wks.	Same	Radiation reaction of endometrium with some enlargement. Uterus showing radiation reaction.	all of mos. later

therapy The task of holding several applicators in place, especially when one cannot be sure what part of the uterus is involved by the tumor or how extensive it is, is rather formidable. This point was discussed at length by Sampson in 1934, who said, "Variations in the situation of the carcinoma

and the degree of its invasion, which can be realized only by the laboratory study of the ovaries, tubes, and uterus, often make the intimate application of the radium to all of the growth a matter of chance or even impossible." He conducted many tests on excised uteri, by filling the cavity

with sodium iodide solution, then placing radium capsules therein with every effort to distribute the capsules over the endometrial surface. Roentgenographs were then made so that the size and shape of the cavity as well as the distribution of the capsules, were revealed. He concluded that

at best, the adequate filling of the uterine cavity with the capsules is a matter of chance, even in uterine cavities not distorted by submucous myomas, polyps, and carcinoma. Benign uterine tumors are of course very common in the age group in which cancer of the endometrium occurs.

In 184 patients operated on for cancer of the corpus, Sampson found 13 cases of secondary cancer of the tubes and ovaries, in which locations the tumor could hardly be expected to receive an effective dosage from intrauterine radium. There were implants in the tubes and ovaries in 2 of our cases. This point has been mentioned by others as a further reason why hysterectomy should be done on all operable patients after irradiation. While in many cases the radium can, with proper technique, be placed in close proximity to the entire tumor there can be no certainty of it in an individual case.

From the material which has come to this laboratory one must conclude that even though the radium was placed close to the tumor as it must have been in a fair proportion of cases, an adequate dose was not delivered. It has been stated that 3500 to 4000 milligram hours should be the upper limit of dosage because of the danger of fistula formation, peritonitis, or other complication which will prevent subsequent hysterectomy or add to the dangers of it.

Heyman has used multiple applicators for the radium since 1934 and has found an increase in the survival rate since he changed from the single applicator technique (8). Thus, we may expect further improvement in the technique of preoperative radiation therapy for uterine body cancer and at present there is no agreement on the most satisfactory method. At present we have some advocating only intracavitary radium, then a combination of radium plus roentgen therapy and at least one author believing that roentgen rays alone should be used before operation (1). Still others believe that roentgen rays should be used after the removal of the radium-treated uterus.

In 1937 Heyman (7) reported on 65 patients treated at the Radnubhemmet by operation and postoperative irradiation. The latter consisted in most cases of one vaginal application of radium plus roentgen rays to 3 or 4 pelvic portals. The results were 78.5 per cent 5 year cure 6

per cent 10 year cure. Moreover this group included 10 patients who had a subtotal rather than a complete hysterectomy the chief reason for this being an error in preoperative diagnosis. He said, "On account of the results thus demonstrated, we feel justified in advocating that cases of corpus cancer suitable for operation should be operated upon and submitted to postoperative radiological treatment."

Also of interest in this connection is the opinion of Healy (12) expressed in 1940. He feels that in grade I and II carcinomas of the fundus, surgery should be carried out on the operable cases without preliminary irradiation.

Finally, we have Heyman's latest publication (8) in which he states that he is not yet ready to advocate that the primary radiological treatment necessarily should be preferred to hysterectomy. Further on he repeats, "We do not wish to draw any conclusions as to the superiority of a primary radiotherapy to a primary hysterectomy in the clearly operable cases. This from a person with one of the widest experiences in treating cancer of the corpus with irradiation. For the inoperable and technically operable patients he recommends his present method of packing the uterus with multiple containers of radium, followed by hysterectomy when possible, in case of failure to effect a cure."

It has been claimed that intra uterine radium therapy will lower the viability of tumor cells even though the cancer is not eradicated and hence make a postoperative recurrence due to implants less likely. Our observations show the tumor to have been eradicated in 5 of 46 cases only. The irradiated tumor in some appeared less damaged than the adjacent normal tissues, in others it was viable though reduced in amount. Even in the most favorable report on the incidence of persistent carcinoma in irradiated cervix, tumor tissue was present in over half the cases at the time of hysterectomy.

SUMMARY AND CONCLUSIONS

Radiation therapy has won for itself an important place as the treatment of carcinoma of the body of the uterus. In the inoperable and technically operable groups of patients it is the only curative form of treatment available and it provides about 1 per cent and 30 to 50 per cent 5 year survivals in these respective groups.

In the operable group of patients there has been a widespread opinion for some years that preoperative irradiation, chiefly by means of intra uterine radium, followed by hysterectomy and salpingo-oophorectomy 2 months later would

accomplish a higher percentage of cures than either irradiation or surgery alone. Accordingly, this has been advocated as the method of choice for treating this type of cancer.

3. More recent publications indicate doubt as to the wisdom of using preoperative radiation therapy as a routine measure in the operable cases. Good results have been obtained from a combination of surgery with postoperative roentgen irradiation.

4. Forty-six proved cases of carcinoma of the uterine body have been reviewed, all of which were treated by intrauterine radon and complete hysterectomy at least 6 weeks after the irradiation.

5. In only 5 cases was the uterus found to be free of carcinoma when removed.

6. This investigation does not throw light on the question of the value of radiation in preventing vaginal metastases.

7. In deciding whether or not to use preoperative radiation, the relative advantages of

possibly destroying the tumor or decreasing its chance of implantation must be balanced against the delay and inconvenience to the patient.

TREATMENT OF ACUTE APPENDICITIS AT THE UNIVERSITY OF MINNESOTA HOSPITALS

CLARENCE DENNIS M.D. FREDRICK B. MEARS M.D. and
BEATTIE H. RAMSAY M.D. Minneapolis, Minnesota

EACH year in the United States, from 12,000 to 20,000 people die of appendicitis (18). A review of reports from a number of clinics shows that nearly 90 per cent of the total deaths occurred in patients in whom the appendix had ruptured before medical aid was sought, a group comprising about a quarter of the total admissions. Among the patients in this collected series without clinically evident extension of the process beyond the appendix itself the mortality ranged from 0 to 0.8 per cent in the various clinics, while in those patients with extra-appendical extension, either with localization as in abscess formation or with spreading or generalized peritonitis, it ranged from 10 to 17.3 per cent, with an average of 14.3 per cent (2, 4, 8, 10, 12, 14). The overall mortality rate varied from 2.3 to 6.3 per cent with a mean of 4.1 per cent. In view of the increased mortality rate among cases with extra-appendical extension, we are reviewing the records of the University of Minnesota Hospitals particularly with regard to this group. In this group the statistics in cases of therapy by operative as contrasted to conservative measures may be compared in our own hospital.

ETIOLOGY

Many theories have been advanced to explain the occurrence of appendicitis. They vary from embolic infection to abnormal fat metabolism, obstruction of the lumen, but the only means by which appendicitis comparable to that seen clinically has been produced experimentally is through luminal obstruction. It has been shown at this clinic (6, 20, 21) that the disease may be produced regularly in man, the rabbit, and the chimpanzee by ligation obstruction of the lumen, spurring the blood supply. In these 3 species, the appendiceal mucosa is capable of secreting fluid against elevated pressures. In a large group of other species, among them the gibbon, none was found in which the appendix or cecal pouch had this property and in them appendicitis regularly did not follow upon obstruction (7). Dennis, Baile, Varco and Wangenstein have shown that in the

rabbit increased intraluminal pressure occludes some of the vessels in the appendiceal wall, leading to areas of ischemic necrosis, which offer an open field to whatever bacteria happen to be present, and which also offer weakened areas through which perforation may occur. Similar changes occur in man.

The nature of the obstructing mechanism in clinical appendicitis was found by Wangenstein and Bowers (19) to be cicatricial stenosis with or without fecaliths in 100 per cent of gangrenous specimens. In a group presenting acute inflammation without gangrene, longitudinal section after formalin fixation failed to show luminal obstruction in 18 per cent of the specimens. Dennis has presented evidence that many of this last group present a spastic muscular obstruction of sufficient degree to account for the appendicitis observed. Other mechanisms are occasionally found, such as kinks from adhesive bands. Edema of the lymphoid tissue of the appendix, paralleling general lymphoid enlargement, has been stressed by Gray and Helfetz. Finally a certain number of cases of appendicitis may rest on some basis other than obstruction.

FACTORS IN EXTRA-APPENDICULAR EXTENSION

A number of uncontrollable factors are involved in the occurrence of extra-appendical extension in appendicitis. Few if any, cases of appendicitis resulting from spastic or other low-grade obstruction proceed to perforation or gangrene (5). On the other hand, nearly all cases in which complete luminal obstruction has occurred, whether from stricture or from stricture plus fecalith, and in which the secretory capacity of the appendiceal mucosa is normal, proceed to perforation or gangrene when appendectomy is not performed.

The identity of the predominant organism in the appendiceal lumen at the time of onset of appendicitis is another uncontrollable factor, probably not of importance in the promotion of perforation, but certainly of great consequence with regard to the influence of the resultant peritonitis.

Two controllable factors are also of importance in extra-appendical extension: time and periga-

From the Department of Surgery of the University of Minnesota Medical School.

tion If appendectomy is performed early enough in the course of the disease, sufficient time for extension is not allowed Purgation after the onset of appendicitis is commonly considered to increase the mortality steeply Bower found that of those patients with acute appendicitis who took no cathartic, 1 in 80 died, of those who took one cathartic, 1 in 15 died, and of those who took more than one cathartic, 1 in 7 died In so far as we have been able to find, no evidence has been presented to show that rupture occurs earlier if cathartics are used Some experiments on rabbits suggest, however, that the increased mortality observed in man following the administration of cathartics in the presence of appendicitis may be explicable on the basis of increased bowel activity and consequent prevention of walling off of the process after perforation (6)

In many instances in which appendectomy is not performed, the inflammatory process subsides spontaneously Evidence has been found in the case of the rabbit that diminution or cessation of fluid secretion occurs under the influence of prolonged intraluminal pressure elevation insufficient to cause rupture (6) Similar though less conclusive evidence of such a diminution in secretion rate has been found in man Seepage of fluid through the appendical wall has also been shown to occur at the pressures involved (5) Such occurrences, as well as localization of the process by adhesions after perforation, go far to explain the success which follows the conservative treatment of late cases

DIAGNOSIS OF APPENDICITIS WITH EXTRA-APPENDICAL EXTENSION

The present policy at the University of Minnesota Hospitals is to perform appendectomy in all cases in which extension of the process has not occurred and in cases in which it is uncertain whether extension has taken place On the other hand, those cases which present evidence of spread beyond the appendix are treated by conservative means This policy requires some discussion of standards of diagnosis

Inasmuch as appendicitis is primarily a closed loop obstruction without interference with the main fecal stream, the initial findings are tenderness and more or less cramp-like pain, with localization of the pain in the right lower quadrant only after the elapse of some hours Only after the ischemic necrosis secondary to increased intraluminal pressure has set the infective factors in motion may one expect to find fever, increase in pulse rate, and elevation in the leucocyte count

The majority of patients with generalized peritonitis of appendical origin exhibit generalized abdominal pain and tenderness, absence of peristaltic sounds on auscultation of the abdomen, rebound tenderness without reference on both sides of the abdomen, tenderness on both sides on rectal examination, and distention

Localization of the process is indicated by limitation of rebound tenderness to the appendical region or reference of the pain to this region after sudden release of pressure from other areas of the abdomen Mass formation, palpable on either abdominal or rectal examination, is strong evidence of localization, but its presence is dependent on the duration of the illness

We have gained the impression that the condition within the abdomen may be accurately described in the majority of cases on the basis of history and physical and laboratory examinations Patients seen in the first 48 hours who present limitation of appreciable spasm, tenderness, and rebound tenderness to the right lower quadrant are considered free of extension of the disease, and are treated operatively Similar treatment is accorded such patients who in addition appreciate pain in the right lower quadrant upon sudden release of pressure from other areas of the abdomen The appreciation of pain at the site of sudden release of pressure from all areas in the abdomen is evidence of generalized spread and dictates conservative management Generalized spasm and tenderness appear after generalized nonreferred rebound tenderness and indicate a well developed peritonitis

If no other cause for fever and leucocytosis is present, and if, as is usually the case, the obstruction to the appendical lumen lies proximally and the bulk of the organ is therefore involved, the level of the leucocyte count is usually a reliable index of the presence or absence of gangrene, counts of 20,000 or more per cubic millimeter indicating gangrene Leucocyte counts much above this level often imply perforation in addition In the few instances in which only the distal portion of the appendix is involved, this is not a reliable index, the process usually being more advanced than the count would indicate

Elevation of the pulse above 120 per minute and fever above 102 degrees F, taken by mouth, are corroborative points strongly suggestive of extension

Signs, symptoms, and laboratory findings have been found to be very unreliable at the extremes of life, and we are more prone, therefore, to use operative therapy in these groups than in the middle age groups

TREATMENT OF APPENDICITIS WITH EXTRA APPENDICULAR EXTENSION

The loss of a few slightly ill patients with extra appendicular localized processes in 1931 and 1932 led to the introduction of conservative management for such cases at the University of Minnesota Hospitals. The wisdom of such a change is supported by the figures of Stanton, which show a rising mortality rate following appendectomy as the interval between onset of the disease and operation increases, a maximum being reached at 4 and 5 days. As Adams and Bancroft have indicated, conservative therapy at this hospital differs somewhat from that advocated by Ochser. Conservative treatment in the cases reported in the present paper includes the following items: (1) rest in bed, in the supine position (2) hot packs applied continuously to the abdomen (3) constant gastric or duodenal suction applied to an intubated duodenal tube (4) clear liquids by mouth in limited quantities—10 liters daily (5) parenteral glucose and sodium chloride solution sufficient to maintain an adequate urinary output (6) morphine or codeine as needed for pain (7) repeated small transfusions, as often as every day or two in the sicker patients (8) drainage of abscesses only if they cause appreciable fever or increase in pulse rate (9) sulfanilamide (used in only 6 of the 107 cases in this series) (10) oxygen occasionally and (11) maintenance of an adequate parenteral intake of protein nitrogen (as plasma) calories (as 20 per cent glucose solution intra-venously) and vitamins [This has been attempted in only the most recent cases, a small proportion of those reported].

When the temperature has returned nearly to normal and clamping of the nasal tube can be tolerated for several hours at a time suction is discontinued, and the oral intake is cautiously increased in the succeeding 3 or 4 days as far as a

soft diet, usually with an ounce of mineral oil twice daily. If this is tolerated, patients are dismissed with this diet and directions to avoid undue exercise. They are given appointments to return to the hospital in 6 weeks for appendectomy. Of the present group, only 13 per cent failed to keep the return appointment; one of these returned a year later with generalized peritonitis, which he again survived.

RESULTS

From January 1, 1935, to July 1, 1938, 1313 patients were admitted to the University of Minnesota Hospitals. They are classified into the following clinical diagnosis groups:

- A. Perforated appendicitis ("interval cases")
- B. Acute uncomplicated appendicitis, or
- C. Appendicitis with extra appendicular extension, rather
 - Group I. Those presenting appendicitis with extra-appendicular localization (abscess or localized peritonitis) or
 - Group II. Those presenting appendicitis with generalized peritonitis.

Of a total of 353 interval cases, the specimens from 30 were considered normal on pathological examination, and in the remaining 223 they were termed suppurative or healing (Table I).

There were 753 cases of clinically acute appendicitis without extension. In 72 the specimens were termed normal on gross and microscopic examination; these may have been errors in diagnosis, or possibly the condition was too early to present polymorphonuclear leucocytic infiltration of the appendicular wall (20). In 93 instances, healing processes or subsiding inflammation were found. In 463, acute suppurative appendicitis proved to be present, and in 124, frank gangrene had developed. In these 753 cases, 6 deaths occurred. The postmortem examinations established the following causes of death: paralytic ileus, acute right heart failure, cyclopropane death, bronchopneumonia and heart failure, 1; peripneumonia considered due to hypothalamic cysts, and portal vein thrombosis and uremia. All 6 deaths occurred in adults, the mean age being 35 years.

In the remaining 207 cases, a diagnosis of appendicitis with extra-appendicular extension was made in 178 on the basis of history and physical

As the statistics presented the term "interval cases" refers to patients treated conservatively elsewhere or in our department clinic, rather than conservatively in our hospital, and who have returned here for appendectomy. In our hospital, their original classification in the present presentation is the basis of the statistics. No such patients have been lost at appendectomy in this paper. As such patients have been lost at appendectomy in the past, it is to be expected that in the future, the statistics of the University of Minnesota will be more complete, and the statistics presented here will be more complete.

TABLE II—TREATMENT AND OUTCOME OF PATIENTS PRESENTING APPENDICITIS WITH EXTRA-APPENDICIAL EXTENSION*

Treatment	Group I Extra-appendicial localization				Group II Generalized peritonitis

Totals	130	100.0	4	2.88	68	100.0	13	19.1

*Of the 10 patients with extra appendicial localization treated by appendectomy with immediate drainage, 2 subsequently developed abdominal masses necessitating drainage by the abdominal route. Two conservatively treated cases were given paroral sulfanilamide solution. Of the 2 patients with generalized peritonitis that died following appendectomy with immediate drainage, both developed inflammatory masses after appendectomy, 1 of which was drained through the abdomen the other by colpotomy. Four conservatively treated patients with generalized peritonitis were given sulfanilamide; 1 died.

and laboratory findings, and in 29 instances upon laparotomy performed because doubt was present whether extension had occurred. There were 17 deaths in this group. Inasmuch as this is the group in which most of the deaths occurred, special emphasis will be placed upon it.

DETAILS OF MANAGEMENT OF CASES OF APPENDICITIS WITH EXTENSION

The details of management of the group presenting appendicitis with extension are given in Table II. Twenty-three patients, with extra-appendicial localization were subjected to immediate appendectomy, in 13 of these the wounds were closed without drainage and of these, 2 died. In the remainder drainage was applied and the patients survived. Six patients with generalized peritonitis also were subjected to immediate appendectomy, and all survived except 2 of the 4 cases in which the wounds were closed with drainage.

Most of the conservatively treated patients, whether with or without localization, recovered without drainage. Of those that were treated

TABLE III—ANALYSIS OF DEATHS IN APPENDICITIS WITH EXTENSION

	Group I Extra appendicial localization	Group II Generalized peritonitis ¹
Number of deaths	4	13
Number of adults	4	6
Number of children	0	7
Number of males	2	8
Number of females	2	5
Average age of adults— years	40	37.6
Average age of children— years	—	10.0
Autopsies—per cent	100	100

¹Two deaths in group I were ascribed to peritonitis; 1 to pneumonia and 1 to gas bacillus infection of the abdominal wall. Contributing factors were eversion perforation of the bowel, mechanical bowel obstruction, hydrothorax, and aortic aneurysm.

Ten of the 13 deaths in group II were ascribed to single dominant factors. These were peritonitis in 7 cases, paralytic ileus in 2 cases, and septicemia in 1. Contributing factors were perforation of the bowel, eversion, emphysema, lung abscess, liver abscess, thrombophlebitis, and hydrothorax.

with drainage, whether by laparotomy, colpotomy, or proctotomy, the numbers are too small to be of statistical significance (Table II).

Sperling and Myrick reported that the mean hospital stay in uncomplicated cases was 9.75 days, while in patients with extension the mean stay was 22.5 days, including the return appointment for appendectomy. In our series of cases of appendicitis with extension, the mean time was 17.7 days for patients with localization and 23.1 days for patients with generalized peritonitis. These figures do not include the return appointment for appendectomy. Conservative management is therefore a more time-consuming course to follow than immediate appendectomy.

COMPARISON OF CONSERVATIVE WITH OPERATIVE THERAPEUTIC RESULTS IN THE TREATMENT OF APPENDICITIS WITH EXTENSION

Of 29 patients with extra-appendicial extension treated by immediate appendectomy, 4 died, a mortality rate of 13.8 per cent. Of 178 cases in which the examiner felt sure that extension was already present upon admission, and in which conservative therapy was therefore used, 13 died, a mortality of 7.3 per cent. The mortality rate, moreover, was lower with conservative therapy in each group than with immediate appendectomy.

ANALYSIS OF DEATHS IN APPENDICITIS WITH EXTENSION

Of 69 children presenting appendicitis with extra-appendicial localization, none was lost, but in 70 adults in this category, the mortality was 5.7 per cent. The mortality rates in generalized peritonitis were 17.5 per cent among 40 children,

TABLE II.—SUCCESSIVE STUDIES ON MORTALITY FIGURES IN ACUTE APPENDICITIS AT UNIVERSITY OF MINNESOTA HOSPITALS

Types of appendicitis	1929-1939 (10)		1935-1935 (11)		1937-1939

	27	64	33.8	66	79	
Total	334	3.4	311.8	3.3	141	7.1

and 21.4 per cent among 38 adults. There were 86 males and 53 females with localization and 45 males and 23 females with generalized peritonitis. There was no significant difference between the sexes in mortality. All deaths in all groups of patients were followed by autopsy. An analysis of the deaths in our series of cases is presented in Table III.

CONSERVATIVE MANAGEMENT OF ADVANCED APPENDICITIS PREFERRED

The figures presented in the present paper are distinctly better than those reported from this clinic either by Taache and Spanio for the years 1920 to 1929, when all patients were appendectomized, or by Sperling and Myrick for the years 1932 to 1935, the period just after the introduction of conservative therapy for advanced cases (Table IV). Although a part of this improvement is due to inclusion of a larger number of less advanced cases in the present series, nevertheless the mortality rates in the cases with extra-appendiceal extension, whether localized or generalized, have fallen materially. Several factors are of importance. Blood transfusion has been more freely used in the first place, and greater care has been given to a proper salt intake and to a less extent to a proper caloric intake by the paroral route. It is felt that a large part of this improvement, however, is due to a more adequate understanding of the pathogenesis of the disease.

As stressed by Sperling and Myrick, abscesses are drained only by extraperitoneal routes and only when in addition to local evidence, fever and elevation of pulse and leucocyte count are present. The McBurney incision exclusively is used for appendectomy, for it gives adequate exposure and can easily be enlarged if need be.

The policy here is to omit drainage unless there is definite indication for it.

Although considerable improvement over previous results is reported in this paper, the experience of Thompson, Brabson, and Walker with the combined use of sulfanilamide and drainage at immediate appendectomy suggests that still more satisfactory methods of treatment of patients with appendicitis with perforation may be at hand.

In our group of children with localized processes we have had no deaths in the present series. We have gained the impression that conservative management is more efficacious in this group than in adults with localization or patients with generalized peritonitis, but our mortality data are not large enough to be statistically significant in this respect. Miller and his associates concluded that conservative therapy is more satisfactory for localized than for generalized peritoneal infection, and the data of Adams and Bancroft also support this conclusion.

Comparison of the results of conservative therapy with those of more radical methods both here and at most other clinics suggests that this is the method of choice in cases in which the process has spread beyond the appendix itself. This is borne out by the fact that there were 29 cases in the present group in which sufficient doubt concerning the exact status of the disease existed so that operation was performed and appendectomy done in the presence of abscess or peritonitis. In this group the mortality was 13.8 per cent. The mortality rate in the 178 conservatively treated cases with frank extension, and therefore usually with more advanced disease on the other hand, was 7.3 per cent. It is such data that cause us to favor the conservative management of advanced cases of appendicitis in spite of the extra cost in terms of patient, drugs, blood, and days in the hospital.

CONCLUSIONS

1. A review of 133 cases of clinical appendicitis in which patients are treated at the University of Minnesota Hospitals from January 1, 1935, to July 1, 1939, shows an overall mortality rate of 1.75 per cent.

Conservative management of the most advanced cases has been the rule. The mortality rate in cases with extra-appendiceal localization (localized peritonitis or abscess formation) was 3.6 per cent, and that in cases with generalized peritonitis was 9.1 per cent.

2. In spite of the fact that it requires the expenditure of more hospital days, drugs, blood, and

care, conservative therapy is probably the treatment of choice in cases of appendicitis with spread of the disease beyond the appendix itself

THE CIRCULATION IN NORMAL AND VARICOSE VEINS

RICHARD E. HELLER, B.S. M.D. Chicago, Illinois

A RECENT review of the literature on the physiology of varicose veins of the leg describes certain phases of the problem which need further clarification (5). Herein is reported the first of a series of studies which have been undertaken to establish a clearer picture of fundamentals and a sounder foundation on which to base treatment.

ANATOMY

The anatomical relationships in the leg are well adapted to perform the necessary functions of that structure, yet because of the close integration of the units involved in the venous circulation, relatively mild interference with these elements will often disrupt the activity of the whole mechanism. It is not proposed to cover completely the anatomy of the veins of the leg, but to indicate the intimate co-ordination existing between veins of the foot and leg with the muscles and fascia.

The superficial veins arise from the dorsal superficial arcade of the foot. This arch lies upon the extensor tendons of the toes which in turn cover a deep group of veins consisting mainly of the *dorsalis pedis* (from which arises the anterior tibial) and numerous perforating vessels. On the plantar surface there is an arcade located at the level of the metatarsophalangeal joints and consists of a large lateral and a smaller median vessel. Communicating veins connect the plantar arch with the dorsal plexus to form a complete circle around the metatarsal bones. In addition, the lateral plantar vein anastomoses with the *dorsalis pedis* through a large vessel which perforates the foot at the base of the first interspace (between the first and second metatarsals).

Around the ankle is a complex and variable series of anastomoses of the long and short superficial veins with both the anterior and posterior tibial vessels (Fig. 1). These communications are adapted to serve as auxiliary or by-pass channels should some local obstruction arise as after a fracture or thrombosis.

In the leg there are three main deep venous trunks. The anterior tibial vein arises from the *dorsalis pedis* and passes upward under the ten-

dons of the long extensors of the toes and onto the lateral surface of the tibia and the anterior surface of the interosseous septum. It passes through the septum near the head of the tibia and empties into the lowest segment of the popliteal vein. The posterior tibial, formed mainly from the plantar tributaries, passes upward along the posterior surface of the septum and enters the popliteal at or near the junction of the anterior tibial. A third channel, the peroneal arises just above the ankle posteriorly and ascends parallel to the peroneus muscles to empty into the popliteal vein at the same level as the two other trunks.

In addition to these *intermuscular* veins, there are important *intramuscular* channels which are of two types. In all the muscles of the leg except the *gastrocnemius* and *soleus* there are numerous fine veins which leave the muscle at right angles to the fibers. The branches of these vessels form a network within the muscle so that a series of arcades connect with the main trunks. These are the *capillaries* which may enlarge and form new channels if an obstruction should occur.

Dissection of the veins within the *gastrocnemius* and *soleus* shows an arborized plexus of large thin walled vessels which traverse nearly the length of the muscle belly and exit close to the upper pole (Fig. 1). These veins are most effectively emptied by muscular activity and contribute a great deal to the maintenance of the normal velocity of flow.

It is well established that muscular activity is a major force in the propulsion of venous blood. The *gastrocnemius* and *soleus* have attachments which make them particularly effective for this purpose. They have a very large range of motion and consequently an unusual ability to exert effective compression.

Around the leg is a strong layer of fascia (*fascia cruris*) which forms a semicircular, rather inclusive envelope. This layer is continuous with the *fascia lata* and with the deep fascia of the foot. It is attached firmly along the anterior margin of the tibia, to the bony prominences of the knee, and to the malleoli to form a chamber which almost completely encloses the deep structures of the leg. This layer tends to limit the effect of contracting muscles to the elements enclosed. Veins outside the fascia are tightly supported and tend to move away when the thickened muscle belly begins to

Note particularly the arrangement of tributary communications

compress the vessel. Therefore, the superficial veins are less completely emptied by this force than are the deep.

In the thigh there is a similar though less perfect system. Large veins are present within the muscles and between muscle planes (especially of the quadriceps group) so that activity probably effectively empties them.

THE VELOCITY OF CIRCULATION

It is universally accepted that gravity is most important in impeding the venous return. In the

erect position, blood must be elevated against a pressure of 5 centimeters of water. This is accomplished by the action of muscle groups segmented along the major trunk veins. Muscles supply a propelling impulse which is effective by valvular control of the direction of flow.

Circulation time studies emphasize the importance of gravity on the venous circulation. Sweeney, and Toth, using the tilting table, found that the circulation time (foot to thigh)

TABLE 1—LEG TO THROAT CIRCULATION TIME (WITH NEO CALGLUCON) 40 INDIVIDUALS WITH VARICOSE VEINS, STANDING POSITION

Case	Trendelenburg test	Rate of vein	Time from beginning of injection to appearance of sensation		Effect of muscular activity
	Negative	++	23 sec.		Kicking intensif. of sensation
	Negative	++	min.		Kicking intensified sensation
	Negative	++	min. 45 sec.		Kicking did not affect sensation
	Negative	++	3 min.		Kicking intensified sensation
	Negative	++	3 min.		Walking did not increase sensation
	Positive	+	57 sec.		Walking increased sensation
	Positive	++	min.		
	Positive	+	min. 33 sec.		Kicking not needed sensation
	Positive	++	min. 44 sec.		Standing on toes increased sensation
	Positive	+	min.		Kicking intensified sensation
	Positive	+	min. 40 sec.		Walking increased sensation
	Positive	++	min.		Standing on toes increased sensation
	Positive	+	5 min.		
14	Positive	++	min.		Walking did not increase sensation
	Positive	+	min.		Standing on toes increased sensation
15	Positive	++	min.		Standing on toes increased sensation
17	Doubly positive	++	sec.		Standing on toes increased sensation
18	Doubly positive	++	min.		Walking intensified sensation
19	Doubly positive	++	min.		Walking did not increase sensation
20	Doubly positive	++	9 min.		

Blood reaction

	Positive	++	No sensation within 1 min. after injection	Still no reaction after walking around for 10 min.
	Positive	+	No sensation within 10 min. after injection	Walking did not bring on reaction
	Positive	++	No sensation within 10 min. after injection	No reaction after 10 min's walk
	Positive	++	No sensation within 10 min. after injection	No reaction after 5 min's walk
24	Positive	++	No sensation within 17 min. after injection	No reaction after 10 min's walk
	Positive	++	No sensation within 10 min. after injection	Walking did not bring on the reaction
26	Doubly positive	+	No sensation within 10 min. after injection	

The effect of muscular activity on amplifying of the superficial veins

17	Negative	++	No sensation within 10 min. after injection	Appeared immediately after kicking 3 times
26	Positive	+	No sensation within 10 min. after injection	Appeared immediately after kicking 10 min.
29	Positive	++	No sensation within 10 min. after injection	Appeared immediately after kicking 10 min.
30	Positive	++	No sensation within 10 min. after injection	Appeared immediately after kicking 5 times
31	Negative	++	No sensation within 10 min. after injection	Appeared 10 sec. after kicking 10 min.
	Negative	++	No sensation within 10 min. after injection	Appeared 10 sec. after standing on toes 10 min.
33	Positive	++	No sensation within 10 min. after injection	Appeared 10 sec. after standing on toes 10 min.
34	Positive	+	No sensation within 10 min. after injection	Appeared 10 sec. after standing on toes 10 min.
35	Negative	++	No sensation within 10 min. after injection	Appeared immediately after kicking 10 min.
36	Negative	++	No sensation within 10 min. 30 sec. of injection	Appeared immediately after kicking 10 min.
37	Positive	+	No sensation within 10 min. 37 sec. of injection	Appeared immediately after kicking 10 min.
38	Positive	++	No sensation within 10 min. after injection	Appeared after standing on toes 10 min.
39	Positive	+	No sensation within 10 min. 40 sec. after injection	Appeared 10 sec. after kicking 10 min.
40	Doubly positive	++	No sensation within 10 min. after injection	

in variability of this test is so great that only general conclusions may be drawn from the results.

vertical position was as much as 6 times slower than in the horizontal. Readings in the horizontal varied between 20 and 40 seconds. In the vertical, in 11 cases, the circulation was so retarded that no sensation was elicited after 221 seconds. However, when these cases were returned to the horizontal, a strong reaction appeared within 10 to 41 seconds.

Bock, Dill, and Edwards likewise found marked slowing in the erect position. In some cases, a standing circulation time of 5 to 7 minutes was noted. In others, no reaction was noted when the subject was standing, yet when he assumed the horizontal, it appeared within 25 seconds. Thus, in the normal long saphenous vein, gravity markedly retards the flow when there is little or no muscular activity.

A study of the rate of circulation in varicose veins has yielded further information on the effect of gravity and the pumping action of the muscles. Five cubic centimeters of 20 per cent calcium gluconogalactogluconate, so called neocalglucon, was rapidly injected into varicosities in the calf of the leg. The circulation time was taken from the beginning of the injection to the moment when the sensations of warmth and sweet taste were noted by the individual. All patients were tested in standing position. Results are shown in Table I.

These records indicate that the velocity of flow in varicose veins is variable, though generally slower than in the normal (2, 9). There is apparently little correlation between the size of the vein and velocity. In 6 of 26 cases, blanks occurred, that is, the subject noted no sensation after standing quietly or even walking around. This is evidently due to dilution of the solution as it is slowly carried upward. A concentration is reached which is below the threshold of the reaction.

In most cases the effect of muscular activity on the emptying of the superficial veins is nicely demonstrated. Kicking, standing on the toes, or walking, intensified the reaction once it had appeared. In other individuals, if no sensation was noted within 2 minutes, the reaction could be brought on almost at once by some muscular activity.

This study clearly indicates the unusual degree of stasis in varicose veins in the erect position, and the rôle of muscular activity in overcoming the effects of this load.

DIRECTION OF THE CIRCULATION IN VARICOSE VEINS

The relation of the direction of flow to valvular incompetence is not established by the circulation

TABLE II—SPECIFIC GRAVITY OF SOLUTIONS PREVIOUSLY USED TO DETERMINE THE DIRECTION OF CIRCULATION IN VARICOSE VEINS

Investigator	Solution	Concentration per cent	Specific gravity
	Diodrast	35	1.185
Pomeranz and Tunick McPheeters, Merkert and Lundblad	Skiodan	40	1.258
Veal and Van Werden	Thorotrast	25	1.270
Patey, Tatham and Nicholas Herlyn	Uroselectan (Neo-Iopax)	50	1.335
McPheeters and Rice	Lipiodal	40	1.302

These determinations were made at room temperature (85 degrees F) by the pycnometer technique. Note the weight of these solutions as compared with blood which has an average specific gravity of 1.055.

time method. It has long been known that when a person with incompetent veins stood up, there was a rush of blood from above downward. This led to the vicious cycle theory (reversed circulation) which was substantiated by observations on the movement of x-ray opaque fluids injected into saphenous varicosities in the erect position. The greater mass of evidence (6, 10, 11, 12, 13, 17) favors a continuous reversal in the direction of flow in incompetent veins. However, these studies are open to criticism because of the high specific gravity of the solutions used. Schmier injected an iodized oil having nearly the same specific gravity as blood and observed a central flow in the erect position and in spite of incompetent valves. Loehr and Toelle obtained similar results with another type of opaque medium.

In order to explain the discrepancy, the specific gravity of the solutions used by past investigators was determined (Table II). All those which appeared to be carried downward were found to be considerably heavier than blood and would naturally sink through a less dense medium. These solutions would have to be diluted from 2.4 to 5.1 times to obtain the same specific gravity as blood.

It was, therefore, decided to repeat this type of experiment with a preparation having a rigidly controlled specific gravity. A sterile aqueous solution of sodium iodohippuric acid, known as hippuran, was made up with a specific gravity approximating that of the patient's blood.

Our patients were placed in the standing position for 5 minutes, after which time a sample of blood was drawn from the varicosity. The specific gravity was immediately determined by

Fig. 3. a, Film showing soft tissue detail before injection. b, At the end of an injection of 3 cubic centimeters of hippuran, with tourniquets placed above and below the puncture site intruts after removal of the tourniquets, c, 3 minutes after injection. The solution has remained practically stationary though it is slowly being diluted. Specific gravity of blood .051; of solution, .053. In all films, the site of injection is marked with lead O.

the falling drop method (without the use of anti-coagulants). In addition, the specific gravity of each ampule of test solution was determined. Roentgenograms were taken as the injection was completed and after various intervals. Test films of uninjected varicosities were also exposed to determine the degree of detail produced by the technique used. This was necessary because of the soft shadow thrown by the diluted hippuran solution.

PROTOCOLS

CASE 1. Normal saphenous vein injected with 3 cubic centimeters of solution at level of calf of leg. A film exposed at the end of the injection shows rapid filling of the vein and tributaries above the point of injection. A second film exposed 3 minutes later shows only a trace of hippuran.

CASE 2. Varicosity of the long saphenous vein with positive Trendelenburg test. Size of vein, 4+. Specific gravity of blood, .051; of solution, .053. Three cubic centimeters of solution was injected at level of the calf of the leg. A film exposed at the completion of the injection showed filling of the vein about 3/4 inches below the point of injection and 3 1/2 inches above. Ten minutes later traces were still present above the site of injection, but none as seen below.

CASE 3. Varicosity of the long saphenous vein with positive Trendelenburg test. Size of vein, 3+. Specific gravity of blood, .051; of solution, .053. Three cubic centimeters of solution was injected into the calf region after tourniquets had been placed above and below the site to localize sharply the opaque medium. A film exposed at the end of the injection showed heavy concentration in the vein around the needle. The tourniquets were removed and after 3 minutes another film was taken. This showed no change in the position of the solution. A film

exposed 5 minutes after injection demonstrated trace above the point of injection.

CASE 4. Varicosity of the long saphenous vein with positive Trendelenburg test. Size of vein, 4+. Specific gravity of blood, .051; of solution, .053. In order to reduce dilution of the medium the tourniquets were placed 4 inches apart around the calf and cubic centimeters of blood was aspirated from the intervening segment of varicosity. This was replaced with 3 cubic centimeters of hippuran. The tourniquets were removed and 3 minutes later film was exposed. This showed heavy concentration of the solution at the level of injection. Three minutes later and after a 30 foot walk, the hippuran as found above the site of injection. Six minutes after injection, and after total walk of 50 feet, the medium as seen in the same position but more dilute.

CASE 5. Varicosity of the long saphenous vein with positive Trendelenburg test. Size of vein, 4+. Specific gravity of blood, .051; of solution, .053. Eight cubic centimeters of hippuran was injected at calf level above the site of tourniquets. At the end of the injection, the solution appeared 3 inches above and 3/4 inches below the needle. Ten minutes later trace was still present above but none below.

CASE 6. Varicosity of the long saphenous vein with positive Trendelenburg test. Size of vein, 3+. Specific gravity of blood, .051; of solution, .053. Three cubic centimeters of solution was injected at calf level above the site of tourniquets. At the end of the injection the solution appeared 3/4 inches above and below the needle. Ten minutes later and after 5 foot walk, trace was still noted above but none below.

CASE 7. Varicosity of the long saphenous vein with positive Trendelenburg test (both legs). Caliber of the veins of both legs, 4+. Specific gravity of blood, .051; of hippuran, .053. Two cubic centimeters of solution was injected into each leg. After injection of the right leg, the medium was found 4 inches above the needle. Five

Fig 3 Case 4 a, Film showing soft tissue detail before injection. Tourniquets were then placed 4 inches apart around the calf of the leg and 10 cubic centimeters of blood was aspirated from the intervening segment of varicosity. This was replaced with 10 cubic centimeters of hippuran and then the tourniquets were removed. b, Film exposed 1 minute after removal of the tourniquets, c, 3 minutes after injection and a twenty foot walk, d, 6 minutes after injection and a total walk of 50 feet. Note that there is little shift in position of the solution but it has become more dilute. Specific gravity of blood 1.051, of solution, 1.053.

minutes later a trace was still present in the same position. One minute after injection of the left leg the solution was noted above the point of the needle. The patient was told to strain as at stool and another film was exposed which showed movement of the hippuran downward.

CASE 8 Saphenous varicosity having a positive Trendelenburg test. Caliber of vein, 3+. Specific gravity of blood, 1.053, of solution, 1.054. Four cubic centimeters was injected. After injection the solution appeared 1½ inches above and below the needle. Five minutes later a trace was still present above but none below.

CASE 9 Saphenous varicosity having a positive Trendelenburg test. Caliber of vein, 3+. Specific gravity of blood, 1.053, of solution, 1.054. Five cubic centimeters was injected just above knee. At the end of injection the solution appeared localized at the site of the needle puncture. Five minutes later a trace was still noted in the same place.

CASE 10 Saphenous varicosity with a positive Trendelenburg test. Caliber of vein, 4+. Specific gravity of blood, 1.053, of hippuran, 1.054. Four cubic centimeters was injected. After injection, the solution appeared in the vein at the level of the puncture. Five minutes later a trace of the hippuran was still present above the level of injection.

CASE 11 Saphenous varicosity with a positive Trendelenburg test. Caliber of vein, 4+. Specific gravity of blood, 1.053, of hippuran, 1.053. A film exposed after injection of 3 cubic centimeters showed all of the material above the needle. Five minutes later, a trace was still present in the same position. After elevation of the leg and then a wait of a few minutes, a second injection of 5 cubic centimeters was given at the same level. Three minutes afterward all of the solution was found above the point of introduction.

CASE 12 Saphenous varicosity with a doubly positive Trendelenburg test. Caliber of vein, 4+. Specific gravity of blood, 1.057, of hippuran, 1.057. Three cubic centimeters was injected. At the end of the injection the solution appeared above and below the site. Five minutes later a trace was still present in the same location. After kicking ten times there was still a trace present.

The accompanying roentgenograms (Figs 2 to 5)¹ substantiate the observations of Schmier, and Loehr and Toelle, and indicate the following:

1 In the normal saphenous vein in the erect position, there is a moderately slow centrally directed flow.

2 In varicose saphenous veins where the valves are still competent, the circulation is centrally directed but the velocity of flow reduced.

3 When the valves are incompetent, the circulation is nearly stationary. There is a very slow upward flow when the upright state has been maintained for a period of time sufficient to allow for complete filling of the vessel.

4 Walking does not markedly affect the direction of flow in the saphenous trunk above the calf of the leg as shown by the movement of the hippuran solution.

5 Coughing or straining rapidly and readily reverses the direction of flow and forces the

¹The roentgenographic studies were carried out at The Chicago Memorial Hospital where Dr. George Landau very graciously supplied necessary technical assistance and aid in interpretation of films.

Fig. 4. Case 6. a, Films exposed immediately after an injection made without the use of tourniquets. b, Fifteen minutes after injection. The fluid has moved upward but is still present in moderate concentration. Specific gravity of blood .33 of solution, .054.

opaque medium downward below the point of injection.

ANALYSIS OF STUDY

The structures of the leg are closely integrated so that the extremity forms a delicate though efficient machine. Muscles, fascia and veins have interrelated functions necessary for the maintenance of normal circulation. The pumping action of the leg muscles—especially of the gastrocnemius and soleus—is made more effective by the heavy layer of crural fascia which controls the application of muscle forces, and by valves which control the direction of flow.

Muscular activity is particularly important in overcoming the heavy load which gravity imposes on the return circulation when in the erect position. The hydrostatic head elevates the venous tension which in turn forces an increase in capillary pressure sufficient to maintain the flow of blood. The capillary pressure thus remains slightly higher than the venous tension at all times. When the patient is standing quietly the venous pressure may be elevated enough to diminish the velocity of flow to half that in the recumbent position (2, 4, 10). This change in pressure and velocity is accompanied by the collection of blood in dependent portions of the body and loss of protein-free fluid from the blood into the tissues.

Fig. 5. Case 7. a, One minute after injection of the left leg. b, Film exposed while patient is straining as at stool. The hipbones has been forced downward by the increased intra-abdominal pressure. Specific gravity of blood .33 of solution, .53.

Loss of fluid occurs as the pressure in the venous segment of the capillary is elevated to the point where blood pressure is higher than the colloid osmotic pressure. Landis directly measured normal capillary pressures and found an average of 43 centimeters of water pressure in the arteriolar limb and 3 centimeters in the venous side. The colloid osmotic pressure of the blood is normally 35 to 36 centimeters of water. Therefore, the pressure on the arteriolar side is 7 or 8 centimeters higher than the osmotic pressure (producing filtration) and on the venous side 9 to 20 centimeters lower (facilitating absorption). Krogh, Landis, and Turner have calculated that an excess filtration would occur at about 25 centimeters of water pressure or possibly even less because venous congestion would raise the pressure of the arterioles as well as the venules. The average normal venous pressure in the upright inactive state is well above this level as demonstrated by the experiment of Carner and Rehberg. An individual was placed standing on one foot on a low chair. The other leg hung relaxed over the edge. At intervals, venous pressures were determined on the dorsum of the relaxed foot. At the outset there was 86 centimeters of water pressure in 5 minutes, 97 centimeters and in 6 minutes, 100 centimeters. After this there was little change. During this period, fluid was lost from the blood as shown by measure-

Fig 6 Diagram of the normal venous circulation of the leg as interpreted from a mechanical point of view. Muscular activity acts as a pump which, during the compression phase, forces blood upward in the deep veins (and to a lesser extent in the superficial), and during the expansion stroke aspirates blood from the superficial veins and capillary bed. Valves prevent transmission of the compression force backward to the capillary bed and superficial veins, and support the column of blood above the active muscle elements. The saphenous trunk in the upper thigh acts mainly as an overflow pipe to carry off that blood which is not removed through the communicating veins.

Incompetence of the valves in the superficial veins permits blood to flow downward when patient moves from the recumbent to the erect position. As soon as the vessel becomes filled the flow reverses to proceed in the normal central direction. The central flow is produced and maintained by the influx of blood from the capillary bed. A rather unstable balance is thus set up which may be readily reversed. Coughing or straining, by increasing the intra abdominal pressure, may force the blood backward and down the incompetent channel. No vicious cycle exists because the superficial vessels receive more blood from the capillaries than is aspirated through the communicating veins. A continuous retrograde flow could be maintained only if blood were aspirated into the deep veins faster than filling occurs from the capillaries. Incompetence of a communicating vein impairs the pumping action of the muscles because with each compression blood is forced outward into the superficial channels rather than toward the heart. This may interfere with capillary function and produce a gross edema.

ments of the foot. At the beginning of the experiment the circumference of the foot was 27 centimeters and 15 minutes later 29 centimeters.

Thompson, Thompson, and Dailey have calculated that an average of 11 per cent of the total plasma volume may be lost in the upright inactive state in 20 to 30 minutes. Edema of the legs is not observed during walking or other muscular activity because peripheral venous pressures are reduced to a level below the critical stage.

The pumping action of muscles affects the superficial veins differently than the deep. During contraction blood is squeezed out of the deep vessels and to a lesser extent out of the superficial. During the relaxation phase, the pressure in the deep veins is reduced so that blood is aspirated into them from the capillary bed and superficial channels by way of the communicating veins. It is this aspirating action which lowers venular pressures to the level at which capillary filtration and absorption may proceed normally. This action is dependent upon proper functioning of the valves in the communicating and deep veins. Should their action be impaired, as after a thrombophlebitis, edema is apt to appear.

Because of the architectural arrangement of muscles, fascia, and veins, most of the pumping activity is confined to the lower leg. This is particularly true of the effect on the superficial trunks. The saphenous vein in the thigh is buried in soft fat, poorly supported, and provided with only a few communicating veins. Consequently, there is little compression of the vessels and limited aspiration.

All superficial veins may be considered as auxiliary to the deep channels and capable of assuming the burden of the venous return should the need arise. These vessels empty by way of either the perforating veins or through the femoral vein into the femoral or its deep tributaries. The fact that frequently the long saphenous has a smaller caliber at the femoral orifice than lower down in the leg suggests that most of the blood in the trunk vessel is carried back through the communicating veins of the leg and that the trunk in the upper thigh acts merely as an overflow pipe. Figure 6 is a diagram in which an attempt is made to illustrate the mechanical arrangement of this system.

Varicosities of the saphenous system involve segments of either the trunk vein or its tributaries or both. The anastomotic portion may be considered as a simple tank or reservoir having little control over the circulation of fluid within it. This pathological arrangement is associated with pooling of large volumes of blood, slow emptying of

the vessel, eddy currents due to tortuosity and roughening of the intima, and fluctuations in pressure. When there is valvular incompetence (most cases) there is a loss in the stability of the circulation. Pressure changes which have little effect in the normal readily obstruct and reverse the direction of flow.

SUMMARY

Muscular activity is a major factor in maintaining normal capillary filtration and absorption in the erect position, and is the only mechanism which prevents the load imposed by gravity from disrupting the function of the leg.

In the recumbent position there seems to be little difference between the circulation of normal and varicose veins. However, when the individual with incompetent veins stands there is an immediate rush of blood from above downward until the empty vessel is filled. Once this is complete, there is established a slow flow in the normal direction. In some patients when standing quietly it may take 10 or more minutes for the saphenous trunk to empty whereas walking or other muscular activity aspirates an appreciable volume of blood from the superficial veins and augments emptying.

This central flow is in contradiction to the vicious cycle theory. Because of the extensiveness of the capillary bed, the limitations on muscular activity and the relatively small caliber of normal communicating veins, only a portion of the blood is aspirated, and enough remains to fill the vessel and produce a slow flow upward. To maintain a continuous flow down the saphenous trunk, the communicating veins would have to draw off more blood than enters the trunk from the capillary bed. Even the increased aspiration produced by walking did not force the hipponic solution downward.

Increasing the intra-abdominal pressure by coughing or straining may partially collapse the inferior vena cava and cause the transmission of a surge in pressure down the incompetent trunk (Adams) and temporarily reverse the direction of flow. It is evident that, because of the lack of support, the superficial venous tree is particularly vulnerable to variations in pressure.

Stasis pooling of blood, and the trauma of pressure surges are believed to contribute to the development of phleboecrosis and intimal damage. These changes make the vein ready site for the onset of a typical phlebitis. This inflammation may extend and damage the blood supply of the overlying skin sufficiently to lead to a state of malnutrition which, in turn, is thought to be re-

sponsible for the cutaneous complications of varicose veins. Similarly, thrombophlebitis of the deep veins may produce the identical scarring by extension of the inflammatory reaction along the short communicating veins found around the lower third of the leg and the ankle.

FIELD FIRE AND INVASIVE BASAL CELL CARCINOMA—BASAL-SQUAMOUS TYPE

JAMES BARRETT BROWN M.D. F.A.C.S., and FRANK McDOWELL M.D.
St. Louis, Missouri

A TYPE of basal cell carcinoma has been observed that spreads through the derma without causing much surface ulceration and without producing much new tissue. It seems to be almost entirely destructive and to leave behind a healed area but to present an ever increasing lesion with a small raised advancing edge with intact or temporarily ulcerated epidermis. Areas may be left in the center which have broken down and remain as definite carcinomas that go on to excess tissue proliferation and invasion. Microscopic sections from the edge and any remaining areas of activity show basal cell carcinoma.

To identify this growth clinically we have called it "field fire basal cell carcinoma." It does not exactly resemble a field fire because the skin in the center and even the edge, may not ulcerate.

From The Department of Surgery, Washington University School of Medicine, St. Louis, Mo.

Basal cell carcinoma as generally occurs so frequently in the literature the other descriptions of this type could be better defined. The closest approach to it is found in a paper by M. B. Hartwell, "Morphea-Like Epithelioma," *J. Am. Med. Ass.* (pop. 53, 902) in which 4 instances are reported of diagnosis of morphea turning out to be basal cell carcinoma. No photographs of lesions or photomicrographs are given.

but in the relation of a slowly advancing active edge and a center that is free of involvement, a field fire might be thought of with its burning edge and its burned out center with perhaps a few areas of remaining activity around brush piles or where any heavy growth has held the fire.

An important clinical point is that the growth may not appear very bad, its diagnosis may even be missed if no burning areas have been left in the center or a burning center may be treated without regard to the menacing advancing edge. It is thought that in reality this is an exceedingly bad growth and that it may be one of the invasive types which carries on in this fashion primarily. This viewpoint is strengthened by having observed this type of growth usually in areas in which there is not any easily invaded deep tissue, as on the scalp and nose, and in these areas themselves by having found deep invasion in which deep soft tissue had present itself such as about the orbit.

It is recognized that this is not a new type of growth but it is so interesting grossly and from points of prognosis and treatment that attention is called to it.

Fig. Field fire basal cell carcinoma: typical advancing edge; uninvolved center; deep invasion left behind; orbit X-ray treatment; widespread surgical removal and secondary repair with thick split grafts. Patient, 67 years. Appearance could be improved with an artificial eye.

Fig 7. left. Invasive basal cell carcinoma coming from below and destroying the repair done 9 years before following removal of the original growth.

Fig 8. Multiple invasive basal cell growths involving the orbit. Fatal

3 years following heavy radiation given by Dr. Sherwood Moore.

The patient in Figure 3 refused operation and the growth was unaffected by radiation.

One question in consideration of this growth is that it might possibly be considered a healing carcinoma which would, of course, be a dangerous stand from the patient's point of view. Although there may be authenticated cases of healed carcinoma (perhaps many unknown ones) there is no way of knowing that any one will heal and, of course, none should be left untreated waiting for this possibility. Dunn and Smith have chosen a somewhat misleading title of this sort in reporting a single patient with a squamous growth that apparently behaved in this fashion. However

they add in the article that, "It is impossible to say what the course would have been had the lesion not been excised. One can easily conjecture that there would have been steady progress and an uncontrollable lesion."

INVASIVE BASAL CELL CARCINOMA

Invasive basal cell carcinoma is a clinical type that probably cannot be determined microscopically. It is the most important type and when once firmly established at the side of the nose about the orbit, or deep in the ear region, this growth is practically incurable at present. This point is important in prognosis and in teaching, as there has been a somewhat general idea that basal cell growths present little difficulty in treatment and in obtaining cures. By widespread surgery or radiation, these growths may be held in abeyance for long periods, but they can apparently persist in scar tissue for long periods in a dormant state and recur even after years. These late growths might be thought to be new growths entirely, but are known to occur often from deep under the surface where no epithelial cells should be. The patient in Figure 7 shows an extensive recurrence about the orbit that has come up through a flap repair of the original growth, which was done 9 years before.

The patient in Figure 8 shows a typical invasive type going into the orbit. Multiple foci often occur as seen here; sometimes the whole side of a face seems destined to form carcinomas, but the invasive tendency is the fatal factor.

It is evident that there are millions of small basal cell tumors that remain quiescent and it is probably because of these that the teaching has

Fig 6. Shows healed scar epithelium taken from healed center of involved area in Figure

Fig 9 Widespread multiple basal, squamous, and basal squamous growths, controlled by wide excision and split skin grafting. Patient well 6 years, but suffering more recurrences in new areas all the time.

arisen that the growths are not dangerous. However, it is possible that every basal cell lesion that takes on activity is headed toward invasive tendencies.

The old term "*rodent ulcer*" was a good one as far as clinical behavior is concerned, as the growths dig in and reappear as rodents do. This term and *Jacobean ulcer* were used for a long time before the pathology was described by Krompecher in 1903. He was the first to use the term basal cell carcinoma and to determine the origin of such growths from the basal cell layer. His general findings on skin cancers were divided into the two types now well known, and they were described as follows: (a) prickle cell cancers, which are infiltrative, metastasize to lymph nodes early, and often contain horny pearls, (b) basal cell cancers, which develop not from the transitional part of the skin and the surface, but from the deepest layers of the epithelium. Most occur on the face, cheek, forehead, and nose, and they are found usually in older people. They develop as small lumps which soon ulcerate, and for a year or 10 years thereafter grow very slowly. However, they can suddenly take on rapid growth, often mushroom like tuberosus tumors appear, and they very seldom metastasize. They develop out of small oval or spindle cells with chromatin-rich, intensively staining nuclei and have no typical prickles or intercellular bridges. Krompecher divided these basal cell growths into solid, adenoid, cystic, and parakeratotic types and a combination of these.

It is generally thought that basal cell growths originate from the basal layers of the epidermis, in fetal rests in the derma, and from hair follicles, and from sweat and sebaceous gland structures. It is possible, however, that all basal cell tumors arise from the hair follicles, as indicated by Mallory, as none seem to arise from mucous mem-

Fig 10 Section from a basal squamous carcinoma.

brane and they apparently do not occur on the palms or soles. It seems to us that the majority of them arise from the sebaceous glands, rather than from the hair forming structures in the follicles. This seems borne out by the fact that most of them occur in the so called *sebaceous area* of the face and that many of them microscopically and clinically seem to have their origin in sebaceous adenomas or plugged sebaceous glands. Rhinophyma specimens in some instances have contained multiple small basal cell lesions, and there is some experimental evidence that sterols similar to those present in sebum can, under certain conditions, be carcinogenic. The basal cell carcinomas of the buccal cavity referred to in the French literature may be adamantinomas, which in the solid type look like basal cell growths of the skin.

BASAL SQUAMOUS TYPES

Krompecher also recognized a basal squamous type. The combination of basal cell tumors with the typical squamous cancer can occur which I have observed in a tumor of the cheek" (Figs. 9 and 10).

Montgomery has studied a large series of supposed basal cell growths and has given the following conclusions: (1) Basal cell epithelioma may through metamorphosis become a basal squamous epithelioma or even a squamous cell epithelioma. (2) In a series of basal cell epitheliomas diagnosed clinically as such 15 to 20 per cent will probably prove to be transitional in character. (3) Basal squamous epithelioma, as a rule, is not the result of roentgenotherapy. (4) Basal squamous epithelioma may occasionally metastasize as such, or it may metastasize as a squamous cell epithelioma. Most, if not all, cases of so called metastatic basal cell epithelioma, will prove on microscopic examination, to be basal squamous cell or squamous cell epithelioma. (5) Basal squamous epithelioma is relatively resistant to x ray and radium. Surgical treatment, with an unusually wide excision, is indicated when possible. (6) The prognosis in these cases must be guarded. The tumor is prone to recur.

Warren and associates have described 5 microscopic types and have concluded:

The form of differentiation indicates the degree of malignancy, differentiation as a basal cell or hair matrix carcinoma is indicative of low malignancy, while differentiation toward epidermoid carcinoma is present in the more malignant tumors.

1. *purely ulcerative type* of basal cell growth has been noted in which there is no new tissue piled

up at all. An open ulcer may persist for a long period with no new bulk of tissue occurring, such as one usually thinks of in any neoplasia. Microscopically there is a basal cell solid type of growth with local infiltration by small deeply staining cells, held in abeyance in some peculiar manner as may be seen in some melanomas or common moles in which the cells extend downward without any basement membrane but which for the moment do not spread as a true cancerous growth. This is an insidious growth, because of being easily overlooked until some feature has become widely involved or deep invasion has occurred.

CONCLUSIONS

1. There is a clinical form of basal cell carcinoma that is apparently not very well known and for want of a better term it has been designated clinically as *field-fire basal cell carcinoma*. So far no distinguishing microscopic feature has been noted.

2. This growth is apt to be misinterpreted as to its true nature and extent.

3. Any basal cell carcinoma is apt to become invasive and the teaching that they are not very dangerous is not correct from a clinical standpoint.

4. The term *invasive type* might be used more often for more accurate clinical description and for more prompt and extensive attempts at eradication either by operation or radiation. As far as is known, this is a clinical type that cannot be definitely distinguished microscopically except that there is apt to be no differentiation of cells.

5. Basal squamous types have been recognized since Krompecher's original description and may run as high as 20 per cent incidence in supposed pure types.

6. A purely ulcerative stage may exist, with no piling up of new tissue and even with surface healing at times, but with slow persistent deep invasion and widening of ulceration.

7. Basal cell carcinomas give best chance of any carcinomas of cure by early removal, either by excision or radiation but they are definitely more dangerous both for destruction of tissue and life than is generally thought and taught.

THE USE OF LATEX AND HYDROCAL IN CASTING MEDICAL SCULPTURE

CHARLOTTE S. HOLT, and FREDERICK H. FALLS, M.S., M.D., F.A.C.S.,
Chicago, Illinois

VISUAL education has become an important factor in the dissemination of medical knowledge. Various forms of medical drawings, photographs, charts, lantern slides, motion pictures, and models have been used to depict anatomical and pathological subjects not easily adapted to or available for clinical demonstration. The realization of a growing demand for new visual methods of presentation has led to the recent development and application of sculpture in making relief models for purpose of obtaining advantages of three dimensional portrayal.¹

The pioneers in this work have been Dickinson and Belski, who have made models of the physiology of conception and labor, and Holt and Falls, working independently, making somewhat similar models of the placenta and intrauterine fetal development. Malvina Hoffman's previous work and advice has been an inspiration and guide to both groups of workers. Recently Holt and Falls have applied their method to the production of models demonstrating pathological subjects such as ectopic pregnancy, premature detachment of the placenta, and cesarean section.² They have illustrated the technique of the low cervical, classical, Porro and vaginal cesarean operations showing the various steps of the actual procedure by means of life sized models and, where necessary, have incorporated instruments.

In order to clarify the discussion of the procedure we are about to describe, it is necessary to distinguish between molding and modeling. According to Frederick—"To model is to construct in some plastic material, as clay, a model which can, if desirable, be reproduced in plaster of Paris,

marble, or similar materials. To mould is to construct in some solid or resisting material, as plaster of Paris, an imprint of an object by means of which a reproduction of the original may be made." Our work was done almost entirely by modeling.

CASTING

For many years physicians and dentists have found impressional casts to be of value when plastic and oral surgery is necessary. For such purposes the making of a cast of the patient's face is purely a mechanical procedure and is usually made before and after surgical operations. In a recent article Peluse has described in great detail this process, using plasticomoulage.³ The negative can be made with agar composition or gypsum and the positives in rubber, wax or any other suitable material. Rubber is now being used for positives such as those for prosthesis of hands, and other artificial parts to be worn to conceal deformities.

The common method of constructing a plaster-of-Paris mold directly over patient's face, whether for normal or pathological masks, has been largely discarded for several reasons, namely, premature separation of positive in mold due to grease used as a separating medium on face, and obliteration, if not loss of skin texture and detail. This method is being replaced by use of a plasticomoulage which is harmless to the skin and can be applied near body temperature, setting almost immediately. The moulage material when hardened is flexible and needs the support of a backing material such as a plaster gauze shell to maintain its shape. This produces a detailed impression or negative. From this a wax positive can be made by the brushing technique which is accomplished by working rapidly and carefully to avoid air bubbles. This can be reinforced by brushing hot wax into a thick layer of gauze laid carefully over first layer of wax. Any defects can be corrected with plasteline. Then a plaster-of-Paris negative is made from this wax working mold and a second positive can then be made successfully of rubber.

The two main substances in common use for making negatives of medical subjects are plaster

of Paris (gypsum) and a hydrocolloidal compound called agar mold, negocoll, or plasticomoulage. Sometimes the wax mold is employed. For inanimate and nonprotoplasmic objects, the rubber and the glue mold are often made. Other substances such as metal, baked sand, terra cotta, Korogel, and numerous other materials are used for mold making by commercial manufacturers.

Some materials are more adaptable for casting models than others to accomplish desired results. If properly mixed, plaster of Paris will produce a negative with a great deal of detail. The great disadvantage of its use is the fact that the negative is not pliable and can be used only once because it has to be chipped from the positive and unless this is done with painstaking skill there is great danger of injury to the original.

The most difficult problem encountered in casting is the reproduction of undercut. An undercut is the space or depression left by cutting the clay away from the edges of the under surfaces of the subject being modeled to increase the third di-

mensional impression. This interferes with the removal from model; therefore, in using plaster it is necessary to prepare piece molds in order to remove the negative from the original clay or the positive from negative where there is any amount of undercutting on a rigid subject.

Glue and gelatin were the first pliable molding materials. They permit large amount of undercutting because the mold will stretch or bend on removal. They both have sufficient elasticity to regain their original shape after having been removed from the cast. Since gelatin or glue and water requires a high temperature for liquefaction before pouring, it cannot be used for making a mold directly over living tissue. Moreover, it takes a long time to cool which renders it even more undesirable.

Agar composition may be used for the same purposes as glue or gelatin and has the added advantage of not setting until cooled to approximate body temperature; however, the latter materials produce stronger and more durable elastic

Fig 2 Model depicting forceps delivery of full term baby during cesarean section Actual instruments are incorporated and the model was painted

molds It, therefore, can be applied directly to the skin without damage or discomfort to the patient Glue or gelatine negatives are damaged by hot wax or other substances which require heat for liquefaction or generate much heat in setting, because heat remelts the mold Glue or gelatin, therefore, can be used only for plaster casting and

Fig 3 Original clay model on which latex is sprayed to make negative mold Note number and depth of undercuts

next to rubber offers one of the best methods of molding numerous positive casts from a single negative

MODELING

The first step in making a medical model is for the clinician and the medical artist to discuss in detail the objectives sought in the finished product If an operation is to be depicted the number of models necessary to clarify the steps of the operation must be determined The scale of the models must be decided upon—whether they are to be

Fig 5 Latex negative held by plaster of Paris mother mold Latter shell was applied after complete vulcanization of rubber

Fig. 6. Finished hydrocol positive. Note that the detail in this model is perfect and that retouching or finishing is not necessary. Compare this reproduction with Fig. 3.

Fig. 7. Hydrocol positive, painted realistically in oil. Inset in upper right corner enhances teaching value. Sagittal sections can be done only by scalpel; saw sawing cannot be used. Life size model—8 months later.

Life size, half or twice scale, etc. The material to be used in the positive and negative casts must be selected, and it may or may not be found advantageous to use impression molds for research in doing the sculpture to produce the best effect. If the models are to be used as exhibit teaching material, it must be decided whether models alone or models supplemented by drawings will be used to illustrate a given subject, since such drawings reduce the necessity for excessive details in models which otherwise would have to be included.

We have found it most practical when possible to have the artist sketch many operations of the type under consideration from life with a free discussion of the steps of the operation with the surgeon before during and after the operation. A composite picture of the operative procedure is thus obtained by the artist and the clinician is led to observe certain points suggested by questions raised in the mind of the artist. From the sketches each drawing is carefully worked out and criticized and approved by the surgeon who checks anatomical and surgical details. When this has been laid out the actual size it is to appear, it is ready to be transferred or traced on clay. The amount and thickness of clay depends upon the depth involved in the operation or procedure to be reproduced and this determines the type of relief. It is necessary to have adequate armatures to support the weight of clay. The size and detail of model to be rendered determines the amount and type of armature. We have found that broad headed nails which are embedded

in wire meshed hardware cloth are satisfactory for reliefs.

The model of plastiline (oil clay) is worked out in three dimensional detail as shown in Figure 3 and is now ready for casting.

If these models are made to scale it is desirable to record and reproduce actual anatomical measurements. The necessity of casting numerous undercuts soon made us abandon the plaster negative method and experiment with agar glue and gelatin molds. After considerable research with casting materials, it seemed that liquid latex material had many decided advantages over the others since it has maximum elasticity, is unbreakable, unaltered by hard usage, and is heat resistant. Storage problems are simplified as models can be packed away in small spaces for ready reference and duplication.

Latex is the natural sap of the rubber tree preserved by addition of ammonium up to 6 per cent by volume to prevent decomposition and coagulation. Additional ammonia is added as needed to replace evaporation. It is thermolabile and, therefore, must be kept at room temperature.

Materials necessary for making rubber mold are (1) liquid latex (2) spray gun (similar to one used for insecticides or if available a special DeVilbiss latex compressed air gun) (3) backing and filler compound (4) flat paint brush 1 inch wide (5) spatula for applying backing material and sharp knife for trimming edges of rubber mold (6) bowl for mixing latex and filler compound (7) liquid green soap for cleaning air gun.

and brushes. It is important to note that before the brush is placed in liquid latex, it should be submerged in liquid green soap which is worked into a lather and then wiped off on gauze leaving a thin layer of soap on bristles. This prevents the latex from adhering to the brush. After use the brush should be washed immediately in liquid soap to prevent air vulcanization of latex on the brush. Carbondisulfide can be used as a solvent.

TECHNIQUE OF MAKING RUBBER MOLD

The original clay model is sprayed with a clear lacquer in order to preserve detail, which a brush is apt to destroy, and allowed to dry. The entire surface of the model is then sprayed with liquid latex with special care to reach all undercut areas. The coat takes 30 to 45 minutes to vulcanize by air in a warm room of approximately 70 degrees F and less time in an oven of 150 degrees F. The latter method can be practiced only when a plaster positive is used. It is not suitable for clay which would soften, obscuring detail. Three or four successive coats are applied with a brush allowing for complete air vulcanization between coats and special attention is given to undercut areas. If the model has deep undercuts, it is now advisable to mix a backing filler with liquid latex to the consistency of a thick paste for the next layer. This is spread on with a spatula, filling in all crevices and depressions solidly to make the mold stronger and more durable. This layer requires a longer period of time for vulcanization and it should stand 24 to 48 hours. When this is hard and firm (especially in the undercut areas) three to five more coats of liquid latex are applied, thus building up the mold to desired thickness, preferably $\frac{1}{8}$ to $\frac{1}{4}$ inch according to size and detail of model. From our experience, it would be well to allow the mold to vulcanize 5 to 8 days, thus giving adequate time to set, thereby preventing undue shrinkage in the negative. The negative shrinks $\frac{1}{2}$ to $\frac{3}{8}$ of an inch over a period of time and if actual measurements are essential this difference should be allowed on original.

When the mold is hard and firm, the edges are trimmed with a knife and the plaster mother mold, which is to serve as a case to support the rubber negative, is made. When dry, the plaster mold is separated from rubber by loosening one corner of the negative and pulling evenly and carefully, it is stripped off like a rubber glove (Fig. 4).

The rubber mold is then washed with water inside and out and placed in the plaster shell, as it appears in Figure 5. The mother mold is now ready for use. The same procedure is carried out for sculpture in the round and is equally simple.

Positive material used may be of plaster or hydrocal, the latter being mixed similar to plaster. However, for best results a soft bristled brush should be used to apply plaster to negative, thereby reducing the chance of the formation of air bubbles in the plaster and insuring sharp detail. Other materials such as resin, wax, compositions, posmouflage, metal, wood, terra cotta, clay, etc., may be preferable.

Hydrocal is a new gypsum base cementation material, discovered by the research department of a large gypsum manufacturer. It has some characteristics of gypsum plaster and some of Keen's cement. It is produced as a dry powder and sets after it is mixed with water. It is characterized by the low amount of mixing water needed, high density, low absorption, high tensile strength and great hardness.

The use of hydrocal is indicated when ordinary gypsum plaster or plaster of Paris is not strong or hard enough. Hydrocal has excellent mixing qualities, settles readily into water, soaks through quickly, and blends to a smooth mix. Setting time is 20 to 30 minutes under ordinary mixing conditions. Four pints of water are used to 10 pounds of dry hydrocal. This amount of mixing water gives a smooth, pourable mix.

PAINTING AND FINISHING MODEL

The model should be thoroughly dry, before it is painted. Small defects may have to be filled in and rough areas smoothed, but it has been surprising how nearly perfect the models come from the rubber mold. After they are removed from the rubber mold they are sprayed with shellac or are boiled in linseed oil, preparatory to painting. They may be finished in a flat color such as ivory, bronze, terra cotta, etc., or painted in natural oil colors. For the purpose of matching colors, we have made a series of color cards corresponding to the colors of tissue seen at operation, recording them with a scale colorimeter in the operating room. Each shade is numbered and numbers of matching shades are recorded on each sketch to assist one in printing realistically.

Success in painting depends largely upon thinness of oil paint and evenness with which it is applied. There should be no "painty" effect or brush marks. Turpentine or linseed oil serve as excellent base mediums. Linseed gives a smooth texture requiring however, a longer period for drying. Sometimes it is advisable to add a bit of Japan drier.

Instruments add to the realism of the model and are embedded in holes provided in the original clay model. After the positive is cast, the instru-

ments are inserted into the grooves and are cemented into place by additional hydrocol. The disadvantage of incorporating instruments is that, during transportation, there is considerable danger of breakage, involving minor repairs.

ADVANTAGES OF LATEX

We have found latex to be far more elastic and pliable than glue and gelatin molds, and the problem of undercuts is solved, for the negative is peeled from the positive cast like a rubber glove and the original shape is resumed. It is stronger and more durable than glue or gelatin, and because of this fact it is possible to produce any quantity of sharp detailed positives, saving time and effort in the long run if duplications are a factor to be considered. The properly prepared mold lasts longer than a glue mold and shrinks less over a period of time. A rubber mold lasts from 5 to 6 years, the approximate life of rubber and can be filed away for future duplication and ready reference.

For many years, rubber in form of dissolved sheet or para-rubber has been used commercially for molding and casting. Such work has proved too technical and involved for average casters and discouraged them for this reason. However latex or natural rubber map in recent years has greatly simplified the process. It is particularly

favorable because it can be applied without heating and exerts no chemical action on surface in contact. It also vulcanizes by air at room temperature, so that damage to the original model which might follow the use of heat for vulcanization is avoided.

CONCLUSIONS

1. Latex mold is far more elastic and pliable than other molds, thus allowing the casting of deep undercuts without damage to either negative or positive.

2. It is strong and durable withstanding harder treatment than glue or gelatin molds.

3. Latex will vulcanize without heat, but the latter is often desirable to hasten vulcanization.

4. The detail of technique is much more simple and the possibility of error is far less than when glue or gelatin are used.

5. Latex molds are more heat resistant than glue molds which make it unnecessary to remove plaster or hydrocol impression from rubber mold when the plaster warms in setting.

6. The properly prepared mold lasts longer than a glue mold and shrinks less over a period of time.

7. The initial expense of preparing negatives of latex is slightly greater than that of glue or gelatin but the original cost is more than offset by the advantage that unlimited duplications can be made.

THE SIGNIFICANCE OF BLEEDING IN EARLY PREGNANCY AS EVIDENCED BY DECIDUAL BIOPSY

ROBERT N RUTHERFORD, M D, Boston, Massachusetts

MOTHER Nature's tolerance of the human reproductive failures would equip her to be the ideal wife of a chronic alcoholic. For too long the human race has believed that once the pleasurable act of impregnation is completed, any subsequent mischance calls for loud lamentations. The old Puritan punished any couple to whom such a calamity befell as having started their family project on the Holy Day—an "iniquitous pleasuring"—until the wife of one of the sentencing justices confounded him. Even today, however, the medical profession manfully strives to maintain the intra-uterine contents far beyond the last metaphysical hope with a necromancy of biologicals and vitamins.

Many and controversial studies of the human spontaneous abortion rate place the "inevitable human wastage" as between 20 and 25 per cent. The percentage throughout the mammalian order runs about 30 per cent of all ovulated or potentially fertilizable ova. If one investigates the expectancy of a successful pregnancy following spontaneous abortion, a certain disbelief of present medical practices is certain to enter one's mind. Malpas, in 1938, beautifully answered this problem. Bradley summarizes Malpas' findings in this fashion:

"At what point in a series of abortions are random or casual factors no longer operable to an appreciable extent? It is manifest that they are still in effect in a series of only two abortions. For example, assuming the rate of spontaneous abortion due to random factors to be 20 per cent, in 100 pregnancies there will be 20 abortions. In the next pregnancy, these patients are still subject to the same rate and therefore 20 per cent of 20, or 4 abortions will occur. And in a succeeding pregnancy 20 per cent of 4, etc. In a large population sample, a certain per cent of abortions will be due to accidental causes, even after 3 or 4 previous catastrophes."

In 6,000 pregnancies which Malpas studied, he found a spontaneous abortion rate of 18 per cent. By an interesting statistical device, he reached the conclusion that chance factors were not ruled out until three successive abortions or stillbirths had occurred. Or, conversely, recurrent factors could not be said to be in operation so that

abortion was habitual until there had been three consecutive failures. In addition, his analysis claims the spontaneous cure rate of abortion to be as follows: 1 abortion—78 per cent will not repeat, 2 abortions—62 per cent will not repeat, 3 abortions—27 per cent will not repeat, 4 abortions—6 per cent will not repeat.

These figures pose the need for revising the term "habitual aborter." One cannot write triumphantly of a small series of cases, in which patients have had one, two, or even three successive abortions, carried to term by what-manner-you-will therapy until the writer corrects his cure rate against the curve of abortion inevitability. By this harsh standard, many successfully treated patients should be reclassified. An 80 per cent cure rate of patients who have had one previous abortion is not phenomenal when 78 per cent of those patients would have carried to term normally without treatment. Bradley suggests that it were far better that habitual abortion as an entity be forgotten, and the terminology be limited to first, second, and third degree, etc., abortion, at least so far as treatment is concerned. In this way, the true problem would be defined and the comparative nature of the successes of therapeutic attempts would not be overlooked.

Again, using our same harsh standards, we must consider the problem of "the pathological ovum." At this point, it is impossible to separate out the pure germ plasma defective ovum from that ovum which, inherently good, undergoes an aberration of development due to defective appendages, poor implantation, local or general causes. We blanket the problem by accepting as a "pathological ovum" one which can be demonstrated either grossly or microscopically as deficient in development. Mall found 48 per cent of his entire collection of abortions were due to this cause. Hertig (4) has found 46 per cent in his series. Mall and Streeter noted that only a fifth of the embryos aborting in the first month were normal, and one-half of those in the second month were normal. In the third and fourth month, eight-ninths of the aborted fetuses had no evidence of pathology. In the latter half of pregnancy, abortions due to pathological ova are found no longer. Monsters

From the Department of Obstetrics, Harvard Medical School and the Department of Pathology, Boston Lying-in Hospital

surviving to term represent an anomaly too slight to cause spontaneous termination of the pregnancy while ova with serious defects involving processes vital to intrauterine growth are aborted early in intrauterine life. One other point worthy of comment is Hertig's (4) finding that 67 per cent of abnormal ova showed signs of hydatid change, while only 11.6 per cent of the normal ova aborted showed this change. Moles were found in 10 per cent of the ova showing hydatid change, and malignancy was found in 20 per cent of the moles.

Hertig (4) in a review of 219 abortions found that 70 per cent of the abortions were due to fetal or placental fault (52 per cent fetal, as defective ova, and 18 per cent defective placental growth or development) and 30 per cent were maternal fault (implantation fault, infection, maternal disease, etc.).

Overwhelmed by this staggering statistical proof of Mother Nature's efficiency in detecting defective fetal development and ridding the womb of such products, the observer is forced to other conclusions. If we accept a 20 to 25 per cent inevitable abortion rate, and if the large majority of those pregnancies are abnormal, what defense is there for treatment which denies a most effective method of terminating unfortunate pregnancies? And, further, how may one select the cases to treat from the bulk of those who should not be treated? At present treatment usually is inaugurated only if the patient complains of uterine cramps, bleeding, or in some instances, a gravid uterus which lags behind the normal growth rate. The patient is given progesterone, vitamins, bed rest, routine sedatives, etc., all or in part, for any one or several of the above signs. Hertig has found that in cases involving a pathological ovum the average abortion date is 10.3 weeks menstrual age, with death of the embryo coming on the average of 6 weeks before the actual abortion is completed (Streeter).

Why continue a pregnancy better to be terminated naturally of an embryo which is not only defective but which has long since ceased in its development? This question emerged quite naturally again and again as a result of the systematic study of all abortions under Dr. Arthur T. Hertig, pathologist of the Boston Lying-in Hospital.

It was such a question which prompted the investigation of this problem. If a safe, easy, accurate, and rapid technique could be developed by which it would be possible to pick out such cases of intrauterine death of abnormal embryos, considerable time, money, and mental anguish could be saved for the patient.

RATIONALE OF TECHNIQUE

We are all familiar with the pathological picture of the decidual cast which is often the only specimen one of these patients will give us. The ovum, with or without the embryo, ruptured or intact, is not always submitted. However, the microscopic picture of abortal decidual apoplexy is well known—consisting of dramatic vascular thromboses, hemorrhage into the decidua and beneath the placental plate, decidual necrosis, and often an acute cellular infiltration. This is the end-state of nature's catharsis.

In any busy sterility clinic, there are numerous instances of early pregnancies which have been subjected unwittingly to endometrial biopsy techniques, usually without interruption of the pregnancy. Sturgis (1) performed 7 unplanned endometrial biopsies in unsuspected intrauterine pregnancies without the interruption of gestation. This same author (11) described the hypersecretory response which sweeps over the endometrium, completed usually by the end of the eighth week.

We have presented to us, then, the picture of final decidual dissolution as contrasted with the picture of development of normal decidua. Let us suppose a case of inevitable abortion due to be completed at the average of 10 to 11 weeks, with fetal death taking place some 6 weeks before. Fetal death *per se* does not precipitate the abortion, for 6 weeks must elapse before the latter takes place. Does the corpus luteum of this ill-fated pregnancy, aware of its frustration, slowly cease its function, until weeks later the uterus no longer progesterone-inhibited, expels its contents? We have no clinical method for detecting such a blighted ovum. Manual examination in early pregnancy is notoriously unreliable. The biological tests of pregnancy are not dependent upon fetal viability, but upon viability of chorionic villi. If such is the case, then one might well detect the early stages of this "decidual apoplexy" before the actual abortion is completed. A decidual biopsy might reveal these early stages. Such a procedure cannot be defended without clinical evidence suggestive of an abnormal pregnancy such as bleeding, cramps, or failure of uterine growth over repeated examinations.

The biopsies performed in this series of cases were done by means of the blunt-tipped Rock endometrial suction curette and the specimens were put into 10 per cent formalin for immediate fixation. After sterile precautions are observed, the curette was inserted gently under direct view into the cervical canal, and the biopsy tissue was taken from the low anterior uterine wall just

within the internal os, a withdrawal stroke being used. If any resistance was encountered on insertion of the curette, the withdrawal stroke was performed without further forward progress. Since the curette is blunt-nosed, there is extremely little danger that viable membranes will be ruptured or soft tissues will be perforated. It was believed that this information would be of value only in the first 14 weeks of gestation, that after this period the information could be gained by other devices, and the technical risk of taking the biopsy tissue was greatly increased,—not only is the placenta fully formed, but the pregnancy tends to fill more completely the uterine cavity.

Before this technique could be applied to a large group of cases, decidual biopsy was performed on 8 cases in the first 4 months of pregnancy which were to be interrupted therapeutically for maternal medical reasons. Biopsy was performed from 2 to 7 days before the pregnancy was interrupted. In no case were there any symptoms or evidence of harm as a result of the procedure. There have been added to the original 8 cases, 30 more cases, in none of which has there been a casualty. The dangers in the technique will be discussed later in the paper.

The patients who appear in this study were all patients in the Out-Patient Service of the Boston Lying-in Hospital. The patients were entirely unselected, and represent routine study of all bleeding cases. Over an 8 month period, 2,500 prenatal patients were observed to collect 100 consecutive cases of bleeding. In other words, bleeding was present as a symptom once in 25 cases, as the average. These patients were of lower and middle class social strata. They all were desirous of continuing their pregnancies, and in no case was there a hint of induced abortion. Needless to say, the latter consideration aided the study greatly. The majority had had no previous abortions, the most any had was 3 previous successive abortions or 5 in all. Any patient who was in the first 14 weeks of her gestation, who, with or without cramps, had had bleeding of a 5 centimeter spot or greater within the 2 weeks immediately preceding biopsy was subjected to examination of a biopsy specimen after speculum examination had excluded extrinsic causes of bleeding. A patient who had had cramps alone was not investigated. Careful pelvic examination to confirm pregnancy and to exclude ectopic pregnancy and tumors was routine. Two ectopic pregnancies were encountered. Also studied were patients whose wombs failed to increase beyond the size of a 4 months' gestation after repeated examinations over at least a month. The biopsy

specimens were obtained in the Out-Patient Department in the large majority of cases, without the use of anesthetics, and the patients were allowed to go home immediately. No effort was made to quiet the uterus with progesterone or opiates after the biopsy specimens were taken. The patient was encouraged to continue with her ordinary life, or her life was modified according to the information gained from the biopsy material on which immediate frozen section was made. The entire procedure, from the taking of the biopsy material to the making of the frozen section and diagnosis, requires an average time of 15 minutes. There is no special pathological knowledge or technique other than those found in the average, well equipped hospital. Permanent sections stained with hematoxylin and eosin were made to corroborate diagnoses from frozen section, which latter can be prepared for permanent mount as well. The frozen section diagnosis was accurate in at least 90 per cent of the cases, for one's interest is not in delicate cytology, but, as will be explained later, is focused on vascular changes and cellular infiltrations.

The site for obtaining the biopsy material—low on the anterior wall just within the internal os—was chosen as being the least likely spot for implantation of the fertilized ovum. In no instance was the implantation site curetted accidentally. Any subsequent biopsy specimen was taken from a different site so that no pathological changes from the first procedure would obscure the picture.

However, before one believes the microscopic picture from such a small and such a distant site, it must be established that this effectively mirrors the generalized decidual changes, as well as those beneath the placental plate. In the first 6 cases of inevitable abortion turned up on decidual biopsy, differential specimens were taken at the time of spontaneous abortion from the four quadrants of the uterus, from the placental site, as well as from the original biopsy site—low on the anterior wall. From the study of these differential sections, it may be said that if any changes are shown by the original biopsy specimen, those changes will be found throughout the decidua and beneath the placental plate in greater degree. In only one case, to be cited later, was there false security given by a normal decidua, but a repeat biopsy was made a week later which settled the question.

In all, excluding the original 8 patients who were subjected to biopsy in preface to a therapeutic abortion, there were 100 consecutive cases thus examined. Each group will be discussed indi-

vidually. The statistical break-down shows fetal defects, 50 extra fetal defects, 41 nonpregnant, 7 ectopic pregnancies, 3. Of these 100 cases, 18 patients, coming entirely from the 41 whose bleeding was shown to have come from extrafetal defects, have gone on to term. Only 91 cases of the series should be considered true pregnancies, excluding the nonpregnant and ectopic pregnancy cases.

MICROSCOPIC APPEARANCE OF NORMAL DECIDUA

Sturgis (11) as before noted has described the glandular changes and the curve of decidual change found within the endometrium in the early phases of pregnancy. For the purposes of this study the changes within the glands are of less interest than certain other features which will presently be described. In preparation for judging a "normal decidua," 39 cases of decidual specimens from therapeutically aborted patients from the Boston Lying-in Hospital were studied for the features which characterize the decidua and placental plate (chorion frondosum) of early pregnancy. In addition to these cases, were added the original 8 cases of patients with normal pregnancy upon whom the safety of this procedure was checked. Since then 41 more cases with normal decidua have appeared in the series.

In Figure 1 is shown a section of normal cytology. The hypersecretory phase of the glands is an outstanding feature in the first few months of pregnancy but, as Sturgis (1) points out, the height of glandular secretion reaches its peak at 8 weeks, and then slowly fades, until at about 23 weeks the glands have lost their secretory function and have degenerated into large sinusoid-like spaces throughout the spongy decidua.

The endometrial stroma follows a similar course. The localized decidual change about the implantation site spreads slowly until at about 8 weeks, it is found to have reached the lower uterine segment and to have extended throughout the entire endometrial thickness. The biopsy specimen often includes a 1 to 3 centimeter strip of lower uterine segment and endocervix. This is occasionally of interest in dating the time of fetal death, for it will show the arresting of this decidual change in the lower uterine segment. Should unchanged lower uterine segment be found after 8 weeks gestational age, fetal death before that time may be suspected.

Of more interest than the stroma however are the changes one finds in the decidual vessels. This will be elaborated shortly in the description of the pathological changes. In the normal decidua, the arterioles are numerous and prominent

and the decidual sinuses are free of thrombosis.

Last of the significant features of normal decidua is the cellular population found dispersed throughout the stroma. Collections of small round cells, apparently lymphocytes, are found in the stroma, usually as perivascular collections (see Fig. 2) or as subepithelial collections (Fig. 3). Present also may be pyknotic nuclei, possibly of degenerating decidual cells, without cytoplasm, and a certain amount of so called "nuclear dust" of fragmented, degenerated cells. This may be the result of wear-and-tear upon the decidua which has no replacement mechanism for its 9 month existence. These collections are usually in close relationship with the lymphoid elements. Phagocytizing large mononuclear cells are rarely seen. The gland lumina are usually filled with secretion and cellular debris.

The so called moth-eaten degeneration of the deciduotrophoblastic function which Hertig describes in the decidua of the full term pregnancy has been noted as early as the 1st week of pregnancy and is fairly constant from the 4th month on. This is a hyalinization and vacuolization of the decidua with shrinkage of both nuclei and cytoplasm. It is of no known significance in this study.

MICROSCOPIC APPEARANCE OF ABNORMAL DECIDUA

To accent heavily the significant changes which follow death of the corpus luteum of pregnancy may Figure 3 be substituted. Here one finds the most marked "decidual apoplexy" for it is the picture presented by sudden complete deprivation of the developing embryo of all the corpus luteum action. Forty-eight hours before, corpora lutea were removed one from each ovary resulting in the expulsion of 17 day normal twin embryos. The pathological picture in the decidua is one of massive acute focal and diffuse necrosis, thrombosis, and congestion of the sinuses, massive hemorrhage into the decidual stroma, and marked acute polymorphonuclear infiltration throughout the stroma. This was a private case and not from the Boston Lying-in Hospital.

To contrast with this, in Figure 4, in which there is slow withdrawal of corpus luteum effect, the thrombosis of the sinuses and hemorrhage into the stroma present, less cellular infiltration—a much less cataclysmic panorama. This is the picture more frequently encountered for it apparently is the mechanism of the usual "spontaneous abortion" in contrast to the surgical abortion shown in Figure 5.

And to take this process back even farther one may demonstrate the pathological picture shown

by the abortion of a pathological early villous ovum 8 days after the first missed period (Fig 5, courtesy of Dr Arthur T Hertig) In this, as in 3 other such abortions, all within 4 to 11 days after the first missed period, is demonstrated thrombosis of the decidual sinuses, necrosis of the decidua, hemorrhage into the stroma, as well as deficient vascularization of the trophoblast Undoubtedly, many such cases are missed because the patient or physician does not recognize the specimen Here, abnormal fetal development seems registered almost immediately upon the ovary

The sequence of events pathologically may be reconstructed in this fashion Due to causes which will be discussed later, the corpus luteum of these abnormal pregnancies degenerates at a variable speed, taking an average of 6 weeks, as before noted As the corpus luteum influence is withdrawn, there appear areas of local ischemia due to spasm of the spiral arterioles These areas are diffuse in distribution, but slowly the process becomes generalized, involving the areas beneath the placental plate as well as the entire decidual coat. With the local ischemia comes stagnation thrombosis in the decidual sinuses Often, however, before this can be recognized microscopically, one can find a change in staining reaction of the decidual cell itself—it becomes more acidophilic, and these patchy areas of decidual ischemia are quite prominent by color contrast With tissue death, the demarcation is complete, and there appears extravasation of erythrocytes through the damaged vessel walls into the stroma, with the ultimate appearance of polymorphonuclear leucocytes slowly appearing to aid in separation of the slough In one case, in which biopsy was performed because of bleeding, the first biopsy specimen showed mostly normal decidua with only a fragment of acidophilic-staining decidua The patient was subjected to biopsy again one week later because of continued bleeding and cramps, and 48 hours later, although she was 12 weeks' pregnant by menstrual dates, she miscarried a macerated fetus of 5 to 6 weeks' menstrual age Apparently the first biopsy specimen caught only a fragment of this first patchy decidual degeneration

With the separation of the decidual cast, including the placental plate, where these changes usually are most marked, the patient is ready for the extrusion of this now-foreign body This separation of the decidual coat takes place through the spongy layer A number of these cases were checked by sharp curettage immediately after their abortions, and the curettings revealed

healthy, viable, spongy and basal decidua left behind This process of slow vascular sealing-off, with leucocytic separation of the slough may well be the explanation for the relatively bloodless, noninfected course so many of these patients run Lochia is of a necessity scant, for there is little left behind to slough

In cases of long standing blighted ova, there is often found a "disuse atrophy" of the villi, yet they still are well nourished as long as they maintain contact with the maternal wall

The vascular picture here described in the endometrium is unlike that of anovulatory bleeding, in which thrombosis is found often in the arterioles as well as in the arteriovenous sinusoids Here the picture is one of sinus thrombosis

It may be seen, then, that a frozen section diagnosis is adequate for the large majority of these cases One can detect the difference in staining reaction, the presence of vascular thromboses, and the infiltration of erythrocytes and leucocytes into the stroma On these criteria rests the diagnosis Figure 6 demonstrates an average frozen section of good decidua

DIVISION OF CASES

1 *Fetal defects* Of the 100 consecutive cases studied, exactly 50 per cent have been thrown into this classification No effort was made to distinguish between primary germ plasm defects as opposed to defective development because of other factors Any gross or microscopic abnormality of the fetus or appendages arbitrarily confined that case to this series The large majority of these cases fell into Hertig's (4) average of about 10 weeks' menstrual age as the time for abortion, and the fetal death took place somewhere between 1 week and 4 months, averaging (10) about 6 weeks before the actual abortion transpired No significant alteration of larger statistical studies can be advanced because of the small size of this series The types of pathological ova in general fell into 3 groups those in which the embryo is absent, very defective, or macerated In 58 per cent of the cases embryos were found, in 4 per cent the unruptured ovisac was found, in 16 per cent the ruptured ovisac without embryo was found, decidual cast alone was found in 20 per cent, one hydatid mole was found Hydatid degeneration was noted in 9 of the 50 cases, but no percentages can be recorded because complete specimens were not obtained in all 50 cases

Detailed case history reports will be given on only one case, for it embodies many of the questions which will be discussed later A number of these cases were referred in to this clinic

because of suspected blighted pregnancies, there being one patient who had been given hormone therapy for a 6 month period, despite the fact that the uterus failed to grow beyond the size of a 3 month pregnancy. Others had been treated for shorter lengths of time.

CASE 1. No. 34-356. Mrs. I. G., a 35 year old housewife, in 1940 had 4 month miscarriages of unknown cause. Menstrual history revealed cyclical flow every 28 to 30 days, lasting 4 to 5 days, with 1 or 3 pads being used daily. Because of her first miscarriage, she consulted a gynecological physician who found a depressed metabolic rate and put her on thyroid extract. Her last normal period was January, 1941. She had no further menstrual flow, noted breast changes, but no other symptoms or signs of pregnancy. On March 1 she fell on the ice, she spotted slightly, was hospitalized immediately and given milligrams of prolon (progesterone) intramuscularly for 7 days. During this time she bled pads daily of brownish blood without clots, and was without cramps. She was not examined other than by abdominal palpation. She was discharged after 5 days of bed rest, but was back again 4 days later because of severe cramps of 24 hours duration, during which time she bled pad of bright blood. Over the next 2 days, she bled pads daily of brownish blood, but had no more cramps. She received 20 milligrams of prolon intramuscularly daily during this period. At the end of this time on March 24, 1941 because she still was bleeding, decidual biopsy was performed. The uterus was about half again normal size, the vessels are negative. There was quantity of old blood in the vagina and on, which as a biopsy dilated. A biopsy specimen was taken caudally from low on the anterior wall. After the speculum was cleaned out, and following the biopsy the patient had no further cramps and bleeding ceased. Pathological examination of the biopsy fragment showed acute necrosis of the decidual fragments, thrombosis of the arteries, and some cellular infiltration. Some unchanged lower uterine segment with hypersecretory glands as also present (Fig. 7). Because of the interruption of the decidual change in the lower uterine segment, it was felt that fetal death had transpired before the 8th week, despite the fact that the patient was by dates to 3 weeks pregnant.

However it was decided to give the patient further trial on hormone therapy, relatively large doses being used, to see if these decidual changes are reversible. As consequence, the patient as given approximately 20 milligrams of progesterone daily for the next 7 days. During the period of therapy the patient felt quite well, she noted no symptoms of pregnancy, she had no further bleeding or cramps. Tissue was then removed from the posterior wall 4 days after the last progesterone, on April 6, just as she again began to flow. Biopsy revealed repeating late secretory endometrium in the lower uterine segment, decidua with vascular thromboses, cellular exudate, and hemorrhage (Fig. 8). If anything, the decidual picture as worse instead of better after progesterone treatment.

Since it was felt that this pregnancy was doomed, the patient had curettage one day after the second biopsy, on April 7 with yield of scanty curettings of slender decidual pathology with no embryo or appendages recovered.

In all, 6 similar cases were treated with progesterone. No apparent improvement in the decidual picture was found in any of them. From these cases, one may suggest that these decidual changes are irreversible. From a sheer point of

logic, since it is demonstrated amply that fetal death has taken place some weeks before the rationale for using any therapy in these cases is difficult of comprehension. All one does is to delay the inevitable abortion, as evidenced in this case. One case as was mentioned before was carried for nearly 6 months on hormone therapy before it was aborted spontaneously. This latter was a mule.

In several cases, the necrotic slough of the decidual cast could be seen elevated from the underlying endometrium which was in the reparative phase. Such a finding as this would damn any further treatment.

3. *Extrafetal defects.* This group comprised 41 per cent of the cases in the series. Twenty-two of these 41 cases have gone on to viability at least 28 weeks, whereas 19 of them aborted within the first 5 months of intrauterine life. By extrafetal defects, one must suppose that there are no germ plasma deficits, but that defects are found in implantation, placentation, or intrauterine maintenance of an otherwise normal fetus. It may be restated that in the 3rd and 4th months, 8 in 9 of the embryos aborted are normal (7/10). Certainly the figures from this small group of 41 cases would bear out those larger series.

The syndrome which evolved on careful study of the normal embryos aborted during the first half of pregnancy is an interesting triad of conditions. Usually the sequence was the premature separation of a low implanted, circumvallate placenta. Several case reports will be presented in detail to adduce this syndrome. Actual digital examination of the uterine cavity was done in those patients in whom abortion appeared inevitable, either from continued loss of blood over a long period of time requiring intervention, or when the os began to dilate under rhythmic spontaneous uterine contractions. If this procedure was not possible because of the stage of labor during which the patient was seen, then the point of rupture in the membranes—determined by postpartum examination of the placenta—was taken as the leading point over the os. Any rupture within 2 centimeters of the placental margin was taken to be evidence of low implantation of the placenta.

Often the area of premature separation actually could be palpated through the dilated os. Differential biopsy specimens taken in these cases from the area of separation as well as throughout the rest of the uterine cavity showed normal decidua everywhere but in the area of separation where the decidua showed thrombosis, hemorrhage and necrosis (Fig. 9).

Varying degrees of circumvallate formation were found. This finding is not incompatible with an entirely uneventful full term gestation—a frequent finding at routine examination of the placenta postpartum. Hertig (4) mentions this as the etiological factor in 10 per cent of spontaneous abortions. In this series, it was a suggestively frequent finding that at the deciduotrophoblastic junction areas of infarcted necrotic decidua were present (Fig 10). In another case, the site of premature rupture of the membranes was in just such a spot. This may aid in explaining the common mechanism of abortion in the middle trimester, either premature separation of the placenta, or premature rupture of the membranes.

In the series of 41 cases of extrafetal cause of bleeding, the following figures may be submitted: evidence of premature separation was found in 82.6 per cent, low implantation in 60.8 per cent, and circumvallate formation in 32.4 per cent, premature labor in 56 per cent. Hobbs, reviewing the clinical significance of circumvallate placenta, found in 150 cases of circumvallate formation that 22 per cent ended in abortion, 16 per cent in premature labor, with a 33 per cent gross fetal mortality. Painless bleeding was present in 22 per cent. This pointed to the deciduotrophoblastic junction as an area of weakness, predisposing toward hemorrhage with premature labor or rupture of the membranes. The exact mechanism of the abortion, or the eventual fate of the pregnancy, depends upon the summation of these separate fractions. Those patients who went on to term following painless bleeding of varying amounts in early or midpregnancy will be shown to have lesser degrees of these conditions. In a few cases, as will be covered in the evaluation of our study, no cause for the bleeding could be found.

CASE 2 No S-41 393 Mrs B K, a 33 year old house wife with one previous normal pregnancy, 4 years ago. Her periods were regular, every 28 days, lasting 4 days, 1 or 2 pads being used daily. Her last normal period was November 27, 1940. She had no bleeding until March 1, 1941, at which time she began to spot bright blood. This continued almost daily until March 28, 1941, at which time she passed at home painlessly an estimated pint of bright blood with clots. She noted no change in her symptoms of pregnancy. Two days later, while she was in bed, she passed a cup of bright blood without pain. On March 30, she was examined, was found to have no cervical erosion, the vaults were clear, the uterus was 2 fingers below the umbilicus, there was old brown blood in the vagina and in the os. A biopsy specimen was taken from low on the anterior wall without event. Pathological examination demonstrated good decidua. Bleeding remained unchanged after biopsy, and at no time did the patient complain of uterine cramps. However, since she continued to stain 2 to 4 pads daily, she was hospitalized on absolute bed rest. As a test case, she was given 10 milligrams of proluton intramuscularly for

5 days, at the end of which time she was using from 6 to 9 pads daily, the discharge being a brownish blood, and had rare mild cramps. On April 11, because of continued blood loss, and evidence of moderate secondary anemia, it was decided to terminate this pregnancy. The os was 2 fingers dilated. Exploratory finger palpated the placenta low down on the right posterior uterine wall, with the lower edge entirely detached, leaving a free rim of about 1 inch of placenta. Membranes were intact. Differential biopsy specimens were taken from the area of separation and from the other quadrants of the uterus. Section of decidua from the area of separation is shown in Figure 11. Decidua from elsewhere in the uterus was uniformly good. A perfectly normal fetus, consistent with dates, was passed after a Braxton Hicks version. The placenta had been sectioned at the trophoblastic-decidual junction where areas of infarction were present (Fig 10). It was a low implanted placenta, whose lower edge had separated. It was completely circumvallate.

Progesterone had no effect in such a case, for, again, the area of separation showed changes which are difficult to conceive as reversible. One similar case treated with progesterone in the same fashion also failed to improve clinically.

CASE 3 No 3 41-385 Mrs B F, a 38 year old house wife whose first pregnancy, 14 years ago was normal. She had regular flow every 26 to 28 days, flowing 5 to 6 days, using 1 or 2 pads daily. Her last normal period had been November 14, 1940. Pregnancy progressed uneventfully until February 14, 1941, when she complained of cramps, without bleeding, for 1 day. On March 14, 1941, she had cramps with bleeding of 1 pad of bright blood. The cramps stopped, but she continued to flow for the next 10 days, still about 1 pad daily, of bright blood, without clots. The uterus was 2 fingers below the umbilicus, fetal heart was heard, of good quality. There was no erosion of the cervix, vaults were negative. The patient had a biopsy March 28, 1941, without event. The specimen showed entirely normal decidua (Fig 2). The patient was discharged home 3 days after biopsy, and began an active life 1 week later. She continued her pregnancy without event and delivered a 7 pound 14 ounce infant on August 17, 1941. The placenta was completely circumvallate with the membranes ruptured at the placental margin.

This patient might well have benefited from progesterone therapy at the time she was having her uterine cramps without bleeding in the late third month—the so called “critical period” when the placental hormones are replacing the senile ovarian corpus luteum. It is an interesting question—whether an irritable uterus predisposes toward premature separation, or whether defective placental implantation predisposes toward an irritable uterus.

It is of interest that in both of these cases—one requiring interruption because of continued severe hemorrhage, and one with less severe hemorrhage, spontaneously quieting down for ultimate normal delivery—the bleeding began about the beginning of the fourth month. This is near the time when the placenta first begins to exist as a discrete organ, although its function has been established

Fig. 2

Fig. 3

Fig. 2. Endometrial biopsy from low anterior wall. Thirty-year-old secundipara with cramps and bleeding for days at 4 weeks. Decidua is good, the few perivascular collections of lymphocytes and pyknotic nuclei. Blood vessels are patent. Patient bled no more and delivered a term, healthy infant. Placenta was low implanted.

Fig. 3. Endometrial biopsy from low anterior wall. Thirty-eight-year-old secundipara with 4 weeks' history of intermittent cramps and bleeding. Sections show good decidua, the intact mucosal surface demonstrating subepithelial collections of lymphocytes and pyknotic nuclei. Patient delivered healthy child at term. Placenta was completely circumvallate and low implanted.

from implantation of the fertilized ovum onward. It may be that with low implanted or a circumvallate placenta as the more rapid uterine growth of the second trimester approaches, this now distinct organ is separated at the margin from the more rapidly growing lower uterine segment. This margin is the already weakened deciduo-trophoblastic junction. This also is the critical period during which hormone production is shifted.

Fig. 4

Fig. 5

Fig. 4. Section from spontaneous abortion of second trimester embryo 48 hours after surgical removal of bilateral corpus lutea. Masses infiltration of decidua coat with polymorphonuclear leukocytes, areas thrombi with complete occlusion, necrotic decidua. This represents sudden, complete withdrawal of corpus luteum influence.

Fig. 5. Section from spontaneous abortion of 6 weeks. Fetal death took place at 3 1/2 weeks. Here the picture one of hemorrhage and thrombosis, without marked necrosis or acute erosion. This represents the slow withdrawal of corpus luteum influence by fetal death 5 weeks before.

One case in this group showed hemosiderin deposits within the decidua phagocytes, indicating an old hemorrhage which bore out her history of bleeding at an earlier phase before eventual abortion in the fifth month. The first separation sealed off again and was not too great for continued fetal life. The second hemorrhage continued its retroplacental dissection resulting in complete separation and abortion of a normal fetus consistent with the dates.

Fig 8

Fig 5 Section of a pathological early villous ovum passed 8 days after the first missed period. There is deficient vascularization of ovum, petechial hemorrhage from a sinusoidal rupture, early acute exudate degeneration of the local decidual change. (Courtesy of Dr A T Hertig)

Fig 6 Frozen section of specimen from low anterior wall. Thirty year old primipara with a 1 week story of painless bleeding, uterus slightly behind dates, estimated at 3½ months. Section shows good decidua, with normal physiological lymphocytic infiltration. Two burned-out secretory glands are present, and between them is a patent blood vessel partly filled with free erythrocytes. This demonstrates the important details sought in any biopsy. Three weeks later, the patient had sudden labor and aborted a normal embryo. Placenta was low implanted, and partially circumvallate.

Fig 7 Tissue from low anterior wall. Thirty five year old secundipara with a 2 week story of bleeding with mild cramps at 12 to 13 weeks. Section demonstrates interruption of decidualization of endometrium. On the left is a fragment of necrotic decidua, with an acute cellular infiltration and early thrombosis. On the right is unchanged hypersecretory lower segment endometrium. Decidualization was thought to have been interrupted before the 8th week of pregnancy by death of a pathological ovum.

Fig 8 Specimen from low posterior wall of the same patient 11 days after first biopsy, 4 days after completion of heavy progesterone therapy. Necrosis is more marked, cellular exudate is more definite, some sinus thromboses are seen. Unchanged lower segment also is present in this section, but is not seen in the photomicrograph. There was no reversal of the picture of necrosis on massive progesterone therapy.

In this group of cases also is the occasional patient who comes in to the hospital well advanced in labor in the early months of the middle trimester. Biopsy tissue taken in these patients, whose stories usually begin either with premature rupture or with premature separation of the placenta will occasionally show focal necrosis

throughout the decidua. This necrosis is not nearly as advanced as in the early trimester complete abortion of a pathological ovum, yet it is not within normal limits. This premature degeneration of the decidua would suggest either a relative or quantitative deficiency of corpus luteum hormone. Usually there is so little warn-

ing before either the membranes rupture or severe hemorrhage ensues that treatment cannot be instituted. Since the weight of the evidence suggests that the changes of decidual necrosis are generalized and irreversible. It may well be that no present therapy would avail. If the membranes have been ruptured for more than 24 hours, there is often such a diffuse polymorphonuclear infiltration throughout the membranes and the basal decidua adjacent to the rupture that no valid conclusions can be drawn.

If separation continues to the point of fetal death due to anoxemia, there seems to be good decidua throughout the uterus nearly to the point of actual abortion because of placental maintenance. Usually the bleeding is sufficient to cause intervention but not sufficient to kill the embryo. One is accustomed to the frequent occurrence of difficulty in removing placentas at this stage of pregnancy. However in the occasional case in which the fetus dies of gradual separation of the placenta, the latter slowly undergoes ischemia and fibrosis so that its hormone effects are abolished. Then labor begins, with less difficulty experienced in the separation of the placenta.

3. *The nonpregnant cases* These cases are included to emphasize the frequency with which such problems are encountered in this clinic. In 7 patients in the series of 100 cases biopsy was done. All of the patients were referred to the clinic because they were thought to be pregnant and possibly were aborting. Only one will be written up in detail.

CASE 4. N. 8-4 386 Mrs R H. 4 year old housewife, had been married for 3 years but without issue. Periods are stated to be regular occurring every 31 to 30 days, lasting 6 to 7 days, and requiring 10 pads daily. Her last normal period was December 2, 1940. She had no bleeding until March 29, 1941, at which time she noted spotting three times in 4 hours following intercourse. She had mild cramps. She had noted pain in the right, although already obese, breast changes, but no other symptoms. She was utterly convinced of pregnancy. On examination the uterus as found to be not enlarged, the cervix as smooth, the vaults are negative. Blood was dark, present in the vagina and in the os. About 40 cc of a biopsy specimen was taken from the low anterior wall. Following the removal of this tissue she showed 6 to 8 pads over the next days, and as exhausted and agonized to the thought she was aborting. The pathological diagnosis was a 30 day atypical edematous secretory endometrium. There are no changes to suggest early intrauterine pregnancy but she as observed for another month. At which time her regular period again ensued. She undoubtedly was not pregnant, but had had a 3 month period of amenorrhea.

It must be emphasized that decidual biopsy material is not suitable as a test for pregnancy. It undoubtedly carries more risk than the biological tests of pregnancy. Unless villi or placental site

giant cells are encountered, one cannot exclude ectopic pregnancy. The finding of either of these would militate against the safety of decidual biopsy. The biopsy material is taken from the lower uterine segment which is not completely transformed into decidua until about the 8th week. Its accuracy must therefore be much lower than the present biological methods. Moreover Telinde and Henriksen have demonstrated the fallacy of using the finding of decidua alone for the diagnosis of pregnancy. Decidua like changes are possible due to unbalanced corpus luteum rhythm or production, or certain ovarian tumors.

4. *Ectopic pregnancies* Two such cases are encountered in this series. The finding of decidual necrosis, thrombosed vessels, and evasive to ectopic pregnancy has been described by Mibell. As in his 2 cases, no harm was done to the patient by the biopsy procedure and the biopsy information when coupled with the clinical stories of the patients made the diagnosis much more secure. In a third case biopsy was done because of a very suggestive clinical history but she was not pregnant, having late proliferative endometrium. This was confirmed by careful pelvic examination and subsequent follow-up. She was transferred to the nonpregnant group of cases already reviewed. The biopsy information aided materially in deciding her case.

5. *Maternal defects.* In the 8 normal early pregnancies in which biopsies were done as controls preparatory to therapeutic abortion, one of the specimens showed an unusual picture. These were patients with severe hypertension, cardiac disease or similar significant maternal diseases. The specimen obtained on biopsy from a patient 20 weeks pregnant, a septipara with severe hypertension, showed diffuse and focal necrosis of the decidua with some infiltration of polymorphonuclear leucocytes. It was believed that her vascular system had undergone changes which resulted in diffuse ischemia of the decidua probably through the spiral arterioles—the picture of progesterone lack, but of different etiology. These patients often show acute atheromatous changes within the decidual vessels (3, 14) and not infrequently the fetus dies before a considerable period before term or premature separation of the placenta occurs. These patients rarely bleed or present bleeding as a symptom, hence do not complicate this study. In an effort to improve the decidual picture and possibly to help in maintenance of its already deficient blood supply the patient was given 10 milligrams of progesterone daily for 7 days, and then a biopsy specimen was taken

Fig 9

Fig 10

Fig 11

Fig 12

Fig 9 Biopsy specimen from area of premature separation of low implanted, circumvallate placenta. Thirty three year old secundipara with a 2 week story of repeated large hemorrhages at 18 to 19 weeks. Decidua from elsewhere throughout the uterus was normal. This specimen shows diffuse polymorphonuclear infiltration.

Fig 10 Cross section of deciduotrophoblastic junction of circumvallate placenta at area of separation in same case. Patient interrupted for continued bleeding despite heavy progesterone therapy. On left are immature villi, next is layer of good decidua, and on the right is focal area

of decidual necrosis with thrombosis, some cellular infiltration.

Fig 11 Section of decidua from area of separation of same case after heavy progesterone therapy. Necrosis is more marked.

Fig 12 Biopsy from low anterior wall. Twenty six year old primipara treated by own physician for 6 months with progesterone for bleeding and cramps at 12 weeks. Specimen shows hydatid degeneration of villi. Twenty-four hours later, the patient passed spontaneously a benign mole.

from the opposite uterine wall. This specimen showed virtually dead decidua, with massive acute exudate, decidual sinus thrombosis, and within the spiral arterioles were the plaques of subendothelial intimal proliferation previously noted as occurring in toxemia, hypertension, and nephritis. This picture was confirmed at the time the patient was surgically interrupted and sterilized. Progesterone in the quantity given was of no avail. The patient had a 1 pound 1 ounce infant which died shortly after birth. The infant

might have died *in utero* within a short time, as suggested by the decidual failure.

As was mentioned earlier, in an effort to determine the allowable changes occurring within the decidua of early normal pregnancies, 59 cases of early pregnancies therapeutically aborted for various reasons were studied. The mothers had nephritis, hypertension, cardiac disease, pernicious vomiting of pregnancy, or other disturbances which conceivably could affect the decidual circulation. These are those same pa-

tients in whom occasionally occurs for no known reason fetal death *in utero* or premature separation of the placenta. Thirty per cent of these cases showed changes within the decidua which we now recognize as characteristic of deficient decidual blood supply but on an entirely different basis than that of the "blighted ovum" or inevitable abortion.

EVALUATION

If one were to emphasize the known effects of corpus luteum hormone they would be (1) initiation of the pregestational changes (2) maintenance of decidual nutrition and thus maintenance of maternal-fetal blood supply, possibly through the spiral arterioles and (3) inhibition of uterine motility. There is no place in this paper for a critical evaluation of the work which has resulted in this now commonly accepted view of the progesterone function. There is no room for discussion of the efficacy of progesterone therapy or vitamin therapy or other present standard forms of therapy. Excellent papers on these subjects are readily available.

Accepting thus the powers of progesterone what is the modus of the pathological picture of the preabortal decidua? We find that in the pathological ovum, which forms the bulk of the abortions in the first trimester fetal death or lack of fetal development due to absence of embryo precedes extrusion by some weeks. Therefore, fetal death must not be directly responsible for kicking off the mechanism of abortion. Fetal death may initiate degeneration of a flourishing corpus luteum of pregnancy. This may come very rapidly as in the cases in which abortion took place within a few days after the first missed period. It may come about very slowly so slowly that one case did not abort for 4 months after fetal death—the *fetus papiraceus* occasionally found years later.

Progesterone works upon different end-organs each of which responds in its characteristic way. The myometrium is inhibited, so that the uterus is relatively quiet, allowing the fetus a calm sea with little ground swell. The decidual development is initiated at first locally by the trophoblast, but as a generalized change is augmented by the ovarian progesterone. The nourishing spiral arterioles are well dilated under progesterone influence. As this influence is withdrawn, the resultant vasospasm, tissue ischemia, etc. result in formation of the decidual slough. When the slough is ready to separate the inhibition threshold of uterine motility is reached, and abortion takes place. Should the expulsive motions

begin before the slough is complete there may be the mechanism of the incomplete abortion with serious hemorrhage. Should the slough be separated and no expulsive movements transpire, there may be the mechanism of the abortus retained for weeks or even months, particularly so if therapeutic corpus luteum is given in the vain hope of continuing the pregnancy.

It appears that the degeneration of the corpus luteum proceeds slowly with the decidual preabortal changes appearing only shortly before the actual abortion, at a time when attention is drawn to the patient because her bleeding either with or without cramps, first calls the problem to the fore. Should the patient bleed from a patch of focal necrosis, biopsy may be misleading unless one perseveres on clinical grounds—as in the case in one patient whose biopsy specimen was normal 5 days before actual abortion. Biopsy tissue taken just before the abortion showed the usual changes.

However the degeneration of the corpus luteum must still remain variable although the average case still requires about 6 weeks following fetal death. One case ended in premature labor at 8 weeks with a normal decidua and normal fetus. Could this be premature senility of the corpus luteum?

What is the mechanism of premature labor occurring in the middle trimester or of premature rupture of the membranes. Here the corpus luteum should have been replaced by adequate placental manufacture. The interesting triad of findings may be invoked in explanation: premature separation, low implantation, or circumvallate placentation.

Yet to be solved are the frequent cases appearing in this mid-trimester group of focal and diffuse necrosis of the decidua, ultimately going on to premature labor. Is this a relative hormonal imbalance or an actual quantitative deficit of progesterone? Is there a lag between the shift from ovarian to placental hormone production. The frequency of focal necrosis at the trophoblastic decidual junctions seems to be of real significance in these cases.

TREATMENT

The help derived from decidual biopsy is definite. In the first trimester it has evolved as a safe procedure which will in the majority of cases indicate the inevitability of abortion. If one finds the so-called irreversible changes within the decidua it can be said either that there is fetal death, that there is defective implantation with separation, or that there is serious maternal cause for impairment of decidual nutrition. It

answers immediately the question "Shall further treatment be attempted?"

If one finds decidual necrosis, the chances that the patient will not abort are very poor. In this study, only 1 case of 51 who miscarried in the first trimester had normal decidua. This case not only had normal decidua, but also a normal embryo and placenta—it is pointed out as a possible case for use of progesterone in the treatment of bleeding at this period of pregnancy with a normal biopsy. The case history is against the biopsy procedure's having caused the abortion. The other 50 cases had pathological ova. Six patients with decidual necrosis treated with progesterone went right ahead and aborted, with the decidual picture unchanged or worse after treatment than it was before treatment. The only apparent effect was to delay the inevitable abortion for as long as the hormone therapy was continued. The large majority of these cases had uterine growth much retarded according to dates, definite uterine cramps, evidence of withdrawal of pregnancy hormonal influence (cessation of nausea, breast changes, etc.). These patients can be encouraged to continue normal life until the slough has separated and labor spontaneously begins. This is the safe, easy, relatively bloodless way. Certainly one is not justified in surgical intervention directly the biopsy findings are made known. It is much easier and safer to wait, yet relieving the patient's mind by a simple explanation of nature's protective device for ablating abnormal pregnancies. One is more than justified in refraining from expensive hormone or vitamin therapy, or long invalidism in the futile hope of maintaining pregnancy. A blighted ovum long retained, may require intervention, as may incomplete extrusion of the abortus.

If one finds decidual necrosis, it can mean as well that one has taken the biopsy specimen from an area of premature separation. In this study, only 4 of the 41 cases of extrafetal disease (low implantation, premature separation, circumvallate placenta formation, irritable uterus, etc.) showed decidual necrosis. In the 4 cases showing necrosis, the patients still showed evidence of continued pregnancy, the uterus was consistent with dates, uterine cramps were absent. The bleeding in these cases tends to appear about the beginning of the fourth month, rather than in the second and third month as in the group of pathological ova. It also tends to be bright blood, with clots, whereas the pathological ova cases tend to have dark, brownish blood. Cramps are rarely encountered in these cases.

The finding of decidual necrosis can mean as well severe maternal circulatory impairment. Only 1 of the original 8 cases to be therapeutically aborted bled, presumably from a focal area of necrosis. Since one is not likely to encounter these cases as a biopsy problem, no more mention is made of them as a treatment problem.

If one finds normal decidua in the first 4 months of pregnancy, yet the patient has a story of bleeding, with or without cramps, no definite diagnosis can be made without the careful correlation of clinical story and findings. Thirty-seven of the 41 patients who had extrafetal defects had good decidua. Two of the 4 cases with decidual necrosis aborted, whereas the 2 other cases went on to term. Nineteen of the 41 cases of extrafetal defect aborted with good embryos. Twenty-two carried to 28 week viability. In each of these 2 groups were 2 cases with poor biopsies. In order to settle this quandary, one must follow the clinical course of the patient. If no more bleeding takes place, if the uterus continues to grow, even in the presence of a poor biopsy, one must have curetted an area of premature separation. If the biopsy is good, additional encouragement can be given. If the biopsy is good, but continued bleeding is present, one must follow increase in uterine size. If there continues progressive enlargement, and the bleeding is not devitalizing the patient, pregnancy may be encouraged. Two such cases (already referred to under extrafetal defects) were given bed rest and progesterone without effect upon the bleeding. Both had to be terminated after the bleeding had continued for 3 weeks and anemia had become marked. If the biopsy is good, and bleeding continues, but uterine size is static, too much separation has occurred, and it has been lethal to the fetus. If one follows a case like this by biopsy, he will find soon decidual disintegration as the placental hormones are slowly withdrawn by placental death. All of these variations have been observed. Prediction must be based upon the following. Those who bleed no more with a good biopsy will do well without any treatment other than bed rest, progesterone is given only if there is any suspicion of uterine irritability. If that indication does not exist, there is no proof that progesterone is of any value. These are the cases *par excellence* who are benefited by a routine of limited activity, quiet, sedatives until the separation has stopped and sealing off takes place. One such patient, progesterone treated, with but one episode of moderate bleeding aborted 48 hours after completion of 1 week of 10 milligrams of proluton daily.

In the case of premature labor or premature rupture of the membranes in which focal decidual necrosis (? inadequate progesterone balance) is often found progesterone may be of value but these cases could not be spotted in advance. Usually no warning is given. They silently rupture membranes or suddenly enter stormy labor.

There is no apparent relationship between the amount of bleeding one encounters in the cases of premature separation or other extrafetal defect, and the prognosis for holding the pregnancy. In general, patients who have one isolated episode of a small amount of bleeding have a good prognosis. Biopsy however will settle these satisfactorily in the majority of cases. There is the old rule that if a patient bleeds more than the amount of blood lost in an ordinary menstrual flow the pregnancy will be lost. Several patients have bled as much as several hundred cubic centimeters on several occasions and still have gone on with pregnancy. Others have bled several times monthly until term, never copiously, but enough to keep one on tenterhooks. Others have spotted several times, and then had sudden tumultuous premature labor. It is because of such confusion that biopsy is advanced as a useful weapon in directing intelligent treatment. Continued bleeding of moderate amount over a considerable period of time carries a bad prognosis, particularly if uterine growth stops. Bleeding, matter not the character or amount, is of less consequence in the face of a steadily growing uterus.

It is of interest to note that in the cases of fetal defect the date of average appearance of bleeding is 1.4 weeks after the last period. In the cases of extrafetal defect, bleeding appeared on an average at 9.4 weeks—slightly earlier than in the case of fetal defects. Bleeding in both series in the occasional case would be noted almost from the date of impregnation. In the cases of fetal defect, abortion occurred on the average 1.4 weeks after the onset of bleeding. In extrafetal defects, abortion took place 8.9 weeks after the onset of bleeding in the average case.

One cause of bleeding shortly after the first missed period has not been mentioned—the so called "placental sign" well known in some of the experimental animals. This is a spotting which is due to a defect in the endometrium at the site of implantation of the ovum (5). It is often thought a period, albeit abnormal, for it approximates the expected date of flow. This may cause some of the miscalculations of confinement. Mention already has been made of abortion occurring within a few days after the first missed period,

possibly a "slightly-delayed profuse period." This may account for the patient's symptoms of pregnancy but for which no subsequent proof can be found.

Morphine is definitely contraindicated in these latter cases, for Falls, Lackner and Krohn found that the postpartum uterus under the usual morphine sedation had enhanced power and frequency of contractions. The barbiturates and paraldehyde are effective agents without morphine's side reactions.

If one were to lay down a plan of therapy to augment as much as possible the natural hormonal processes, one might recommend progesterone just before the time of ovulation and impregnation. Ten milligrams in oil intramuscularly would enhance the normal secretory phase of the endometrium. Just before the 13rd day of the cycle, when implantation takes place another similar dose might be given, as a maintenance dose. No effect would be exerted on the locus of implantation—the hope would be to give the ovum a succulent bed. Since at the time of the first period, there is a slight chance that the fertilized ovum may be extruded, if the improper hormone balance exists, or if it is poorly implanted, a third similar dose might be given just before flow is anticipated. Three cases in the series were so treated following abortion of pathological ova, and all three are now at least 4 months pregnant. No disturbed menstrual rhythm was noted following treatment. Obviously no conclusions can be drawn, but if one wishes to employ hormone therapy, this is a rationale which may have more effect than the present scheme of therapy. One cannot attempt to give adequate progesterone of foreign source to replace the patient's own deficiencies. At best it is adjuvant therapy.

In the chronic aborter who has had at least three successive abortions, or the low fertility case, weekly injections of progesterone over the first two trimesters may be tried. This is experimental, and would be aimed largely at the problem of decidual maintenance and of quieting of uterine irritability as well as covering the hormone production shift from ovarian to placental source. Many writers have covered this field already. At any stage of pregnancy in which uterine irritability is an annoying symptom, progesterone is ideal. It is impossible to evaluate properly at the moment the "hyperirritable uterus."

One danger of treatment cannot be overlooked. Hertig (4) found, as previously noted, hydatid change in 63 per cent of abnormal ova. Molar were found in 10 per cent of the ova showing

hydatid change, and malignancy was found in 20 per cent of the moles. The one constant cause for malignant degeneration is retention of abnormal or degenerated trophoblastic material. If one injudiciously uses progesterone, and causes retention of such products, there is created a very real danger. One case in this series had a mole. Figure 12 illustrates just such hydatid change in a specimen procured by biopsy.

DANGERS IN THE PROCEDURE OF DECIDUAL BIOPSY

There is a well founded distaste extant for inserting foreign bodies into the gravid uterus. Only 4 patients came to grief, not from hemorrhage, not from infection—neither of these complications was seen a single time. These 4 patients all had blighted ova, proved by subsequent pathological examination by a neutral observer to be pathological ova dead for some weeks. All were within the first 4 months, although one was a blighted ovum, rather Siamese twins of 3½ months, which had been retained for 4 months *in utero*. Membranes were ruptured in these 4 cases because maceration of the intrauterine contents was so complete that the resistance offered by normal viable membranes was not encountered as the curette was introduced. Again, may it be reiterated that no patient had any other untoward effects from the procedure, and that hemorrhage, infection, increased morbidity, or greater tendency toward abortion were not noted in any cases. No perforation is known.

One other source of error in the study was in the interpretation of the early frozen section specimens at a time when the allowable changes within the decidua were still under consideration. These mistakes were corrected by study of the permanent sections, taken as a double check on accuracy. In but 1 case of the 50 pathological ova was the decidual biopsy wrong. This case had been mentioned as such an error before,—a biopsy specimen taken a week after the negative biopsy, 48 hours before abortion, was this time indicative of decidual slough. In the case of biopsy specimens demonstrating good decidua, 7 frozen section diagnoses had to be changed from suspicious to good decidua after the permanent sections were reviewed. This error was not found in the later portion of the study, as greater familiarity with the frozen section details developed. The problems of interpretation of biopsy specimens have been mentioned in treatment.

No biopsy should be performed until all extrinsic causes of bleeding have been eliminated, such as cervical erosion, polyp, vaginitis, and the

like. Actual manual pelvic examination should precede the biopsy to prove pregnancy, if possible, and to exclude ectopic pregnancy or tumors. Needless to say, in a case in which ectopic pregnancy was considered, the patient was in the hospital before the examination was performed. This technique of biopsy is not suitable as a pregnancy test. It is not suited for general use but should be done by one who is acquainted with the usual gynecological biopsy techniques. It is of no value after the 14th week of pregnancy, for the cause of bleeding can be determined by methods less perilous to the gravid uterus, which after that period is well filled by the developing ovum. As with any other procedure, one must weigh biopsy information with the clinical story and physical findings.

SUMMARY

1. An investigation into the causes of bleeding in 100 cases during the first 4 months of pregnancy is outlined.
2. The technique and use of decidual biopsy are described and defended.
3. The histopathological pictures of normal and abnormal decidua are described and the significance of each is elaborated.
4. A general and hormone therapy program is suggested, after exception is taken to present practices regarding bleeding in early pregnancy.
5. Bleeding in the first 4 months of pregnancy in 100 consecutive cases is a significant symptom,—only 22 of 91 presumably normal pregnancies survived to fetal viability after the appearance of this clinical sign.

A BIOLOGICAL TEST PROPOSED AS A GUIDE IN THE ADMINISTRATION OF THIAMIN

DAVID L. FARLEY M.D. Philadelphia Pennsylvania

In 1935 R. R. Williams (5) announced the chemical identification of vitamin B. This substance was given the name thiamin. Williams worked with a concentrate of rice polishings. Shortly after the chemical identification of this substance from natural sources (rice polishings) Williams and Cline (6) were able to prepare the substance (thiamin) synthetically. The synthetic thiamin has been widely accepted as crystalline vitamin B and is said to be as effective as natural vitamin B in the treatment and prevention of vitamin deficiency states.

Many methods have been proposed for guiding the administration of vitamin B and for assessing its quantity in various foods. References to the details of the various methods may be found in the published data of a symposium arranged under the auspices of the Council on Pharmacy and Chemistry and the Council on Foods of the American Medical Association (1). The method detailed in this article is proposed as a procedure peculiarly adapted for the guidance of thiamin administration to patients.

In September 1933, Duhig, of the University of Queensland, Australia, published an article on the serum inhibition of hemolysis. The reason for this inhibition was not apparent. In November 1939, Farley, concluded that the administration of thiamin caused the synthesis of a secondary substance in the blood, the amount of which could be quantitated by titrating against digitonin hemolysis the power of inhibition of the serum of the recipient of vitamin B.

The hemolytic systems against which there was inhibition by serum included saponin hemolysis, streptohemolysis, specific amoebocyte system hemolysis, etc. After considerable search it was found that digitonin, one of the saponins, possessed the most desirable properties as a stable hemolytic agent. Hence in the test to be described a standard solution of digitonin is used to study the antihemolytic substance in serum with the idea that the level of antihemolytic power of the serum reflects its content of the substance produced by thiamin. Thiamin itself was found to cause no inhibition of digitonin hemolysis either in watery or serum solution.

From Medical Service A. Pennsylvania Hospital

METHOD

A stock solution of digitonin is prepared by dissolving 80 milligrams of digitonin in 300 cubic centimeters of normal salt solution. For the test 1 cubic centimeter of this stock solution plus 9 cubic centimeters of 0.85 per cent sodium chloride solution is prepared and titrated to establish a factor of complete hemolysis for 0.1 cubic centimeters of a 5 per cent suspension of washed sheep cells. This second solution is called the standard solution. A standard solution of digitonin is freshly prepared and titrated for use on each day that tests are done.

To a series of 10 tubes, the standard digitonin solution is added as follows. 1.0 cubic centimeter to the first tube, 0.9 cubic centimeter to the second, 0.8 cubic centimeter to the third, 0.7 cubic centimeter to the fourth, and so on, decreasing the volume by 0.1 cubic centimeter until the last tube contains 0.1 cubic centimeter salt solution is then added until the total volume in each tube is 1.0 cubic centimeters. To this, 0.1 cubic centimeter of a 5 per cent suspension of washed sheep cells is added. All tubes are incubated at 40 degrees C. in a water bath until no further hemolysis occurs. This usually takes about 3 minutes. The last tube showing complete hemolysis is considered the factor or the amount of digitonin solution to be used in the test. The serum to be tested is diluted 1:1000 in 0.85 per cent sodium chloride solution. Eleven tubes are set up, and to the first 10, beginning with 1.0 cubic centimeter of serum dilution in the first, the amount is decreased by 0.1 cubic centimeter until the tenth contains 0.1 cubic centimeter. Tube 11 is the control, containing no serum. Digitonin standard solution the amount determined by the previous titration, is added to each tube and normal salt solution is added to make 1 cubic centimeters in each tube. To each tube 0.1 cubic centimeter of a 5 per cent suspension of washed sheep cells is then added.

The tubes are incubated at 40 degrees C. until hemolysis is complete in the control. (This usually takes about 3 minutes.) The test is read immediately after the control shows complete hemolysis. The dilution values read refer to the original dilution of the serum in 1.0 cubic centi-

meter and are not based on the total volume of 22 cubic centimeters. This is done because of greater ease in reading and because the comparative power of the serum of patients to inhibit is desired.

Readings The tubes showing complete inhibition of hemolysis, i.e., the end point, constitutes the reading on the particular serum being tested. Instead of reading the end point as a dilution, it is assumed that the dilution contains the number of units corresponding to the last figure of the dilution, for example, a serum which inhibits hemolysis in a dilution of 1:1000 is read simply as 1000.

Rationale of proposed test An original observation was made that individual blood serum varied widely in its power of inhibiting hemolysis. A search was undertaken for the explanation of this phenomenon. Attention was directed to the vitamin content of serum as a possible explanation. It was found that yeast, which had been autoclaved for 6 hours, when fed to rabbits caused no rise in serum inhibitory power of their serum. When unautoclaved yeast was used to feed the animals, a rise in serum inhibitory power occurred. At this point it was noted that the yeast being used was a commercial product to which thiamin had been added. Yeast to which no thiamin had been added was obtained. When this yeast was fed to rabbits the rise in inhibitory power was not spectacular as it had been in the artificially thiaminized yeast. Attention was, therefore, focused on thiamin. A small dose of thiamin chloride (1 milligram 3 times a day) was taken by the experimenter for 1 week. At the end of 1 week the titer of his serum had risen from 5000 to 100,000. After an interval of several weeks, with the return of titration of his serum to 5000, the same individual took 6 milligrams a day for 1 week, with a rise in the titration of his serum to 350,000. It was thought that thiamin not only caused a rise in the inhibitory power of the recipient's serum, but also that this rise was quantitative and that the height of the rise depended on the amount of thiamin given.

EXPERIMENTS ON RABBITS

Rabbits were given varying amounts of thiamin. A rise in the inhibitory power of the rabbit's serum invariably occurred regardless of whether thiamin was given by mouth or by injection, subcutaneously or intravenously. There was usually an interval of 2 or 3 days before the rise began. Rabbits given a relatively small dose of thiamin, 3 milligrams daily for a week, showed at the end of that time a serum titer of about

100,000, whereas the initial titer of their sera was, for example, 1600. The degree of rise in titer appeared to depend upon the amount of thiamin used. The massive dosage used in the experiments quoted was to illustrate the spectacular effect of a large quantity of thiamin. The rabbits appeared to suffer no ill effects from the large dosage used. (Table I)

TABLE I—RESULTS

Group A Administration hypodermically, 50 milligrams daily for 1 week

Rabbit No	Preliminary titer	Titer after 1 week
1	1250	1,000,000
2	1600	500,000
3	1000	500,000
4	500	330,000
5	1500	500,000

Group B Administration intravenously, 50 milligrams daily for 1 week

Rabbit No	Preliminary Titer	Titer after 1 week
6	1200	5,000,000
7	650	3,000,000
8	1050	3,000,000
9	1550	2,500,000
10	1600	5,000,000

Group C Administration intravenously, 50 milligrams daily for 1 week

Rabbit No	Preliminary titer	Titer after 1 week
11	2000	1,450,000
12	1450	2,500,000
13	500	3,300,000
14	1450	5,000,000
15	2000	5,000,000

Group D Administration hypodermically, very massive doses—100 milligrams daily for 1 week

Rabbit No	Preliminary titer	Titer after 1 week
16	1250	10,000,000
17	1000	10,000,000

Group E Administration by mouth, 6 milligrams daily for 1 week

Rabbit No	Preliminary titer	Titer after 1 week
18	500	90,000
19	500	90,000

CONTROL ANTIHEMOLYTIC EXPERIMENTS ON RABBITS WITH SUBSTANCES OTHER THAN THIAMIN

Obviously it was difficult to control the possibility that substances other than thiamin, when given intravenously or by mouth to animals, might also cause a spectacular rise in the inhibitory titer of the serum of the recipient. This was true because many vitamins have not been

isolated and therefore are not available and there is no limitation to the number of other substances which might be used. Therefore, four unrelated substances were selected, one a vitamin of the so called water soluble vitamin group a second possessing vitamin like activity the third a product with a high protein content and the fourth a substance commonly used to produce therapeutic shock.

Typoid vaccine, massive doses intravenously for week. Results: There was slight rise in the antihemolytic power of the serum of the recipient, but in no way comparable with that given by thiamin.

Nicotinic acid, large doses by mouth for week. Results: No rise of inhibitory power of the serum of the recipient.

3. Casein, large doses by mouth for week. Results: No rise of inhibitory power of the serum of the recipient.

4. Vitamin C; ascorbic acid, large doses intravenously for week. Results: The inhibitory power of the serum showed no rise.

With the four substances used there was no marked rise in inhibitory power of serum of the recipient against digitonin hemolysis.

RESULTS OF TITRATIONS OF SERA FROM HUMANS

Many titrations on the sera of humans have been done. The results of titrations of the sera of 345 individuals are shown in Table II.

TABLE II

Number of individuals	Disease	Average titration	Maximum titration	Minimum titration
	Pneumonia lobar	1,849	2,200	300
30	Asthma-bronchial	1,743	2,000	150
	Diabetes mellitus	2,000	2,000	2,000
100	Moderately advanced to advanced carcinoma	1,363	2,000	200
100	Pregnancy	1,171	2,000	200
	Pellagra	1,000	1,500	50
	Active rheumatic heart disease	1,744	2,000	200
	Cerebral sclerosis	2,000	2,000	1,500
	Myocardial infarct	2,000	2,000	2,000
	Cirrhosis of liver	2,000	2,000	1,100
100	Normals	1	2,000	100

Of the individuals suffering from bronchial asthma listed in Table II 23 of 30 cases showed a titration below 2,000 of the cases of lobar pneumonia, 24 of 46, of diabetes mellitus, 4 of 2 of carcinoma, 1 of 20 of pregnancy, 13 of 100 (4), of rheumatic heart disease-active, 13 of 23 of coronary occlusion, 2 of 8 of cirrhosis of liver 2 of 3.

Analysis of the tests on sera from diseased individuals failed to show a consistently low inhibitory titer in any one disease. There was, however, a marked variation in inhibitory titer of the sera of diseased persons.

The average of tests on the sera of 100 presumably normal individuals was 2,712. The sera of 98 per cent of these showed a titration between 2,000 and 5,000. Eighty nine per cent were between 2,000 and 3,500. We assume therefore that the minimum normal is 2,000. In other words titrations below 2,000 are considered by us to be deficient in the inhibitory substance following thiamin administration. The 100 individuals were young men and young women, either student nurses or medical students. All were in good health as far as could be determined by ordinary history and physical examination. Their diet consisted of that ordinarily selected by each. In the case of the student nurses, this was the hospital diet given to such individuals. No attempt was made to supervise such diet as to its vitamin content, as the object was to learn what would be the inhibitory titer of the sera of such individuals on an unselected diet. There was no apparent difference between the sera.

RESULTS BEFORE AND AFTER THIAMIN ADMINISTRATION

Following are details of the findings in some patients who had been on a low vitamin B₁ dietary intake before admission to the hospital with the results of their serum inhibitory titration before and after treatment by thiamin.

CASE 1. H. R. aged 42 years, diagnosis, pellagra, starvation, stevedore. Patient had been on relief for 3 years and had lived on an inadequate diet consisting largely of bad whiskey known locally as "goatshead," and potatoes. Before treatment the inhibitory power of the serum was 1,500. He was given thiamin chloride 10 milligrams daily by mouth, also nicotinic acid (11 have found that nicotinic acid causes no rise in inhibitory power) 1/2 cc given high calorie diet. The effect of this on the inhibitory power can not be exactly calculated. After 5 days his serum titer was 2,500 and his symptoms of diarrhea and skin eruptions were greatly improved.

CASE 2. H. C. aged 35 years, diagnosis, tuberculosis and pleural effusion, occupation, stevedore. Patient had suffered from poor appetite with marked limitation of food intake and loss of 5 pounds in eight or a period of 6 months. Before treatment his inhibitory power was 50. He was given thiamin chloride 10 milligrams daily by mouth, and high calorie diet. After 10 days his inhibitory titer was 2,500.

CASE 3. P. C. aged 38 years, diagnosis, alcoholism, occupation, shoestring salesman. For 5 years before admission to hospital he had been living on a budget of 50 cents a day for food. Inhibitory titration before treatment was 1,500. He was placed on thiamin chloride 10 milligrams daily and high calorie diet with strict supervision. 7 days later his titration was 2,500, 10 days later 3,500.

INGUINAL HERNIAS

IF we accept the theory of Professor Earnest Hooton in his book *Apes Men and Morons* we may expect to find more hernias today than ever before. He wrote

With the development of urban civilization and industry physical deterioration becomes appallingly common every sort of physical abnormality is increasingly prevalent. The expanding mechanization of this age however with the use of labor saving devices in home, field, and factory should favor a reduction of hernias, which might offset the physical deterioration of civilized man mentioned by the distinguished anthropologist.

Some notion of the incidence of hernias can be gained from figures furnished by the selective service examination boards. In 1917 and 1918, out of more than two million men examined for the draft, 4 per cent showed either a hernia or enlarged inguinal rings. Among the present draftees, 1.8 per cent of the million men so far examined have been rejected because of the presence of a hernia.

The somewhat lower percentage of hernias in the men now being called for army duty is not a reliable measure of the actual number of such defects in the entire population. The draftees are young men. Hernias show a marked tendency to increase in frequency with age, and the lengthening of the average life cycle has resulted in an increased number of older persons in our population. We must infer therefore that in a study including all age groups a higher percentage of hernias would be found than that expressed in the figures from selective service examinations.

Statistics from life insurance companies and the United States Public Health Service indicate that the incidence of hernia in the general population has not varied much in the past thirty years.

On the basis of such meagre reliable data as is available today however the most careful biometrician could not offer us any final judgment as to whether hernias are becoming more or less prevalent.

About 10 per cent of the surgery of the large general hospital is devoted to the repair of hernias of all types. Approximately 90 per cent of these are of the inguinal variety. The recent increase in the number of inguinal hernias operated on can probably be attributed, at least in part, to the fact that most states have put into effect some form of workmen's compensation laws in the past few years. These laws have so placed the responsibility of the employer that he has found it wise to have every prospective employee examined before he begins work. Men who are found to have hernias when they seek employment must have them repaired in order to be accepted for the position.

Surgical correction, when expertly done,¹ offers the most reliable form of treatment of these congenital or acquired defects. The methods of repair have changed very little in the past fifty years. Such slight variations and modifications of the early operations of Bassini and Halsted as have been introduced have probably had little influence on the success of herniorrhaphies. The most outstanding innovation, namely the use of autogenous fascia, was first described by McArthur in 1901, but recently it has enjoyed an increased popularity. There is a good deal of discussion and difference of opinion at the present time as to its true value, some men presenting statistics to show that its use will greatly lower the incidence of recurrences and others giving figures to show a large percentage of failures, even when fascia is routinely employed. It would seem that its greatest value lies in bridging structural defects which are common to the direct hernia and which exist in only a small measure in the indirect type of inguinal hernia.

Another era of enthusiasm for the injection treatment of hernia is just quieting down. During the past five years certain members of the profession have rejuvenated this early method of treatment until it has attained a considerable vogue. Its rather extensive use has yielded but few crumbs of comfort for its sponsors. It has been found to be serviceable in only a limited number of cases, and when it has been employed without a careful selection of patients, the very high percentage of failures has aroused a skepticism of its usefulness that is fully warranted. The most that can be said for the injection treatment of hernia is that its field is limited and its permanent successes few.

The profession was rudely startled rather recently by reports from surgical centers that the incidence of recurrence in direct hernias

was as high as 20 to 30 per cent. Most statistical studies on indirect hernias report a recurrence rate of 3 to 7 per cent.

It must be kept in mind that in the direct hernia we are dealing with a gradually developing structural breakdown. Bodily reparative processes are at a low ebb, and hence the success of ingenious methods of repair is curtailed both by the inadequacy of the body and by the dearth of satisfactory tissue to be used in closing the defect.

It is lamentable that many surgeons of this age are inclined to devote less and less study to the anatomy of the inguinal region and to the understanding of the basic structural factors which cause a hernia. Therefore, they cannot be as well prepared to deal with this condition as were the anatomist-surgeons of a few years back.

Because the younger generation tends to neglect the foundations essential to an intimate knowledge of this problem, a renewed interest must be periodically stimulated. Too often today a hernia repair is not considered of enough importance to merit enthusiastic study. It comes to the attention of many older surgeons that their young colleagues not infrequently are working at a great disadvantage because of their lack of fundamental knowledge of the structures they are attempting to repair. Those who are called upon to perform herniorrhaphies must be familiar with the anatomical relations of the normal parts and the changes in anatomical arrangement which take place with the appearance of a hernia. Even before intraperitoneal surgery was attempted, there were many accurately descriptive and beautifully illustrated texts on the repair of hernia. The anatomist-surgeons, who were pioneers in this field, with meticulous care prepared atlases of anatomy which residents and fellows in surgery today would do well to study diligently. Before these young

men give too much of their time to newer and possibly more dramatic developments in the surgical field, they should see to it that they are fully conversant with the problems of hernia repair.

It behooves us then, to put more stress on the thorough training of our medical students in the anatomy of these regions and in the understanding of the structural factors causing a hernia.

RAYMOND W. MCNEELY

THE NEED FOR TRAINED PERSONNEL IN ARMY DEPARTMENTS OF PHYSICAL THERAPY

IN the modern military hospital the department of physical therapy plays an important part. Traumatic lesions commonly encountered in military practice often require physical treatment during the stage of rehabilitation. During the last war it was estimated that 50,000 to 75,000 reconstruction cases would be received per year from each 1,000,000 men overseas and by June 1919, there were forty-five officers, fifty-four enlisted men and 700 reconstruction aides devoting their time to physical therapy.

At the present time there is an extreme shortage not only of physical therapy physicians, but also of physical therapy technicians (physical therapy aides). It has been estimated that 300 physicians and more than 2,000 physical therapy aides will be needed in military hospitals. At present there are in this country only about 1,600 qualified physical therapy technicians to take care of civilian needs. There was a shortage of such workers prior to the war and since Pearl Harbor the need for trained medical specialists and trained technicians in physical therapy has become extremely acute.

Plans have been developed for the training of a certain number of medical officers to con-

duct military physical therapy departments, and a number of schools for physical therapy technicians are in existence. The great need at the moment is to obtain a sufficient number of qualified students for both courses. The Surgeon General's Office is now assigning active and reserve medical officers interested in the subject of physical medicine for special training in the field and any medical officer who is interested in such training should consult the Office of the Surgeon General. The physician who is not a reserve officer and who desires such service should make application for it through Procurement and Assignment Service for Physicians, Washington, D. C.

The technicians who are being trained in emergency courses should now be drawn from the schools for physical education throughout the country and from the colleges of liberal arts. The Army has expressed its preference for female physical therapy aides, and any young woman who is a graduate of an approved college of physical education or who has had two years of academic college work, including courses in physics and biology in an approved college is eligible for admission to most of the approved schools for physical therapy technicians.

The young women of the country who are desirous of serving their country and who have the training which has been mentioned should be urged to communicate with the nearest school for physical therapy technicians and attempt to receive the necessary training in order that they may serve this tremendous need. In a recent official communication appears the following statement: "With the great expansion of the Army and the paucity of the required number of Physical Therapy Aides, something must be done and must be done immediately. The schools for physical therapy technicians which have been approved by the Council on Medical Education

and Hospitals of the American Medical Association and which, therefore, are the only ones which are acceptable to the Office of the Surgeon General are as follows

Name and location of school	Medical director	
Children's Hospital, Los Angeles, California	Steele F Stewart, M D	Hospital for Special Surgery, New York, New York
Stanford University, Stanford University, California	W H Northway, M D	D T Watson School of Physiotherapy (affiliated with University of Pittsburgh School of Medicine), Leetsdale, Pennsylvania
Walter Reed General Hospital, Washington, District of Columbia	B A Strickland, Jr, Capt, M C	College of William and Marv, Richmond, Virginia
Northwestern University Medical School, Chicago, Illinois	John S Coulter, M D	University of Wisconsin Medical School, Madison, Wisconsin
Bouve-Boston School of Physical Education, Boston, Massachusetts	Arthur L Watkins, M D	University of Minnesota Medical School, Minneapolis, Minnesota
Harvard Medical School, Boston, Massachusetts	Frank R Ober, M D	
Boston University, Sargent College of Physical Education, Cambridge, Massachusetts	Louis Howard, M D	
Posse Institute, Kendal Green, Massachusetts		
Mayo Clinic, Rochester, Minnesota	Frank H Krusen, M D	
St Louis University School of Nursing, St Louis, Missouri	Alexander J Kotkis, M D	
University of Buffalo School of Nursing, Buffalo, New York	George G Martin, M D	

Kristian G Hansson, M D
 Jessie Wright, M D
 Thomas Wheeldon, M D
 Ernst A Pohle, M D
 Miland E Knapp, M D

The schools listed are equipped to train students in physical therapy, and they must receive an adequate supply. In one of the civilian institutions of this country, approximately a twelfth of the total number of patients receive some form of physical therapy, in army hospitals, the percentage of patients is even higher. For example, it has been estimated that at the Walter Reed General Hospital in Washington, D C, approximately a fifth of all the patients who are admitted receive some form of physical treatment. It is imperative that these needs be met.

FRANK H KRUSEN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN modern English or American literature there is no other encyclopedia of epilepsy which treats the subject so completely, concisely, and yet simply as does *Epilepsy and Cerebral Localization*. The authors, particularly the senior author, are recognized authorities in their subject, and not only have they drawn upon their own clinical material and experience, but they have freely used recent and as yet reliable data from many other important sources. The title of the book should not overawe any physician. While it is indeed scholarly treatment of an evasive subject, yet in no wise has it been prepared solely for the intellectually elite. It is a practicable readable book, so arranged as to subject matter that each topic is broken down into simple components, discussed to the point of clarity without overall detail, and freely enlivened by a well selected choice of clinical illustrations.

Many commonly used expressions and names of epileptiform phenomena are defined with simplicity especially in Chapter IV dealing with "Seizure Patterns." The authors believe that in the strict sense of the word there are no extracerebral causes of epilepsy which disease they define simply as "an excessive or abnormal neuronal discharge." They do believe that various extracerebral disease states may cause epilepsy through interference with cerebral circulation or through an effect on cerebral metabolism or function.

A long and well written chapter on the use of electroencephalography by Herbert H. Jasper is included. Recognizing the rapidly changing status of this diagnostic procedure the author ventures to state that the electroencephalogram cannot be depended upon to give a certain diagnosis of clinical epilepsy without the aid of other data, and, therefore, no single pattern of electrical activity of the brain which is pathognomonic of that usually considered an "idiopathic" disorder.

The chapters on the various forms of treatment, including the authors' surgical methods, are useful

to the physician directly concerned with his own epileptic patients. The relative merits of bromides, phenobarbital and dilantin, together with many other forms of medical treatment, are presented. The discussion of surgical treatment handled with reserved brevity, indicates the success and failure to be expected by such therapy as exemplified by the large epilepsy series of the Montreal Neurological Institute. The intelligent and successful management of the epileptic man or woman as a member of society (which more likely than not is void of understanding and tolerance) is a final test of one's ability to treat the epileptic state.

JOHN MARRELL

APPROXIMATELY fifty per cent of patients have no demonstrable physical findings or sign but are all complaints or symptoms. With increased emphasis upon the pathogenesis of disease and with advances in the uses of laboratory procedures the value of the interpretation of symptoms has been underestimated.

In *Symptoms in Diagnosis* the author gives his attention to symptoms encountered in clinical medicine. No attempt is made to be comprehensive. The book is not profound and contains nothing new. On the contrary symptoms are interpreted in a concise and practical manner but in the light of recent scientific and clinical knowledge. Its clarity and brevity makes it easily usable.

The chapter on disturbances in sensation is of particular value and well presented. Here the author is presenting the commonest and often the most elusive symptoms with good clinical sense. Exceptions might be taken to some of the views expressed. For example in discussing pericardial pain it is stated that, "pain due to pericardial lesions is localized to the pericardium."

This book will be of greatest service to the student of physical diagnosis. To the clinician it will serve as stimulus to analyze more carefully the symptoms presented by the patient.
